THE ENGINEER'S YEAR-BOOK

OF

FORMULÆ, RULES, TABLES, DATA, & MEMORANDA

FOR 1949

A COMPENDIUM OF THE MODERN PRACTICE OF

CIVIL, MECHANICAL, ELECTRICAL, MARINE, GAS, AERO, MINE, & METALLURGICAL ENGINEERING

(*Originally compiled by H. R. KEMPE, M.Inst.C.E., M.I.Mech.E., and W. HANNEFORD-SMITH, F.R.S.E., Assoc. Inst.C.E.*)

55th ANNUAL ISSUE

(IN TWO VOLUMES)

Revised under the direction of

B. W. PENDRED, M.I.Mech.E., M.I.S.I.

EDITOR-IN-CHIEF of 'THE ENGINEER'

Volume Two

PUBLISHED BY

MORGAN BROTHERS (Publishers) LTD.

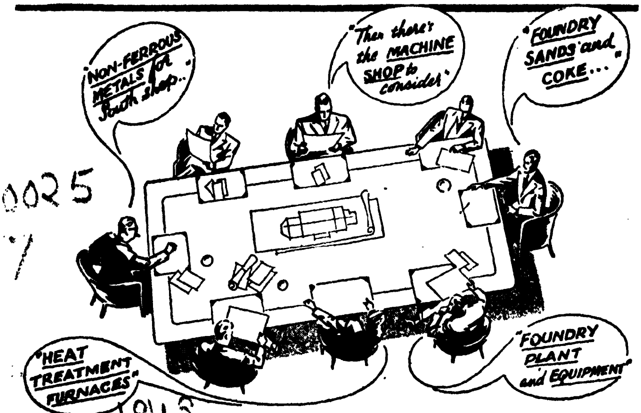
PROPRIETORS OF 'THE ENGINEER'

AT 28 ESSEX STREET, STRAND, LONDON, W.C. 2

Obtainable from the Publishers and sold by the leading Booksellers in the United Kingdom, the Dominions Overseas, India, and Foreign Countries

1949

Printed in Great Britain



WARDS MIGHT HAVE IT

It is common knowledge wherever engineers meet together that WARDS can provide anything from a bench drill to a complete mechanization scheme, but it may not be so generally known that the WARD organization can plan and provide a comprehensive engineering service for any industrial undertaking. When the scope of these resources is fully appreciated, the suggestion 'WARDS MIGHT HAVE IT' is sound enough to voice at any board meeting.

The WARD GROUP of INTERESTS cover
NEW and RECONDITIONED MACHINERY: ENGINEERS' SMALL TOOLS: ELECTRICAL PLANT: FOUNDRY SUPPLIES: FOUNDRY PLANT: IRON, STEEL and NON-FERROUS METALS: POWER PLANT: LOCOMOTIVES and CRANES: RAILS and SIDINGS: CEMENT, BRICKS and ROAD MATERIALS.

PROPERTIES OF STEAM—FLOW OF STEAM—POWER PLANT THERMAL EFFICIENCIES.

(Revised by R. H. Parsons, M.I.Mech.E.)

Steam Tables.

Engineers who have to make calculations which involve the properties of steam are recommended to use the Callendar (1939) Steam Tables, published by Messrs. Edward Arnold & Co. London, which cover the range of pressures and temperatures up to 3,200 lb. per sq. in., and 1,000° F. and are recognised as the standard by British manufacturers. The figures in Tables I and II below have been abstracted from the Callendar tables, and are sufficiently complete to enable intermediate values to be obtained with reasonable accuracy by interpolation. Interpolation is best effected by plotting two or three tabulated values on either side of the required value, and drawing a smooth curve through the points so obtained. The required value can then be read from the curve.

Many calculations will be greatly facilitated by the use of a Mollier Diagram, an example of which will be found on page 1305 (Vol. I). A complete diagram, plotted in accordance with the Callendar Tables, is published by Messrs. Edward Arnold, under the title 'The 1939 Heat-Entropy Diagram for Steam.'

Atmospheric pressure in this country is taken as 14·69 lb. per sq. in. At this pressure water boils at 212° F., and has a latent heat of 970·6 B.Th.U. per lb. Gauge pressures, being measured above the atmospheric pressure, are approximately 14·7 lb. less than the absolute pressures for which the tables are computed.

One inch of mercury column at 32° F. is equal to 0·491 lb. per sq. in. This pressure is reduced by one hundredth of 1 per cent. for every extra degree Fahrenheit of the mercury column temperature.

For properties of steam at low pressure, see p. 176.

TABLE I.—PROPERTIES OF SATURATED STEAM (CALLENDAR 1939).

Absolute Pressure. Lb. per Sq. In.	Vacuum or Gauge Pressure.	Temperature. ° F.	Total Heat of Steam B.Th.U.	Heat of Water above 32°.	Volume Cu. Ft. per Lb.	Entropy of Water.	Entropy of Steam.

THE THROTTLING CALORIMETER.

The percentage of moisture carried as vapour in wet steam may be determined experimentally by the use of a throttling calorimeter. This can be made up of ordinary pipe fittings. Steam is taken from the main by a perforated sampling tube, the flow being controlled by a stop-valve. The steam then escapes to atmosphere through a pipe between the flanges of which is fixed a disc pierced with a hole about one eighth of an inch in diameter. Thermometers are inserted in the pipe to measure the temperature of the steam before and after it passes through the orifice in the disc. The steam leaving the orifice at atmospheric pressure should be in the superheated state, and if this is the case the dryness fraction of the steam in its original condition is obtained from the formula:

$$\text{Dryness fraction} = \frac{H + 0{\cdot}47\,(t_2 - t_1) - h}{L}$$

in which H is the total heat per lb. of dry saturated steam at the pressure of the atmosphere, t_1 is the temperature of dry saturated steam at the same pressure, t_2 is the temperature of the superheated steam after passing the orifice, h is the heat in 1 lb. of water at the absolute pressure of the steam in the main, and L is the latent heat of 1 lb. of steam at the absolute pressure in the main.

FLOW OF STEAM FROM AN ORIFICE OR NOZZLE.

Accurate methods of calculating the amount of steam that will flow through an orifice or nozzle under different conditions are given in the Section on Steam Turbines, p. 103. When the absolute pressure on the down-stream side of the nozzle does not exceed 56 per cent. of the absolute initial pressure, the weight of steam that will pass through the nozzle can be found with sufficient accuracy for most practical purposes by the Napier formula:—

$$W = A \times P \div 70$$

in which W is the weight of steam in lbs. per second; A is the cross sectional area of the nozzle in square inches; P is the absolute initial pressure in lbs. per sq. in.

The above formula holds for a well-shaped nozzle. If the orifice is in the form of a short pipe, the calculated flow should be multiplied by 0·93. If the flow is through a hole in a thin plate, or through a safety valve, the calculated flow should be multiplied by 0·63.

QUANTITY OF STEAM REQUIRED TO HEAT WATER.

Let G denote gallons of water to be heated, T and t = temperatures of water after and before heating; H = total heat per lb. of steam (column 4, Table I); and W = lbs. of steam required; then:

$$W = \frac{10 \times G \times (T - t)}{H - T + 32}$$

Note.—One cubic foot of water contains 6·24 gallons. One gallon of water weighs 10 lb.

The Efficiency of Power Stations.

The usual way of expressing the efficiency of a power station is by stating the percentage of the heat in the fuel that is converted into useful work. On this basis the efficiency of the best steam plants in the world is only about 30 per cent., and the great majority are far below this figure. The objection to this method is that it takes no account of what is theoretically possible, having regard to the temperatures and pressures employed, and therefore does not permit of a fair comparison between the performances of different plants, nor does it allow of the comparison of any performance with that of an ideally perfect plant working under the same steam conditions.

The first attempt to meet the difficulty was by using the Rankine Cycle as a standard of comparison. It was employed mainly for the comparison of engine and turbine efficiencies, but it applies, of course, equally to a complete power station, for in the ideal power station the boiler room losses would be nil. The Rankine Cycle is dealt with in the section on Thermodynamics, p. 1299 (Vol. I).

The defect of the Rankine Cycle is that it assumes the feed water to be heated entirely by heat supplied directly from the fuel. This was formerly in accordance with practice, but in all modern stations the feed water is raised regeneratively to a high temperature before entering the boiler, by means of partially expanded steam tapped from the turbine at successively higher pressures. The calculation of the theoretical efficiency of an ideal steam plant working with regenerative feed heating is a very simple matter, provided that the feed-heating is assumed to take place in an infinite number of stages, instead of in three or four stages as commonly adopted in practice. This assumption, moreover, is essential to the conception of an ideal plant, for otherwise there would have to be an irreversible temperature drop at each stage, and this is inconsistent with the notion of a theoretically perfect operation. It follows, then, that all calculations of an ideal cycle that are based on the assumption of a finite number of stage heatings are illogical and unsound, because it would always be possible to obtain a higher cycle efficiency with the same steam conditions, and this is, by hypothesis, impossible. The point is an important one, because attempts are frequently made to calculate cycle efficiencies by taking into account the number of feed-heating stages.

With regenerative feed-heating, the theoretical maximum amount of heat that could be turned into work per pound of steam is given by the expression:

$$\mathrm{U} = \mathrm{H} - h - \mathrm{T}(\phi_1 - \phi_2)$$

in which H represents the total heat of a pound of steam at the upper pressure and temperature, h is the total heat in a pound of water at the final feed temperature; T is the vacuum temperature; ϕ_1 is the entropy of steam at the upper pressure and temperature, and ϕ_2 is the entropy of the final feed water.

The cycle efficiency, expressed as a fraction, is therefore:

$$\text{Cycle efficiency} = \frac{\mathrm{U}}{\mathrm{H} - h}$$

and the performance of the station, expressed as a percentage of its cycle efficiency, which is the true figure of operating merit, is:

$$\frac{3{,}412 \times 100}{\text{Cycle efficiency} \times \text{actual heat consumption per K.W.H.}}$$

The cycle efficiency of modern British power stations is about 44·0 per cent., and the maximum figure so far attained with the highest steam pressures and temperatures yet employed in practice is slightly over 50 per cent. The progress made in steam conditions since 1914 may be illustrated by the fact that at that time a cycle efficiency of less than 30 per cent. was considered good.

(Revised by R. H. Parsons, M.I.Mech.E.)

General.

Commercial steam boilers fall into three main classes: (*a*) the so-called 'tank' boilers, of which the Lancashire, Cornish and Scotch marine are the best known examples; (*b*) locomotive boilers, and (*c*) water-tube boilers such as the Babcock and Wilcox, Stirling, Yarrow, Thornycroft, etc.

Boilers of the Lancashire and Cornish types are very largely used for factory work. They are simple in construction, free from breakdowns, cost little for maintenance, and are easily operated by semi-skilled labour. They are probably the best boilers to use with impure feed water. Another good feature is their large water capacity which renders them immediately responsive to sudden increases on the demand for steam. Their size and weight, however, are disadvantageous for transport, and they are rarely built for pressures of more than about 250 lb. per sq. in. They are practically always used in conjunction with economisers, and then provide a reliable and economical steam raising plant.

The Scotch marine boiler, which has many of the advantages and disadvantages of the Lancashire boiler, is almost exclusively used in mercantile steamers except where the demand for higher pressures has led to the introduction of the water-tube boiler.

The locomotive type of boiler is rarely used for stationary duties, as other types are more efficient, and it is badly adapted for buring low grade fuels, but for purposes where its self-contained nature and range of steaming are important, it is unsurpassed.

For power station work, and whenever really high pressure steam is required in large or small quantities, the water-tube type of boiler is supreme. Single water-tube boilers are now being built with an evaporative capacity of more than a million pounds of water per hour, and units capable of evaporating several hundreds of thousands of pounds per hour are common. There is also no difficulty in building such boilers for the highest commercial pressures, 1,400 lb. per sq. in. being frequently employed nowadays in central station practice.

The Rating of Boilers.

It was formerly the practice to rate boilers according to 'boiler horse-power' and the term is still met with in American publications. The assumptions were made that 34 lb. of steam were required to develop one horse-power in an engine, and that a boiler would evaporate about 3·4 lb. of water per sq. ft. of heating surface. Hence, a boiler with a heating surface of 5,000 sq. ft. was called a 500 h.p. boiler, and so on. The term boiler horse-power is happily becoming obsolete as it has no useful meaning under present conditions.

The proper rating of a boiler is the number of pounds of steam it will produce continuously per hour at a stated pressure and temperature from feed water at a stated temperature, when steaming under its most economical conditions. It is usual also to specify the maximum continuous output of steam obtainable by forcing the boiler.

Evaporation rates of over 15 lb. per sq. ft. per hour (including the economiser surface) are now common, and in the tubes exposed directly to the radiant heat of the furnace, the rate may exceed 100 lb. per sq. ft. of exposed surface per hour.

The output of a boiler will naturally depend upon the rate at which fuel can be burnt in the furnace. In the case of solid fuels this is limited by the grate area and the draught available. For stationary boilers bituminous coal can be economically burnt at a rate of about 25 lb. per hour per sq. ft. of grate surface, though this figure may be greatly exceeded if ample draught is available. For fuels of all kinds the volume of the combustion chamber is important, and in large power station boilers it is customary to arrange for a heat liberation of 15,000 to 50,000 B.Th.U. per cub. ft. of volume per hour, a figure of 20,000 B.Th.U. per cub. ft. being common practice.

Typical proportions of heating surfaces, grate areas and combustion chamber volumes for large power station boilers are given in the two following tables.

Power Station	Hackney	Kirkstall	Deptford West	Battersea
Maker of boiler	Simon-Carves	Stirling	Thompson	Babcock & Wilcox
Normal evaporation (lb. per hour)	125,000	160,000	160,000	440,000

Proportions and Duty of Lancashire Boilers.

The Lancashire boiler has been in use for more than 100 years and is still a favourite type for many industrial purposes. Its very large water capacity enables it to respond to sudden short and erratic demands for steam without loss of pressure; its operation and maintenance are easy and well understood, while it is more tolerant of impure feed water than boilers of the water tube type. Lancashire boilers are constructed in sizes from 6 ft. diameter by 18 ft. long, to 10 ft. diameter by 30 ft. long, and when hand-fired with bituminous coal will give evaporations from 3,000 lb. per hour for the smallest size, to 12,500 lb. per hour for the largest. Although a large proportion of the boilers are fired by hand, there are on the market several types of mechanical stokers suitable for them which include forced draught equipment, and with these an increase of about 20 per cent. of output can be obtained. The usual working pressure is 160 lb. per sq. in., 200 lb. being rarely exceeded, but modern methods of construction enable Lancashire boilers to be built for pressures up to 300 lb. per sq. in.

The typical Lancashire boiler has two flues, each fitted with from two to five cross tubes, depending on the size of the boiler. The diameter of the flues is generally 9 in. less than the radius of the boiler shell. The ends are generally flanged for riveting directly to the shell plates, and for higher pressures they are dished to a radius equal to the diameter of the shell. The width of each grate may be taken as equal to the diameter of the flue, and the length is about twice the width. The maximum practical length of grate for hand firing is 7 ft., and 6 ft. is generally considered to be quite long enough.

The heating surface of a Lancashire boiler is given approximately by the formula:

$$\text{Heating surface in sq. ft.} = 4 \times \text{length in ft.} \times \text{diameter in ft.}$$

The rate of evaporation is usually reckoned as 6 lb. of water per sq. ft. of heating surface per hour for boilers without economisers, or 7 lb. per sq. ft. per hour if economisers are used. The weight of coal burnt per sq. ft. of grate area will vary from 20 lb. to 30 lb. per sq. ft., according to the draught, etc., but for economical working a rate of 25 lb. per sq. ft. per hour should not be exceeded.

The foundation of the brickwork for the boiler setting should be a solid raft of concrete never less than 12 in. thick, as the boilers are heavy, a Lancashire boiler 8 ft. diameter by 30 ft. long, for a working pressure of 160 lb. per sq. in. weighing about 28·5 tons without the water.

Setting of Lancashire Boilers.

In ordinary practice, as developed by long experience, a Lancashire boiler is set upon two longitudinal walls, parallel to one another, and distant apart half the diameter of the boiler (see figs. 1 and 2). On these walls are laid specially formed seating blocks of firebrick. These blocks should not be less than 9 in. deep and the seating edge should not exceed 3 in. in width. The edge is often made convex in profile so as to touch the boiler plate along a line only. Where the ring seams cross the seating blocks, a rectangular gap should be cut across the seating for inspection purposes. These gaps are closed by special wedge pieces, which should be carefully replaced after an inspection. Seating blocks provided with asbestos cushions to take the weight of the boiler, and to provide a resilient gas-tight packing are supplied by Messrs. Pearson of Stourbridge. Asbestos cushions are also recommended to form the joints between the flue covers and the shell plates, as air leakage is very liable to occur along these joints. The side flues are generally

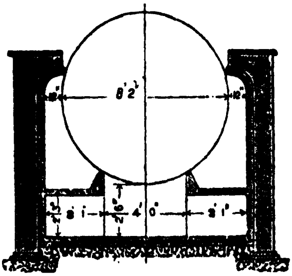

Fig. 1.

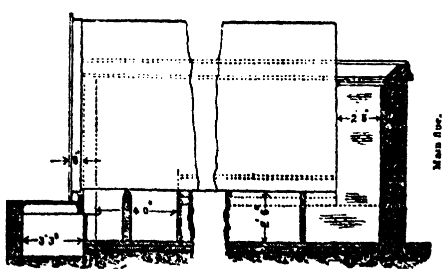

Fig. 2.

made 12 ins. wide at the horizontal diameter of the boiler, and the dividing walls between the flues of adjacent boilers may be 18 ins. thick, so that the distance from centre to centre of boilers in a battery is equal to the boiler diameter plus 3 ft. 6 ins.

The gases leaving the boiler are usually returned to the front end by a flue centrally beneath the boiler, and then returned to the back end by two side flues, from which they pass into the main flue by two separate dampers. Sometimes, however, the gases return to the front end by the side flues, from which they flow into the bottom flue and so to the stack. This latter type of setting may be condemned on theoretical grounds, but it would not be advocated by leading boiler makers were there any real objection to it. The superheater, when used, is placed at the back of the boiler in the path of the gases as they issue from the boiler flues. The economiser is installed separately in the main flue between the boiler and the chimney, where it will serve a number of boilers. The standard type of economiser for Lancashire boilers is constructed of a number of vertical cast-iron pipes assembled in sections, each pipe having a heating surface of 10 sq. ft. As a rule the aggregate economiser surface is equal to the total heating surface of the boilers served. The economiser pipes are usually longer than the height of the flue. In this case the economiser should be set with its lower end level with the bottom of the incoming flue, and its upper end level with the top of the out-going flue. The gases which traverse it will therefore rise during their passage through it, and there will be no gas pocket at either the top or bottom of the economiser. A gas pocket at the top may give cause for a gas explosion, while one at the bottom conduces to the sweating of the pipes.

The flues should be lined with 4½ ins. of firebrick set in fireclay and bonded into the red brick-work at every fourth course. Bricks set in fireclay should be laid with the least possible thickness of clay between them. The clay should be used in a fluid state, and the bricks thoroughly wetted with it and then rubbed into place. Fireclay alone has no 'body' and eventually crumbles away if used in any thickness. A satisfactory fireclay mortar may, however, be made by mixing one part by weight of fireclay with two parts of fire brick dust and a suitable quantity of water. The dust should consist of firebrick crushed to the size of a pea and smaller. Such mortar forms a refractory binding under the action of heat, and is about as strong as the brick itself.

The boiler must be set with a fall towards the front end of half an inch for every 10 ft. of length. The firing floor should be 2 ins. below the lowermost point of the boiler front. The side flues should be not less than 12 ins. wide at the centre line of the boiler, and the underside of the flue covers should be 3 ins. above the crown of the internal flues. The side walls of the end boilers of a range should be not less than 18 ins. thick, and should preferably be faced with white glazed bricks. Access doors and dampers should be arranged so that flue dust may be cleaned out while the boiler is under steam. There should be no sharp corners nor abrupt turns in the main flue, as these may seriously affect the draught.

Dampers.

A Lancashire boiler has two dampers, one at the end of each of the side flues. These dampers may either consist of iron plates sliding in vertical iron guides, or may be of the butterfly type rotating about a vertical spindle. The plate dampers are counterbalanced by weights connected to the dampers by chains passing over guide pulleys, and arranged for operation from the boiler front. The objection to this type of damper is that gas pockets may be formed when it is partly open. Plate dampers usually give a clear opening 12 ins. wide. The opening should be 4 ft. high for boilers up to 7 ft. in diameter, and 6 ft. high for boilers of 9 ft. diameter and over, the height of opening being roughly two-thirds the diameter of the boiler.

Leaky Boiler Settings.

It is impossible to operate a Lancashire boiler efficiently unless the setting is kept in first class condition, for any leakage of air inwards serves both to carry away heat up the chimney and to spoil the draught. For the external surfaces of brickwork settings, white glazed bricks are unsurpassed, as they are not only impervious to air but contribute notably to the lightness and clean appearance of the boiler house. Ordinary unglazed brickwork is very porous and should always be given two or three good coats of paint or tar, to prevent the infiltration of air. Every crack that appears in a setting should be attended to at once, even though it may not appear serious. Leakage can be detected by holding a lighted candle close to the suspected place, when the flame will be drawn towards it if the air is entering in appreciable quantities. If any part of the setting, especially in the neighbourhood of a crack, feels cool to the hand, it is a fairly certain sign of the entrance of air, and any local accumulation of dust is also suspicious. It is difficult to make a satisfactory job of repairing cracks with mortar or cement because these substances shrink and get loose. It is better to fill up the cracks by caulking them tightly with some fibrous material such as asbestos string or rope, or cotton waste saturated with a slurry of fireclay.

Air leakage has to be particularly guarded against at the joints where the flue covers and down-take covers meet the shell. Asbestos packing makes a good joint at these places. Air leakage round the head of the superheater, even when this is covered by a supposedly air-tight casing, is always to be feared, and the possibility of air entering the flue system through the blow-down pit must not be overlooked. The expansion of the boiler, which may amount to as much as three-quarters of an inch in its length, makes the back end very difficult to keep air and gas-

STEAM POWER

Simon-Carves Limited
provide a comprehensive service in steam power generation, from first conception to commissioning of complete power stations. This service is backed by 65 years' experience of fuel combustion, and includes site survey, foundations and buildings, coal, ash and dust handling, electrical and civil engineering.

Note: The flue dimensions are for flat-topped rectangular flues.
The chimney diameters are the smallest internal diameter.
For single Cornish boilers, etc., the flue area should equal one-third the grate area.
For single Cornish boilers, etc., the chimney area should equal one-quarter the grate area.

CORNISH BOILERS.

The Cornish boiler is very similar to the Lancashire boiler, the chief difference being that it has only one furnace and internal flue. It possesses all the advantages of the Lancashire boiler as regards steam reserve, low cost of maintenance and tolerance of impure feed water, and is specially suitable for factories requiring only a comparatively small amount of steam. Cornish boilers up to 6 ft. 6 in. diameter by 24 ft. long with an evaporation of 3,160 lb. of steam per hour are obtainable.

VERTICAL BOILERS.

Vertical boilers are characterised by a vertical cylindrical shell containing an internal fire-box. The shell is usually anything from about 3 ft. diameter by 7 ft. high, to 7 ft. diameter by 14 ft. high, though larger sizes are made. The usual working pressure is about 100 lb. per sq. inch and the evaporation ranges from about 250 to 2,500 lb. of steam per hour.

There are two main types, one employing fire-tubes and the other water-tubes. Of the fire-tube boilers, the Cochran is characterised by a hemispherical fire-box from the back of which the gases rise to a dry-back combustion chamber inside the boiler shell, and pass thence through a number of small horizontal fire-tubes to the up-take at the front. The Cradley boiler is generally similar, except that the combustion chamber is surrounded by water on all sides. In another common design, from 50 to 100 small fire-tubes rise from the flat crown of the fire-box, and are expanded into a horizontal plate at the top of the boiler. A steel chimney rises centrally from the smoke-box above.

In the water-tube type, the fire-box is extended upwards, and its upper part is traversed either by two or three large water tubes, or by a large number of smaller tubes, according to the design. A central chimney rises through the steam space and tends to dry the steam.

A great economy is not to be expected from any of these boilers, though the absence of air-leakage is a point in their favour. The more important consideration is the facility that may be afforded for cleaning the tubes inside and out, and the ease with which necessary repairs may be effected.

THE ECONOMIC BOILER.

The so-called 'Economic' boiler is the land counterpart of the Scotch marine boiler. It is a short cylindrical boiler, fitted generally with two furnaces and internal flues from which the gases pass into an external brick-lined combustion chamber forming an extension of the boiler shell at

the back whence they return to the uptake at the front of the boiler through a large number of small tubes. The boiler is thus entirely self-contained and needs no brick work setting. It is supported by cast iron stools at the front and back. The brick lined combustion chamber becomes red-hot when the boiler is working, and facilitates the combustion of all smoke and volatile matter in the gases. Another good feature of the boiler is the absence of flues, and therefore the avoidance of the air leakage which is so detrimental to the efficiency of brick-set boilers.

Economic boilers are particularly favoured for factories where the demand for steam is not too great, and where boiler house space is limited. They should be supplied with softened water, and the tubes brushed out every two or three days. They are constructed in numerous sizes ranging from 11 ft. diameter by 9 ft. 6 ins. long with an evaporative capacity of 2,500 lb. per hour to 11 ft. diameter by 16 ft. long, with an evaporation of 16,000 lb. per hour. Firing can be done either by hand or by one of the mechanical stokers suitable for the furnaces of Lancashire boilers.

Large Water Tube Boilers.

For power station work the water tube boiler holds the field alone. The forms in which such boilers are constructed are so numerous and the variety of arrangements is so great that it is impossible to do more than touch upon the salient features of design. In modern British power stations steam conditions range from 375 lb. pressure at 730° F. to 1,420 lb. pressure at 965° F. at Battersea, and 2,000 lb. pressure at 940° F. at Brimsdown. A pressure of 600 lb. per sq. in. at 800° F. is characteristic of the majority of the modern stations. Outputs of single boilers range up to 550,000 lb. of steam per hour, though boilers with a capacity of over a million pounds of steam per hour are in service in the United States.

The size of modern boilers is a consequence of the increase in the capacity of steam turbines, and of the tendency to reduce the number of boilers per turbine. In America power stations have been built with one boiler per turbine, but, according to Sir Leonard Pearce (*Inst. Mech. Eng.* 1940) a reasonable compromise is to provide two boilers per turbine, these being of such a capacity that 65 per cent. of the full load of the turbine can be carried continuously by one boiler only. The dimensions of modern boilers have increased almost in proportion to their capacity, largely because of the size of furnaces now employed. The Battersea boilers mentioned above require a total head room of 160 ft. measured from the basement floor, this height including the room occupied by the air heaters and fans situated above the boiler proper.

Water tube boilers fall broadly into two classes, according to whether the tubes are straight or curved. The Babcock and Wilcox, Yarrow and Thompson boilers are designed with straight tubes, while the Stirling is typical of the many types of bent tube boilers. The advantage claimed for straight tubes is the greater facility they afford for inspection and cleaning, but with the care now taken to exclude scale forming substances from the feed water, the straightness of the tubes has practically lost its importance.

Boiler drums for Babcock and Stirling boilers range from 36 in. to 48 in. diameter. For pressures above 450 lb. per sq. in., and outputs exceeding 150,000 lb. of steam per hour they are of seamless construction, manufactured either by forging from the solid or by welding from rolled plate. In the latter case the perfection of the weld is confirmed by X-ray examination.

Large furnaces are now frequently water-cooled on all sides. The cooling arrangement consists of a number of parallel tubes forming part of the water circulation system of the boiler, and built into the furnace wall. The Bailey furnace wall is built up of cast iron blocks clamped to the tubes in such a way as to present an unbroken surface towards the fire. The blocks may have smooth or chequered faces, or they may be faced with a layer of refractory material, according to the conditions of use. Asbestos rope packed between the blocks allows for expansion. The tubes are backed with plastic magnesia covered by a thin coating of hard setting cement, the complete wall being 9 ins. thick from face to face. A feature of modern furnaces is the tendency to eliminate all brickwork exposed to the fire, and to adopt dimensions corresponding to a liberation of 20,000 to 30,000 B.Th.U. per hour per cub. ft. of furnace volume. Under such conditions excellent combustion can be obtained, while the maintenance costs of the furnace are very low.

A few years ago it looked as if all power station boilers except those of quite moderate size would be fired by pulverised coal, because of the limitations of mechanical stoking. Stoking machinery, however, has been greatly improved and developed, and is now used for boilers evaporating more than 500,000 lb. of water per hour. Heavy duty chain grate stokers will burn on an average 55 lb. of coal per sq. ft. per hour, and can be operated up to 80 lb. They have been built with grate surfaces as large as 756 sq. ft. Retort type stokers, being of unit construction, can be built up to any size required, the number of retorts being only limited by the furnace width. Each retort will burn from 1,700 to 1,800 lb. of coal per hour, and the grate area of a large stoker may extend to nearly 800 sq. ft. Ashes from mechanical stokers are disposed of by dumping them from the furnace ash-pit, either into trucks or preferably into an ash-sluice whence they are washed away by a rapid stream of water into a settling pit.

When coal is burnt in a pulverised form, it is usually ground to such a fineness that 65 per cent, of it will pass through a sieve with 200 meshes per linear inch. Finer grinding than this is not worth the extra expense. Grinding is effected by ball mills, roller mills, or impact mills. The power consumption may be from about 12 to 21 kW.h. per ton, at the rated capacity of the mill, the figure depending naturally on the class of coal and the kind of mill. Whatever type of mill is used, the wear of the internal parts is a considerable item of expense.

In most of the earlier pulverised fuel installations, the coal was first dried by hot flue gases or otherwise, then pulverised and delivered into a storage bin, whence it was fed to the furnaces as required. Modern practice is to eliminate both drying and storage, the coal being delivered straight from the pulverisers to the furnace. Modern burners are designed to promote the utmost turbulence of the entering coal and air, so as to give rapid combustion with a short flame. Such burners are constructed in sizes that will liberate more than 100,000,000 B.Th.U. per burner per hour.

Furnaces for pulverised coal are either of the dry-bottom or wet-bottom type. In the former there is sometimes a screen of widely spaced water tubes across the lower part of the furnace, which chill the molten ash and cause it to be deposited as dust. The ashes fall into a hopper-shaped bottom, which may have water-cooled sides, and are discharged at intervals in a dry state. When the ash is of a very fusible kind, it may be allowed to run down the furnace walls and collect in a liquid state in the bottom of the furnace. It is kept in a molten condition by the action of the burners which are directed downwards on to it. The melted slag is run off at intervals, and the molten stream is chilled and broken up by jets of water at high pressure, to be finally carried away by a water sluice.

Forced Circulation Boilers

The water in boilers working at moderate pressures is kept in rapid circulation mainly by the action of the rising bubbles. At a working pressure of 200 lb. per sq. in. abs. the density of the water is about 125 times that of the steam in the bubbles, so that the buoyancy of the latter has a powerful effect. At 1,200 lb. pressure the ratio is reduced to less than 16, and the size of the bubbles is also greatly reduced. It is evident, therefore, that at high pressures the forces causing natural circulation are much diminished, and in view of this fact, several types of boilers have been designed for the forced circulation of water through the tubes. The adoption of this principle not only ensures an adequate water velocity over all parts of the heating surface, but enables smaller and therefore thinner tubes to be used for high pressure boilers. It is also claimed that forced circulation tends to prevent deposits in the tubes.

In the La Mont boiler, water is withdrawn from the drum by a pump which forces it through the tube system and back to the drum, the quantity of water thus circulated being always about eight times the maximum continuous steaming capacity of the boiler. In the Velox boiler a similar procedure is carried out, but the rate of circulation is considerably higher.

The Benson, Sulzer and Ramsin boilers may be classed as forced circulation boilers, although the water in them has no circulation in the proper sense of the term. It is merely forced once through a long pipe system by the feed pump, coming out as steam at the far end. These boilers have no steam drums, and water must be fed to them at a rate exactly equal to the demand for steam.

The Loeffler boiler is characterised by an external drum in which water is evaporated by direct admixture with superheated steam. Saturated steam formed by the evaporation of the water, is withdrawn from the drum by a pump which forces it through tubes which constitute radiant heat and convection superheaters. The amount of steam thus pumped is about three times that of the actual output of the boiler. One-third of the superheated steam is taken away as useful output, and the remaining two-thirds are discharged into the drum to evaporate more water. The Loeffler boiler can only be used for pressures above about 1,700 lb. per sq. in. because of the excessive power that would be absorbed in pumping steam at lower pressures and therefore of greater volume. The Sulzer, Ramsin and Benson boilers all work at 1,400 lb. or more, the Benson boiler being originally designed to work at the critical pressure of about 3,200 lb. per sq. in., though now used for lower pressures.

The most important forced circulation boilers in Great Britain are three of the La Mont type, with an output each of 150,000 lb. per hr. at 1,400 lb., 960° F., at the Willesden Station, London, and one of 350,000 lb. capacity at 350 lb. pressure at the Deptford West Station, London. There are two Sulzer boilers with an evaporation of 130,000 lb. per hour at 1,565 lb., 770° F. in the Powell Duffryn Collieries, and three more, somewhat smaller, at a Warrington Paper Mill. There are four Loeffler boilers at the Brimsdown Station, London, the largest pair having a maximum rating of 250,000 lb. per hour, at 2,000 lb. pressure and 940° F.

Automatic Boiler Control.

Quite a number of systems have been devised for the purpose of automatically controlling the operation of large boilers, and thus relieving the attendant of the necessity of continual intervention. The general problem is to regulate the supply of both fuel and air in conformity with the variation in the demand for steam. The water supply is always taken care of by an automatic feed water regulator which keeps the water level constant in the drum at all loads. Since it is an essential feature of good operation that the steam pressure should be kept constant, it is usual to arrange for slight changes in the steam pressure to bring about what other changes are necessary to restore the normal pressure. Alternatively, the changes of the rate of steam flow from the boiler may be used, to actuate some form of relay mechanism which will cause the speed of the mechanical stokers, or of the feeders of the pulverised coal mills to be raised or lowered, and the speed of the draught fans likewise to be adjusted to the new conditions. The superheat temperature is also subjected to automatic control, usually by by-passing more or less of the hot gases.

Some of these automatic systems are very elaborate, and all have to be so arranged that their action may be over-ridden by the attendant in case of necessity. The apparatus also needs skilled supervision, in order that it shall be maintained in a reliable condition. It seems, however, to be demonstrated that automatic control can be productive of an efficiency from 1 to 3 per cent. higher, over considerable periods, than is obtainable by ordinary manual control, while it relieves the operators of the continual interference that would otherwise be necessary to maintain the most efficient combustion conditions at all loads.

Balanced Draught.

When stoker-fired boilers are working with forced and induced draught the air may be delivered under the grates at a pressure of several inches of water, and the pressure in the furnace might therefore exceed that of the atmosphere unless the power of the induced draught fans is sufficiently great. To avoid the escape of furnace gases into the boiler-house it is necessary to keep the furnace pressure slightly below atmospheric, and a suction of from 0·1 to 0·2 in. w.g. is generally aimed at. The object of a balanced draught system is to maintain this furnace pressure automatically constant under all conditions of load. In the application of the system, any variation of the furnace pressure is made to actuate a relay which, by electrical or other means, alters the speed of the induced draught fans or operates dampers in the induced draught circuit so as to restore the desired furnace conditions. The supply of air to the furnace by means of the forced draught fans may therefore be regulated, by hand, to suit the load on the boiler without the necessity for any simultaneous attention to the induced draught. With a fully automatic system of boiler control, both the forced and induced draught fans are regulated in accordance with the load on the boiler and in such a manner that the draught is always balanced.

Superheaters.

Steam leaving a boiler drum is in the saturated condition, and is almost always passed through a superheater before being used in a turbine or engine. In modern power stations the steam may be raised to a temperature as high as 960° F., though from 800° to 900° F. is more usual. A limit to the temperature is imposed by the metal of the superheater, the tubes of which are made of molybdenum steel for steam temperatures of more than 750° F. When the steam is to be used in a reciprocating engine, the practical limit of temperature is 450°–500° F., as lubrication presents difficulties with higher temperatures.

Boilers of the Lancashire type have the superheaters placed in the downtake flue at the back. Water-tube boilers are usually built with integral superheaters located above or between the tube banks, at some point where the temperature is about 300° F. above the desired final temperature of the steam. In locomotive boilers superheater tubes are placed inside the boiler tubes, and the same practice may be followed in boilers of the Scotch marine type.

Superheater tubes are generally about 1·5 ins. external diameter, bent into a hairpin or a zigzag shape with the ends terminating in headers. The length of each tube, and the number of tubes in parallel are determined by the steam temperature required. For temperatures of more than 750° F. the tubes are made of alloy steel, usually molybdenum. As a further safeguard against temperature difficulties with the metal, the saturated steam enters the hottest portion of the superheater, instead of flowing from the coldest to the hottest end, although the necessary surface is somewhat increased by this arrangement. A rapid steam velocity in the tubes is also adopted, and it is usual to ensure this by allowing a pressure drop equal to about 3 to 5 per cent. of the boiler pressure, although a drop up to 15 per cent. is occasionally allowed.

Superheaters that absorb heat from the gases by convection tend to give a superheat which increases with the output of steam. This characteristic tends to give an excessive steam temperature at high loads. To correct this tendency, a portion of the superheater surface is sometimes placed in the furnace where it is exposed to radiant heat only. Since the furnace temperature does not vary greatly at different loads on the boiler, the temperature of the steam leaving the radiant heat superheater tends to fall at high loads because of the greater steam flow. The two parts of the superheater are connected in series with each other, the steam passing first through the radiant heat portion which therefore has the greatest advantage from its cooling effect. This combination of the radiant heat and convection principles results in the production of a fairly constant degree of superheat at all loads, which is a very desirable achievement.

Other methods of providing for a constant superheat temperature consist in by-passing a part of the flue gases by means of a damper, so that the whole quantity does not pass through the superheater at times of heavy load. Alternatively, a de-superheater may be installed. The most usual method of de-superheating consists of spraying a sufficient quantity of water into the superheated steam to lower its temperature to the required degree. The control of the water supply to the de-superheater is effected by a thermostatic device.

It was once considered necessary to flood superheaters during the period when boilers were getting ready to go on load, but this practice has been generally abandoned. Sufficient protection against burning the superheater tubes is obtained by opening the drain and thus allowing a small amount of steam to pass through the tubes and thus prevent overheating.

Each superheater must be provided with a safety valve, set to blow before the safety valve on the boiler drum, after allowing for the pressure drop through the superheater.

Head Office: 53 HAYMARKET, LONDON, S.W.1
Works: TRAFFORD PARK, MANCHESTER, 17

The minimum velocity of steam through superheater tubes should not be less than 40 ft. per second, and the maximum will be determined by the permissible pressure drop. The rate of heat transmission may be anything from 4,000 to 14,000 B.Th.U. per sq. ft. per hour under average operating conditions, with a maximum of 20,000 B.Th.U. Higher rates are employed with superheaters of the radiant type. For such apparatus, tubes with walls ⅜ in. thick have worked satisfactorily with heat transmission rates of 45,000 B.Th.U. per sq. ft. per hour, and thin tubes have been used to transmit heat at the rate of 60,000 B.Th.U. per sq. ft. per hour and over.

According to Gaffert (*Steam Power Stations*, 1940), convection superheaters can be designed on the assumption that the value of K, *i.e.* the rate of heat transmission from gas to steam in B.Th.U. per sq. ft. per hour per °F., will range from 6 to 10 according to the load on the boiler. For radiant heat superheaters the same authority gives a formula which may be written as:

$$K = 12 \cdot 9 \left(\frac{C}{d}\right)^{0.214} \times (MS)^{0.785}$$

in which d = the internal diameter of the tube in inches.

M = the mass flow of the steam in thousands of lb. per hour per sq. ft. of cross-sectional area.

S = the mean specific heat of the steam.

and C = the conductivity of steam = $0 \cdot 0131 + 0 \cdot 000029t$, where t is the temperature in °F.

Economisers.

An economiser is an apparatus designed to heat the feed water by means of the flue gases before it enters the boiler proper. It is a characteristic of economisers that the water passes straight through them, without recirculation as in a boiler. The standard Green's economiser is almost universally used in conjunction with Lancashire and Cornish boilers, and frequently with boilers of the water tube type. Economisers for high pressure water-tube boilers are constructed of steel tubes, and are usually built integrally with the boiler. In some cases they are of the 'steaming' type, in which the tubes discharge a mixture of steam and water directly into the steam drum of the boiler.

In the design and operation of economisers, the following points should be observed. (1) The flue gases must not be cooled to their dew-point or there will certainly be trouble with external corrosion and fouling of the tubes. To prevent this, the feed water should enter the economiser at a temperature never below 100° F. If cold water has to be used as feed, and this should never be necessary, even in the smallest industrial plants, the economiser may be prevented from 'sweating' by delivering the feed water through a sort of injector which draws a certain amount of hot water from the economiser outlet and returns it to the inlet mixed with the fresh feed. (2) Unless the feedwater is properly de-aerated, it should not enter the economiser at less than 180° F., or the dissolved gases are likely to corrode the interior of the tubes. (3) The feed water should be softened and preferably dosed in addition with about 4 parts per million of sodium metaphosphate, which prevents the deposition of any scale in the tubes, even though the water contains some residual hardness. (4) Economisers should not be installed under conditions which would cause them to generate steam, unless they are specially designed to deal with the increase of volume of their contents due to the formation of steam. It is usual to design for a hot water temperature from 20° F. to 50° F. lower than the boiler steam temperature. (5) If the economiser is fitted with by-pass valves, it must also be equipped with a relief valve. (6) The necessity of providing access for inspection, and means of cleaning is obvious. (7) It must be possible to drain the economiser, and blow-off valves are often provided. (8) When a separate economiser is set in a brick flue, care must be taken to avoid gas pockets, as these may result in explosions. When, as usual, the economiser is higher than the flue, the best practice is to make the bottom of it level with the bottom of the incoming flue, and the top level with the top of the out-going flue. (9) The water inlet should be adjacent to the gas outlet so as to get the advantage in heat transmission due to counter flow. (10) The resistance to the flow of gases should be kept as low as possible. It is usual to allow a draught loss equal to 0·25 in. w.g. for an economiser of the Green type, when coal is being burnt at the rate of 20 to 25 lb. per sq. ft. of grate area.

Air Heaters.

The pre-heating of the air supply to boiler furnaces by means of the waste heat of the flue gases is now common practice in power stations. It not only enables more heat to be recovered from the gases than would be possible with an economiser supplied with water at the high feed temperatures now usual, but it has also the advantage of promoting the more efficient combustion of the fuel. The air heater is generally used in conjunction with an economiser, abstracting further heat from the gases after they have passed through the economiser. It has been estimated that an air-heater effects a saving of about one per cent. for every 30° F. rise in the temperature of the air supplied to the furnace. With pulverised coal firing the air may be heated to any degree consistent with the economical design of the whole plant, and temperatures up to 550° F. are employed in practice. With mechanical stoking it is questionable whether there is any net gain by exceeding an air temperature of about 300° F. on account of the increased maintenance charges on the stoker, although temperatures up to 450° F. have been used.

Air heaters are designed either on the recuperative or the regenerative principle. Recuperative heaters may be of either tubular or plate construction. In the former type the hot gas is caused to flow through vertical tubes surrounded by the air to be heated. The tubes, which are 2·5 ins. or 3 ins. in diameter and from 10 to 14 B.W.G. in thickness, are expanded into tube plates above and below. The length of the tubes may be as much as 30 ft. Soot blowers are used for cleaning them internally.

In plate type heaters the gas and air pass through alternate channels separated by the plates of which the heater is composed. In both designs the counterflow of air and gas is provided for as far as possible. With recuperative heaters, whether of the tube or plate type working under ordinary conditions of temperature and draught, the rate of heat transmission will not in general exceed from 2 to 3 B.Th.U. per sq. ft. per hour per degree of mean temperature difference. The heat transmitting surface required is therefore very large, and generally exceeds that of the boiler served.

The rate of overall heat transmission from gas to air in both plate and tubular heaters is given very closely by the formula:

$$K = W^{0.8}$$

in which K has its usual meaning of B.Th.U. per sq. ft. per hour per ° F. of mean temperature difference, and W is the weight of gas, in thousands of lb. per hour passing per sq. ft. of the area of flow.

A type of regenerative air heater which is largely used in power stations is that invented by Mr. Frederick Ljungstrom in 1922. This consists essentially of a large drum mounted on a vertical spindle. The interior of the drum is filled with a honeycomb arrangement of very thin steel sheet. The flue gases pass upwards through one half of the honeycomb, while the air passes downwards through the other half. The drum is kept in constant slow rotation at about 3 r.p.m. by means of a small motor, the power required being insignificant. As the drum rotates the portion heated by the passage of the flue gases moves continually into the path of the incoming air to which it gives up its heat, while the cooled portion continually returns to be heated again by the gases. Special arrangements are made to prevent, as far as possible, leakage between the gas and the air sides.

This type of heater has considerable advantages over the convection heater where space is important. It has been estimated that every inch of the height of the drum is equivalent in effect to a foot in the height of a convection heater. The regenerative type, moreover, can deal safely with gases at a higher temperature than would be advisable in an ordinary heater.

Little information as to details of design have been published, but it would appear that in the earlier apparatus of the Ljungstrom type, the rate of heat transmission from gas to air was about 930 per sq. ft. per hour, and that about 117 sq. ft. of surface were contained in each cu. ft. of the volume of the drum. The value of K from gas to air, was about the same as for convection heaters, which is to be expected, since the necessity of heat transmission from gas to metal and from metal to air is the same in both types.

Efficiency of Air Heaters.

There is a difference of opinion as to the way in which the efficiency of an air-heater ought to be calculated. If the air-heater is regarded as an apparatus for recovering the heat of the flue gases, it is evident that a perfect heater would reduce the gas temperature to that of the atmosphere. The efficiency of an actual heater would then be:

$$\frac{\text{Drop in gas temp.} \times 100}{\text{Gas inlet temp.} - \text{Air inlet temp.}}$$

It should, however, be noted that on this assumption, it might be impossible for even an idea heater to show an efficiency of 100 per cent.

Another way of looking at the matter is to consider that a perfect heater would raise the temperature of the air to that of the inlet gases. According to this view, the efficiency would be:

$$\frac{\text{Increase of air temp.} \times 100}{\text{Gas inlet temp.} - \text{Air inlet temp.}}$$

This is the formula endorsed by the U.S. Code for boiler testing. It is open to the objection that the specific heats of air and gas and the quantities of air and gas are supposed to be equal. To take these factors into account, the expression should be multiplied by W_2S_2/W_1S_1 in which W_1 and W_2 represent respectively the weights of gas and air passing through the heater per hour, and S_1 and S_2 represent the corresponding specific heats.

Air Required for Combustion.

When the analysis of any fuel is known, the quantity of air required for complete combustion and the nature and quantity of the products of combustion can be obtained from the following tables taken from 'Principles of Combustion in the Boiler Furnace,' by A. D. Pratt.

Pounds per Pound of Combustible.

Substance (one lb.)		Air theor. required Lbs.	Products of Combustion. CO_2	H_2O	N_2	CO	SO_2
Carbon (to CO_2)	C	11·49	3·67	—	8·82	—	—
Carbon (to CO)	C	5·75	—	—	4·42	2·33	—
Carbon Monoxide	CO	2·46	1·57	—	1·89	—	—

The weight of air theoretically required to burn one pound of fuel can also be obtained from the formula—

$$\text{Weight of air required} = 34\cdot48\left\{\frac{C}{3} + \left(H - \frac{O}{8}\right) + \frac{S}{8}\right\}$$

where C, H, O, and S represent percentages of carbon, hydrogen, oxygen, and sulphur in the fuel.

To secure complete combustion, and prevent the loss due to the presence of combustible gases in the flue gases, it is necessary to allow, in practice, from 30 to 60 per cent. more than the quantity of air theoretically required.

The above formula is not very suitable for gaseous fuels because its use would necessitate reducing the combustible gases to their constituent elements. When dealing with gases it is therefore preferable to make the calculation in terms of volume rather than weight, and the following formula is given by A. D. Pratt for the purpose:

Cu. ft. of air required per cu. ft. of gas

$$= 2\cdot38(CO + H_2) + 9\cdot52\,CH_4 + 11\cdot91\,C_2H_2 + 14\cdot29\,C_2H_4 + 16\cdot67\,C_2H_6 - 4\cdot76\,O_2.$$

The products of combustion can be obtained from the Table.

Effect of Excess Air on the Products.

If W is the weight of air theoretically required for perfect combustion, the effect of supplying x per cent. of excess air will be to add $\frac{W \times x \times 0\cdot232}{100}$ lb. of oxygen and $\frac{W \times x \times 0\cdot768}{100}$ lb. of nitrogen to the products of combustion.

In the case of gaseous fuels, if V is the volume of air theoretically required for perfect combustion, the effect of supplying x per cent. by volume of excess air will be to add $\frac{V \times x \times 0\cdot21}{100}$ cu. ft. of oxygen and $\frac{V \times x \times 0\cdot79}{100}$ cu. ft. of nitrogen to the products of combustion.

CALORIFIC VALUE OF FUEL.

To determine the efficiency of a boiler it is necessary to know the weight of fuel burnt, the calorific value of the fuel and the weight of steam produced. Practically all fuels contain a certain amount of moisture, and of hydrogen in a free or combined form. Consequently water vapour is present in the products of combustion. When such fuels are tested in a bomb calorimeter the water-vapour is condensed, and its latent heat is included in the calorific value of the fuel. The calorific value so determined is called the 'higher calorific value' (H.C.V.), and is generally used in English and American tests. On the Continent, however, the latent heat of the water-vapour is deducted, on the grounds that it is unavailable for use in a boiler, and the calorific value so obtained is called the 'lower calorific value' (L.C.V.). In comparing boiler tests it is important to know whether the H.C.V. or the L.C.V. has been employed, as a considerably higher boiler efficiency is shown by using the L.C.V.

To obtain the L.C.V. it is necessary to have an ultimate chemical analysis of the fuel, in order that its hydrogen content may be known. We have then—

$$\text{L.C.V.} = \text{H.C.V.} - 1{,}055(m + 9\text{H}).$$

where H is the weight of hydrogen, and m the weight of moisture in the fuel as fired.

Typical figures for the difference between the L.C.V. and H.C.V. of various fuels are as follows. Ordinary bituminous coals 3·5 per cent.; undried wood 16·0 per cent.; oil 6·4 per cent.; coke oven gas 11·5 per cent.

When an ultimate analysis of the fuel is available, the calorific value may be obtained very approximately by the use of the formula—

$$\text{H.C.V.} = 14{,}590\ \text{C} + 61{,}340\left(\text{H} - \frac{\text{O}}{8}\right) + 3{,}930\ \text{S}$$

in which C, H, O, and S represent respectively the percentages of carbon, hydrogen, oxygen, and sulphur in the fuel. The determination of the calorific value, however, directly by the calorimeter is the most satisfactory method.

BOILER EFFICIENCY AND HEAT LOSSES.

In a complete boiler test the whole of the heat given out per lb. of fuel as fired has to be accounted for. To do this it is necessary to compute the heat usefully absorbed by the boiler unit and that lost in various ways. The calculations require a chemical analysis of the fuel as fired and a complete determination of the constituents of the dry flue gases by means of an Orsat apparatus.

Heat absorbed by boiler.—If W = weight of steam produced per lb. of fuel, and F = temperature of feed water in deg. Fahr., the heat in B.Th.U. usefully absorbed per lb. of fuel is given by the expression—

$$\text{W} \times \left\{\text{Heat in steam} - (\text{F} - 32)\right\}$$

The heat in steam is the total heat per lb. for the particular pressure and temperature as found in the Steam Tables. The efficiency of the boiler is—

$$100 \times \frac{\text{Heat usefully absorbed}}{\text{Calorific value of fuel}}$$

Heat lost in dry chimney gases.—We have first to obtain the total weight of the dry chimney gases per lb. of fuel burnt, from the formula—

$$\text{W} = \frac{11\,\text{CO}_2 + 8\,\text{O}_2 + 7(\text{CO} + \text{N}_2)}{3\,(\text{CO}_2 + \text{CO})} \times \left(\frac{\text{C}}{100} - \frac{\text{A} \times \text{B}}{10{,}000} + \frac{\text{S}}{183}\right)$$

in which C and S are respectively the percentages of carbon and sulphur in the fuel as fired, A is the percentage of ash formed and B the percentage of combustible in the ash. Also, CO_2, O_2, CO and N_2 are respectively the percentages by volume of these several constituents in the flue gases.

The heat, in B.Th.U., carried away by the dry flue gases per lb. of fuel as fired, equal is to

$$\text{W} \times 0{\cdot}24 \times (\text{T} - t)$$

where T is the temperature of the flue gases and t the atmospheric temperature.

Expressed as a percentage, the heat loss on the dry flue gases is therefore

$$\frac{0{\cdot}24\ \text{W}(\text{T} - t) \times 100}{\text{calorific value}}$$

Loss due to presence of CO.—This is computed from the expression—

$$\frac{\text{CO}}{\text{CO}_2 + \text{CO}} \times \left(\frac{\text{C}}{100} - \frac{\text{A} \times \text{B}}{10{,}000} + \frac{\text{S}}{183}\right) \times 10{,}240$$

which gives the B.Th.U. lost per lb. of fuel due to the incomplete combustion of the carbon. The result, multiplied by 100 and divided by the calorific value of the fuel, is the percentage loss due to the above cause.

***Loss due to carbon in the ash.*—The loss due to carbon in the ashes, expressed as B Th.U. per lb. of fuel as fired, is**

$$\frac{A \times B}{10{,}000} \times 14{,}590$$

where A is the percentage of ash, and B is the percentage of carbon in the ash.

Multiplying the result by 100 and dividing by the calorific value gives the loss as a percentage of the heat in the fuel.

***Loss due to moisture in fuel.*—If m is the percentage of moisture in the fuel as fired, the heat lost due to this is**

$$\frac{m}{100}\left\{(212 - t) + 970 + 0{\cdot}48\,(T - 212)\right\}$$

B.Th.U. per lb. of fuel as fired. This loss may be expressed as a percentage by multiplying the result of the above by 100 and dividing by the calorific value of the fuel.

***Loss due to Hydrogen content of fuel.*—The hydrogen in the fuel combines with oxygen to form water, which passes away as superheated steam in the flue gases. The loss due to this, expressed in B.Th.U. per lb. of fuel as fired, is**

$$\frac{H}{100} \times 9\left\{(212 - t) + 970 + 0{\cdot}48\,(T - 212)\right\}$$

which can be expressed as a percentage by multiplying by 100 and dividing by the calorific value.

HEAT BALANCE.

By adding together the heat absorbed by the boiler per lb. of fuel, and the various losses enumerated above, the result should almost equal the calorific value of the fuel, the difference being accounted for by 'radiation and other losses.'

DETERMINATION OF CHIMNEY LOSSES.

An exact method of determining chimney losses from a knowledge of the economiser temperatures was described by R. H. Parsons in the *Beama Journal* of June 1939. The method avoids the necessity for an analysis of the flue gases, or a knowledge of their CO_2 content, and its accuracy is quite independent of the cleanliness or the efficiency of the economiser.

The chimney losses, in B.Th.U. per lb. of water evaporated in the boiler are given by the formula:

$$\text{B.Th.U.} = (T_5 - T_6) \times (T_2 - T_1)/(T_3 - T_4).$$

in which T_1 and T_2 are the temperatures of water at inlet and outlet of the economiser; T_3 and T_4 are the temperatures of the gases entering and leaving the economiser; T_5 is the temperature at the stack inlet, and T_6 is the temperature of the outside air.

Hence, if W be the weight of water evaporated per lb. of fuel, and C is the calorific value of the fuel, the stack losses expressed in the usual way as a percentage of the heat of the fuel, are:

$$\text{Stack losses} = \text{B.Th.U.} \times W \times 100/C.$$

Also, if R be the lbs. of flue gas per lb. of water evaporated:

$$R = 4{\cdot}167(T_3 - T_4)/(T_5 - T_6)$$

which gives a useful indication of the amount of excess air.

Many calculations relating to combustion are much simplified by a knowledge of the maximum percentage of CO_2 that is theoretically obtainable with the particular kind of fuel being burnt. When this is known a whole range of useful facts can be deduced merely from the readings of any ordinary CO_2 meter.

The maximum theoretical percentage of CO_2 in the dry flue gases, which will be denoted by M, will vary, of course, with the nature and quality of the fuel; representative figures are about 18·7 for bituminous coal, 20·5 for coke and 15·5 for oil. The value of M can be found either from the chemical analysis of the fuel, or more simply from an Orsat test of the flue gases.

From the analysis we get

$$M = \frac{21C + 7{\cdot}875S}{C + 0{\cdot}375S + 2{\cdot}37H - 0{\cdot}296 \times O}$$

in which C, S, H and O denote respectively the percentages by weight of the carbon, sulphur, hydrogen and oxygen in the fuel. This equation assumes that sulphur dioxide is reckoned as carbon dioxide, because neither the Orsat apparatus nor the ordinary CO_2 meter makes any distinction between these gases.

Alternatively we can obtain M from the results of an Orsat test by the formula

$$M = \frac{21(CO_2 + CO)}{21 - O_2 + 0{\cdot}395CO}$$

which simplifies to

$$M = \frac{21CO_2}{21 - O2}$$

when no CO is present.

Having obtained M for any fuel, the amount of excess air, expressed as a percentage of the minimum quantity theoretically required for perfect combustion, is obtained from the reading of the CO_2 meter by the formula

$$\text{Excess air} = \frac{79(M - CO_2)}{CO_2(1 - 0 \cdot 01M)} \text{ per cent.}$$

With complete combustion there is neither CO nor H_2 present in the flue gas, and in such a case the weight of the dry gases (including excess air) per lb. of combustible matter actually burnt is given by

$$\text{Weight of dry gas} = \frac{721M + CO_2(4M - 21)}{CO_2(1 \cdot 734M + 26 \cdot 58)} \text{ lbs.}$$

The weight of the water formed by combustion will be :

$$\text{Weight of moisture} = \frac{9(21 - M)}{21 + 1 \cdot 37M} \text{ lbs.}$$

and the total weight of the products of combustion, together with excess air, per lb. of combustible matter burnt, will be

$$\text{Weight of total gases} = \frac{569 \cdot 59M - CO_2(5 \cdot 84M - 172 \cdot 41)}{CO_2(21 + 1 \cdot 37M)} \text{ lbs.}$$

When a fuel can be considered as a pure hydro-carbon, which is approximately the case for oils, its composition may be obtained from the CO_2 in the flue gases, by the formula

$$\frac{H}{C} = \frac{2 \cdot 37M}{21 - M}$$

provided that its combustion is complete. C/H is the carbon-hydrogen ratio of the fuel.

Approximate Combustion Formulæ.

Accurate formulæ concerning combustion have been given above, and should be used for all important calculations. There are, however, a number of approximate formulæ which are sometimes useful, although they should be employed with discretion as they are not applicable to all fuels.

Weight of air theoretically required per lb. of coal $= \dfrac{\text{Calorific value}}{10{,}000} \times 7 \cdot 2.$

Weight of air entering furnace per lb. of coal $= \dfrac{132 \times \text{Calorific value}}{CO_2 \times 10{,}000}$

Weight of flue gases per lb. of fuel = (lbs. of air + 1)

Percentage of excess air $= \left(\dfrac{18 \cdot 9}{CO_2} - 1\right) \times 100.$

(*N.B.*—This applies to normal bituminous coals, burnt with no CO present in the flue gases.)

Percentage loss in flue gases $= 0 \cdot 35 \left(\dfrac{T - t}{CO_2}\right)$

in which T = exit temperature of gases and t = temperature of air.

Rate of Combustion and Draught.

With natural or chimney draught the air pressure at the grate depends on the height of the chimney, the temperature of the gases in the chimney, and the lay out of the flues. A typical figure is 0·65 in. of water per 100 ft. of chimney height, above the grate. The effective draught at the grate for a Lancashire boiler battery with economiser will be about one-third of this figure, and rather less for a water-tube boiler installation with economiser.

The coal burnt per hour per square foot of grate will be about :—

20 lbs. average steam coal ; 5–10 lbs. anthracite very thinly spread.

For other chimneys and draughts the rate of combustion increases not quite in proportion to height.

The draught at the base of the chimney is due to the difference of the weight of the column of hot gases in the chimney and the weight of a similar column of external air.

If t_1 = temperature of external air ; t_2 = mean temperature of gases in chimney ; h = height of chimney in feet ; d = draught in inches of water, measured at foot of chimney ; density of gases (of typical composition) at 32° F. and atmospheric pressure = ·084 lb. per cu. ft. ; density of air = ·0807 lb. per cu. ft., then,

Mean density of gases at chimney temperature $= \cdot 084 \times \dfrac{493}{t_2 + 460} = \dfrac{41 \cdot 4}{t_2 + 460}$;

Density of external air $= \cdot 0807 \times \dfrac{493}{t_1 + 460} = \dfrac{39 \cdot 8}{t_1 + 460}$

Pressure difference at base of chimney in lbs. per sq. foot $= h\left(\frac{39\cdot8}{t_1 + 460} - \frac{41\cdot4}{t_2 + 460}\right)$;

or

d in inches of water gauge $= h\left(\frac{7\cdot64}{t_1 + 460} - \frac{7\cdot95}{t_2 + 460}\right)$.

This is the 'theoretical' draught. The actual available draught is less than the theoretical by that required to produce the velocity of flow of the gases and by that required to overcome friction in the flues, economiser, and chimney. The loss due to velocity (in inches w.g.)

$$= d_v = 0\cdot10 \times \text{density of gases} \times \text{pressure} \times \frac{V^2}{t_2 + 460}$$

$$= \text{for typical gases } 0\cdot123 \frac{V^2}{t_2 + 460}$$

where

V = velocity of gases in chimney.

The friction loss (in inches w.g.) in the chimney

$$= d_f = 0\cdot40 \times f \times \text{density} \times \text{pressure} \times \frac{V^2}{t_2 + 460} \times \frac{L}{D}$$

where

f = friction coefficient = 0·016 say;

L = length of gas path in feet;

D = diameter of chimney in feet;

$$\therefore \text{ friction loss } d_f = 0\cdot0079 \frac{V^2}{t_2 + 460} \frac{L}{D}$$

It is convenient to relate the losses in the chimney to the weight of gas flowing rather than to the velocity.

If W = rate of flow of gas in lbs. per sec., the velocity loss d_v becomes

$$d_v = 0\cdot000117 \frac{W^2 (t_2 + 460)}{D^4}$$

and the friction loss

$$d_f = 0\cdot0000075 \frac{W^2 (t_2 + 460) L}{D^5}$$

Example.—A boiler battery consists of six boilers with a grate area of 38 sq. ft. each. What will be the draught at the foot of a chimney 150 ft. high and 7 ft. diameter, when the rate of combustion is 25 lbs. per hour per sq. ft. of grate area and the mean chimney temperature is 600° F.?

The coal burned per hour is 5,700 lbs.

The flue gases will amount to about 19 lbs. per lb. coal, or 108,000 lbs. per hour = 30 lbs. per sec.

The 'theoretical draught' (with external air at 60° F.)

$$= 150\left(\frac{7\cdot64}{520} - \frac{7\cdot95}{1060}\right) = 1\cdot08 \text{ inches w.g.}$$

$$\text{Loss due to velocity} = 0\cdot000117 \times \frac{30^2 \times 1060}{7^4}$$

$$= 0\cdot046 \text{ inches w.g.}$$

$$\text{Loss due to friction} = 0\cdot0000075 \times \frac{30^2 \times 1060 \times 150}{7^5}$$

$$= 0\cdot064 \text{ inches w.g.}$$

∴ available draught at foot of chimney

$$= 1\cdot08 - (0\cdot046 + 0\cdot064)$$

$$= 0\cdot97 \text{ inch w.g.}$$

From this, the friction losses at flues, economiser (if any) and dampers must be deducted in order to find the draught at the boiler furnaces. Note, in the above example, if there were an economiser, the chimney temperature would be lower than 600° F., and hence the 'theoretical draught' itself would be less. The economiser thus reduces draught both by reducing chimney temperature and by its additional frictional resistance.

Effect of Altitude on Draught.

At high altitudes, the barometric height is less than at sea-level, and hence the density of the atmosphere is less. Hence also the 'theoretical draught' of a given chimney is reduced.

In order to obtain the same draught the height of the chimney must be increased.

The approximate ratio of the height required to the height required at sea-level is given in the following table:

Altitude above sea-level (ft.)	500	1,000	1,500	2,000	3,000	4,000
Ratio of heights	1·02	1·04	1·06	1·08	1·12	1·16

The diameter of the chimney at altitudes should also be increased by about 1½ per cent. for each 1,000 ft. of altitude.

DRAUGHT AND RATE OF COMBUSTION.

Even if the draught at the grate is accurately known, this alone does not fix the rate of combustion, which is influenced by the kind of fuel and thickness of fire; the following tables, due to W. S. Hutton, must therefore be regarded as approximate only.

RATE OF COMBUSTION FOR DIFFERENT DRAUGHT PRESSURES.

Height of Chimney above Grate, in Feet.	Total Draught Pressure, in Inches of Water.	Rate of Combustion, in Pounds per Square Foot of Grate per Hour.	Height of Chimney above Grate, in Feet.	Total Draught Pressure, in Inches of Water.	Rate of Combustion, in Pounds per Square Foot of Grate per Hour.
25	·182	10	130	·948	30
50	·364	16	140	1·029	34
60	·437	17	150	1·095	40
70	·512	18	180	1·313	50
80	·583	19	200	1·459	60
90	·657	20	225	1·641	70
100	·729	22	250	1·825	80
110	·802	24	300	2·189	90
120	·875	27	400	2·553	112

TOTAL DRAUGHT REQUIRED FOR EFFICIENT COMBUSTION OF DIFFERENT KINDS OF FUEL.

Fuel.	Total Draught, in Inches of Water.	Fuel.	Total Draught, in Inches of Water.
Straw	0·20	Slack, very small	0·7 to 1·1
Wood	0·30	Coal-dust	0·8 to 1·1
Sawdust	0·35	Semi-anthracite coal	0·9 to 1·2
Peat, light	0·40	Mixture of breeze and slack	1·0 to 1·3
Peat, Heavy	0·50	Anthracite, round	1·2 to 1·4
Sawdust, mixed with small coal	0·60	Mixture of breeze and coal-dust	1·2 to 1·5
Steam coal, round	0·4 to 0·7	Anthracite slack	1·3 to 1·8
Slack, ordinary	0·6 to 0·9		

In hand-fired plants, using coal for fuel, the rate of combustion should not be permitted to fall below 15 lbs. per sq. ft. of grate surface per hour. With stokers the rate of combustion may be as high as the design of the plant will permit. When firing with fine steam-size coal, the rate should not be less than 10 lbs. per sq. ft. of grate area per hour.

A typical working figure for the rate of combustion in stationary boilers with good natural or moderate assisted draught is 25 lbs. coal per hour per sq. ft. of grate area. For locomotives the rate is about 60 to 70, but may rise to 200.

Transmission of Heat in Boilers.

The transfer of the heat developed by the combustion of the fuel in the furnace to the water in the boiler takes place in two ways: (1) by radiation from the incandescent fuel and the hot gases; and (2) by convection and conduction—i.e. conduction through the materials in the path of the heat flow and by the contact of the gases and water with the metal separating them.

The transmission of heat to that part of the heating surface which is directly exposed to the fire is practically entirely by radiation, and that to the remainder of the heating surface practically entirely by convection.

Transmission by Radiation.

The heat transmitted by direct radiation in most boilers is strikingly large, so that the fire-box surface is much the most powerful evaporating surface.

The amount of heat radiated from a fire of temperature T_1 (° F. absolute) to the fire-box surface at T_2 is

$$1{,}600 \times \frac{T_1^4 - T_2^4}{1{,}000^4} \text{ B.Th.U. per hour per sq. ft.}$$

or practically, since T_2^4 is always negligible in comparison with T_1^4,

$$\text{Radiant heat} = 1{,}600 \left(\frac{T_1}{1{,}000}\right)^4.$$

Whether the radiating surface to be taken into account in calculating the total heat radiated is the grate area, or a larger amount, is debatable. The formula indicates, however, the importance of the direct heating surface, and also the importance of high combustion temperature for high rates of transmission.

Radiant Heat Transmission in Boiler Furnaces.

In a discussion of heat transmission by radiation in boiler furnaces in *The Engineer*, May 16, 1930, a conclusion is reached endorsing the formula given originally by Hudson and modified by Orrok, viz.:

Heat in B.Th.U. per hour entering one sq. ft. of water-cooled surface exposed to radiant heat is equal to

$$\mathrm{OH}\left(\frac{1}{1 + \frac{A\sqrt{O}}{27}}\right)$$

where O = lbs. coal burnt per sq. ft. of heat absorbing surface per hour

H = calorific value of coal;

A = lbs. air per lb. coal.

This formula agrees well with the results of Wohlenberg's analysis (for which see *Trans. Amer. Soc. Mech. Eng.*, 1925, 1926, 1928, 1929).

Transmission through Plates or Tubes.

The transmission of heat from a fluid to another fluid on the other side of a metal tube depends on a large number of factors, including, as well as the area of tube surface and the temperatures, the velocities of the fluids, the diameter of the tube, and the nature of the fluids and of the tube surfaces. The change of temperature of the fluid passing through the tube is, of course, itself dependent on the factors named, so that the factors are not all independent. Differences of conductivity and thickness of the metals of the tube are negligible, the resistance to the passage of heat through the metal being a very small portion of the total resistance from fluid to fluid.

The coefficient of heat transmission is the number of heat units transmitted per unit time per unit area per degree of mean temperature difference (see p. 170, and for determination of mean temperature difference see p. 172).

For the conditions prevailing in the tubes of fire tube boilers, such as boilers of the locomotive type, waste-heat boilers, and air heaters, that is, where the current of hot gas—and for an air heater, the current of air being heated—is along the tubes, the coefficient of heat transmission can be related approximately to $\frac{w}{a}$, where w is the rate of gas flow in lbs. per sec., and a the cross section of the gas path in sq. ft. The results of investigations on different boilers and heaters vary widely, but for values of $\frac{w}{a}$ between 1 and 4, mean values of the transmission coefficient h are given by formulae of the type $h = c\left(\frac{w}{a}\right)^n$ where h = B.Th.U. transmitted per second per sq. ft. of heating surface per degree F. of temperature difference *between the gas and the metal*.

For cases in which the heat is transferred mainly by convection, say for temperatures up to 700° F., c may be taken as 0·0014, n being 0·67.

Where radiation also assists the heat transference, as in the tubes of boilers exposed to gases at or near flame temperatures, the formula $h = 0\cdot0025\left(\frac{w}{a}\right)^{0\cdot67}$ may be used.

Note that these formulae are to be used in conjunction with the temperature *between gas and metal*, and not that between the two fluids separated by the metal wall.

If, as in a boiler, one side of the tube metal is in contact with water, the temperature difference between metal and water is negligible compared with that between gas and metal, and in this case the temperature difference between gas and water may be used instead of that between gas and metal.

When both the substances separated by the tube wall are gaseous, the temperature differences on *each* side of the tube must be considered, or else the overall coefficient of transmission calculated.

Schack (in *Die Industrielle Wärmeübertragung, Berlin,* 1929) gives a formula, which, in British units, becomes.

$$h = 0\cdot000165\,\frac{v_0^{\,0\cdot8}}{4\sqrt{d}}$$

where v_0 = velocity of gas, reduced to 32° F., in feet per sec.
d = tube diameter in inches.

For air, this becomes
$$h = 0\cdot00124\,\frac{\left(\frac{w}{a}\right)^{0\cdot8}}{4\sqrt{d}}$$

and for flue gas,
$$h = 0\cdot0019\,\frac{\left(\frac{w}{a}\right)^{0\cdot8}}{4\sqrt{d}}$$

The procedure that may be adopted is illustrated by the following examples :

Example 1.—A tubular boiler, in which the gases pass through the tubes at the rate $\frac{w}{a} = 2$; temperature of water (and of steam) = 350° F., gas temperatures 1,000° F. at inlet to 450° F. at outlet.

Mean temperature difference (M.T.D.) between gas and water

$$= \frac{(1{,}000 - 350) - (450 - 350)}{\log_e \dfrac{1{,}000 - 350}{450 - 350}} = 294.$$

This may also be taken as the M.T.D. between the gas and the tube metal.

$$\text{Coefficient } h = 0\cdot0014 \times 2^{0\cdot67}$$
$$= 0\cdot0022 \text{ B.Th.U. per sec. per sq. ft. per } ^\circ\text{ F.}$$

∴ heat transmission rate = $0\cdot0022 \times 294 = 0\cdot646$ B.Th.U. per sec. per sq. ft. (the heating surface being measured on the *gas* side of the tube).

If the tube is 2 ins. internal diameter, $a = 3\cdot14$ sq. ins. $= 0\cdot0218$ sq. ft.

$$\therefore w = \frac{w}{a} \times a = 2 \times 0\cdot0218 = 0\cdot0436 \text{ lbs. per sec.}$$

Taking $0\cdot25$ as the mean specific heat of the gases, the heat given up in each tube

$$= 0\cdot0436 \times 0\cdot25 \times (1{,}000 - 450) = 6 \text{ B.Th.U. per sec.}$$

$$\therefore \text{tube surface required (internal)} = \frac{6}{0\cdot646} = 9\cdot3 \text{ sq. ft.}$$

$$\therefore \text{ tube length} = \frac{\text{surface}}{\text{perimeter}} = \frac{9\cdot3 \times 12}{6\cdot28} = 17\cdot8 \text{ ft.}$$

Evaporation (from and at 212° F.) per tube

$$= \frac{6 \times 3{,}600 \text{ (B.Th.U. per hour)}}{970 \text{ (B.Th.U. per lb. steam)}} = 22\cdot2 \text{ lbs. steam per hour.}$$

∴ for 2,000 lbs. steam per hour

Number of tubes required = 90

Total tube heating surface = 836 sq. ft.

Evaporation per sq. ft. of heating surface = 2·49 lbs. per hour (from and at 212° F.)

Example 2.—A tubular air heater, with tubes 2 ins. internal and 2¼ ins. external diameter, gas flowing inside tubes, air flowing in counter current direction outside tubes: $\frac{w}{a}$ for gas = 2; $\frac{w}{a}$ for air = 1·86; gas temperature 700° F. and 450° F. at inlet and outlet; air temperatures 60° F. and 334° F.

h_g = coefficient of heat transmission on gas side = 0·0022.

h_a = do. on air side = 0·00212.

Mean temperature difference between gas and air

$$= \frac{(700 - 334) - (450 - 60)}{\log_e \frac{700 - 334}{450 - 60}} = 378.$$

It would be incorrect to take either h_g or h_a multiplied by 378 as the heat flow per sq. ft. per sec., since h_g and h_a refer respectively to the transmission between gas and *metal*, and *metal* and air only.

It can be shown that the mean temperature difference (M.T.D.) between gas and metal

$$= \text{M.T.D. between gas and air} \times \frac{1}{1 + \frac{h_g \times A_g}{h_a \times A_a}}$$

where A_g, A_a are the metal surfaces exposed to gas and air respectively.

In the example, $\frac{A_g}{A_a} = \frac{\text{internal diameter of tube}}{\text{external diameter of tube}} = \frac{2}{2 \cdot 25}$

$$\therefore \quad \text{M.T.D. gas to metal} = 378 \frac{1}{1 + \frac{0 \cdot 0024 \times 2}{0 \cdot 00228 \times 2 \cdot 25}} = 195 \cdot 3$$

$$\text{Similarly, M.T.D. metal to air} = 378 \frac{1}{1 + \frac{0 \cdot 00228 \times 2 \cdot 25}{0 \cdot 0024 \times 2}} = 182 \cdot 7$$

∴ heat transmitted per sec. = 0·0022 × 195·3 B.Th.U. per sq. ft. of surface exposed to gas = 0·430 B.Th.U. per sq. ft.

Also heat transmitted per sec. = 0·00212 × 182·7 = 0·388 B.Th.U. per sq. ft. of surface exposed to air.

These heat transmission rates must be inversely proportional to the areas on the gas and air sides, *i.e.* $\frac{0 \cdot 430}{0 \cdot 388}$ should be $\frac{2 \cdot 25}{2 \cdot 00}$, which is fulfilled very closely.

The length of tube required may be calculated as follows:

Rate of flow of gas in tube = $\frac{w}{a}$ × area of tube

$$= 2 \times \frac{3 \cdot 1416}{144} = 0 \cdot 0436 \text{ lbs. per sec.}$$

Specific heat of gas = 0·25.

∴ heat given up by gas in tube

= 0·0436 × 0·25 × (700 − 450) B.Th.U. per sec.

= 2·725 B.Th.U. per sec.

∴ heating surface required (on gas side) = $\frac{2 \cdot 725}{0 \cdot 430}$ = 6·32 sq. ft.

Internal perimeter of tube = 3·1416 × 2 = 6·283 in. = 0·5236 ft.

∴ tube length = $\frac{6 \cdot 32}{0 \cdot 5236}$ ft. = 12·1 ft.

The temperature differences are the chief factors in determining the length of tube (for usual values of $\frac{w}{a}$).

The number of tubes is determined from the total gas flow compared with the flow per tube.

Thus if the gas flow is 4·4 lbs. per sec., the number of tubes for the above example would be $4 \cdot 4 \div 0 \cdot 0436 =$ say 100.

Example 3.—An alternative method of finding the heat transmission rates in the previous example is as follows:

If the overall coefficient of heat transmission from gas to air (neglecting the relatively small resistance of the metal) $=$ H,

then $$\frac{1}{H} = \text{resistance to heat flow}$$
$$= \frac{1}{h_a} + \frac{1}{h_g} = \frac{1}{0 \cdot 0022} + \frac{1}{0 \cdot 00212}$$
therefore $$H = 0 \cdot 00108.$$

The overall mean temperature difference is 378°.

∴ rate of heat transmission

$$= 0 \cdot 00108 \times 378 \text{ B.Th.U. per sec. per sq. ft. of mean area}$$
$$= 0 \cdot 408 \text{ B.Th.U. per sec. per sq. ft. of mean area.}$$

The ratio of the areas on the gas and air sides is 2 : 2·25, or the areas are respectively 6 per cent. below and above the mean area.

The transmission rates are thus $0 \cdot 408\,(1 - 0 \cdot 06) = 0 \cdot 384$ and $0 \cdot 408\,(1 + 0 \cdot 06) = 0 \cdot 441$ B.Th.U. per sec. per sq. ft. of the respective areas, agreeing with the former calculation.

General Remarks on Tubular Heaters.

For a given range of temperatures, and a given value of $\frac{w}{a}$, the required tube length is proportional to tube diameter.

Hence if the length for a particular diameter has been calculated, the lengths for other diameters can be very readily found.

The tube length is *not* proportional to the drop of temperature of the heating medium; the extra tube length for each additional ten degrees say of temperature reduction at the outlet end becomes successively greater. Thus, if in a waste heat boiler, with water at 350° F., and initial gas temperature 1,000° F., the tube length is 12·2 ft. for outlet temperature 450° F., it will be 13·7 for 430° F., and 15·5 ft. for 410° F. (the rate $w \div a$ and the diameter remaining the same)

The loss of pressure in the tubes, in inches of water gauge, may be taken as approximately

$$\left\{ 0 \cdot 0000216 \frac{l}{d} \mathrm{T}_m + 0 \cdot 000075 \left(\frac{\mathrm{T}_1}{2} + \mathrm{T}_2 \right) \right\} \left(\frac{w}{a} \right)^2;$$

where

$l =$ tube length in ft.;

$d =$ internal diameter of tube in ins.;

$\mathrm{T}_m =$ mean gas temperature, ° F. absolute $= \frac{\mathrm{T}_1 + \mathrm{T}_2}{2}$;

$\mathrm{T}_1 =$ inlet gas temperature, ° F. absolute;

$\mathrm{T}_2 =$ outlet gas temperature, ° F. absolute;

$\frac{w}{a} =$ lbs. of gas per sec. $\div$ area of section of tube in sq. ft.

In this formula, the pressure of the gas is assumed to be atmospheric within a few ins. water gauge.

Fry's Empirical Formula.

In the case of boiler tubes with flue gases passing through them, the change of temperature of the gases, and thus also the heat transferred, can be calculated from the following equation (Lawford H. Fry, *Engineering*, Aug. 27, 1920):—

$$\log\log. \frac{\mathrm{T}_1}{t} - \log\log. \frac{\mathrm{T}_2}{t} = \mathrm{M}x \quad . \quad . \quad . \quad (1),$$

in which T_1, T_2 are the mean flue gas temperatures, ° F. absolute, at two sections of the tube x feet apart, t the mean temperature (absolute) of the tube wall, and 'lolog.' means 'logarithm of the logarithm.'

M is given by $\log. M = B - m \log. \dfrac{W}{p}$. (2) $\log. (B + 1\cdot3) = \bar{1}\cdot71 - 0\cdot54 \log. d$. (3)

$$\log. m = \bar{1}\cdot36 + 0\cdot37 \log. d \quad . \quad . \quad . \quad (4)$$

where,

d = internal diameter of tube in inches; p = perimeter of tube ($= d \times 3\cdot1416$); W = rate of flow of gas in lbs. per hour.

Having determined the fall of temperature of the gases from the above, the heat given up —*i.e.* the heat transferred—is equal to

$$W \times (T_1 - T_2) \times \text{mean specific heat of gases.}$$

The following table gives the values of M for a number of tube diameters and rates of flow. These values may be used directly in equation (1).

VALUES OF M.

d inches.	W in lbs. per hour.				
	100	200	400	800	1,600
0·5	0·133	0·117	0·104	0·092	0·081
1·0	0·074	0·063	0·054	0·046	0·039
2·0	0·050	0·040	0·033	0·027	0·022
4·0	0·040	0·030	0·023	0·018	0·014
8·0	0·037	0·026	0·019	0·013	0·009

EXAMPLES.

(1) To find fall of temperature in flue tube 2 ins. diameter and 12 ft. long, with rate of gas flow of 400 lbs. per hour, boiler pressure 180 lbs. per sq. in., and temperature of gases 2,000° F. at entrance of tubes.

The temperature of the metal of the tube is nearly that of water in the boiler—*i.e.* nearly that of steam at 180 lbs. per sq. in.; thus t = 380° F., about. (Slight differences in t have very little influence as a rule.)

From the table, for 2-in tube, and W = 400 lbs. per hour, M = 0·033;

$$\therefore \text{lolog.} \frac{2{,}000 + 460}{380 + 460} - \text{lolog.} \frac{T_2}{380 + 460} = 0\cdot033 \times 12$$

$$\therefore \text{lolog.} \frac{T_2}{840} = \bar{1}\cdot273;$$

$$\therefore \log. \frac{T_2}{840} = 0\cdot1875.$$

$$\therefore T_2 = 1{,}293° \text{ F. abs., or } 833° \text{ F.}$$

(2) To find the heat transferred.

The mean specific heat of flue gases at the temperature in question may be taken as 0·31. Then the heat transferred in B.Th.U. per hour

$$= 400 \times (2{,}000 - 833) \times 0\cdot31 = 145{,}000.$$

The tube surface is 6·29 sq. ft., and heat transferred per sq. ft. = 23.100 B.Th.U. per hour.

(3) To find length of tube required to reduce the gas temperature to 700° F., rate of flow and diameter being as before:

$$\text{lolog.} \frac{2{,}000 + 460}{380 + 460} - \text{lolog.} \frac{700 + 460}{380 + 460} = 0\cdot033 \times \text{length.}$$

From which, length = 15·8 ft.

FIG. 4.

GRAPHIC CALCULATION OF HEAT TRANSMISSION THROUGH BOILER TUBES.

Fig. 3 (p. 30) replaces equations (2), (3) and (4), and gives directly, without calculation, the value of M for any given values of W and d, or if required the value of any one of the three quantities W, M, d when the other two are known. In fig. 3 any straight line will cut the three scales graduated in terms of W, M, d at graduations which satisfy equations (2) (3) (4).

Fig. 4 enables equation (1) to be solved graphically. The values of $\frac{T_1}{t}$ and $\frac{T_2}{t}$ are marked on the two end scales and values of Mx on the middle scale. Any straight line cuts these scales at graduations which satisfy equation (1).

Example 1 :—To find the length of flue necessary for a temperature drop from 2,000 deg. F. to 720 deg. F. in a half-inch flue, with a wall temperature of 380 deg. F. and where 100 lb. of gas are passing per hour.

In fig. 3 draw a straight line joining the points W = 100 and $d = 0{\cdot}5$. This line cuts the M scale at the required value of M = 0·132.

Since

$$\frac{T_1}{t} = \frac{2{,}000 + 460}{380 + 460} = 2{\cdot}93, \text{ and } \frac{T_2}{t} = \frac{720 + 460}{380 + 460} = 1{\cdot}41,$$

therefore a straight line drawn in fig. 4 joining these graduations on the $\frac{T_1}{t}$ and $\frac{T_2}{t}$ scales, will cut the Mx scale, at the required value of Mx, which is seen to be 0·50. Therefore, since $M = 0{\cdot}132$, $x = \frac{0{\cdot}50}{0{\cdot}132} = 3{\cdot}78$ ft., *i.e.*, a flue 3·78 ft. in length will be required for the given temperature drop.

Example 2 :—To find what drop in temperature will take place in a half-inch flue, 5 ft. in length, when 1,600 lb. of gas are passing per hour and the temperature of flue gas at entry is 2,000 deg. F., the flue wall temperature being 420 deg. F.

From fig. 1, by joining W = 1,600 and $d = 0{\cdot}5$, we get $M = 0{\cdot}081$, therefore,

$$Mx = 0{\cdot}405.$$

But $\frac{T_1}{t} = \frac{2{,}000 + 460}{420 + 401} = 2{\cdot}80$, therefore, joining $\frac{T_1}{t} = 2{\cdot}80$, and $Mx = 0{\cdot}405$, in fig. 2, we get

$$\frac{T_2}{t} = 1{\cdot}50,$$

therefore,

$$T_2 = 1{\cdot}50 \times 881 = 1{,}322° \text{ C.} = 861° \text{ F.}$$

Actually, lines need not be drawn on the diagrams, as it is sufficient to lay a rule on the scales through the required points.

(A. J. V. Umanski, M.Sc., *Engineering*, June 10, 1921.)

Experiments made by Yarrow and Co., Ltd. (*W. W. Marriner, in discussion on paper by Dorey, 'Tubes for Water Tube Boilers,' Inst. Marine Engineers*, 1930) indicated the following rates of heat transmission in boiler tubes: ordinary boiler, evaporating 6 to 8 lb. steam per sq. ft. of H.S. per hour, in fire rows, between 40,000 and 60,000; in outer rows between 1,000 and 3,000 B.Th.U. per hour per sq. ft.

In destroyer boiler at full power, evaporating 16 to 18 lb. per sq. ft. per hour, fire rows between 100,000 and 120,000; outer rows, between 2,000 and 8,000 B.Th.U. per hour per sq. ft.

Heat Transfer in Cross Flow.

The following formulæ are considered to be the most satisfactory in practice for determining the transfer of heat from gases to tubes when the gases flow at right angles to the tubes. They are taken from 'Industrial Heat Transfer,' by Schack, Goldschmidt and Partridge (1939), which

contains valuable information on all heat transfer questions. In the formulæ, K = rate of heat transmission in B.Th.U. per hour per sq. ft. of tube surface, per ° F. of temperature difference between gas and tube. V = the velocity of gas in feet per sec. between the pipes, supposing its volume to be reduced to that corresponding to 32° F. and atmospheric pressure. D = external diameter of tubes in feet.

For a single tube $K = 0 \cdot 7 \dfrac{V^{0 \cdot 56}}{D^{0 \cdot 44}}$

For banks of tubes, not staggered $K = A \times \dfrac{V^{0 \cdot 654}}{D^{0 \cdot 346}}$

where A = 0·615 for two rows ; 0·635 for three rows ; 0·65 for four rows, and 0·66 for five rows.

For staggered banks of tubes $K = A \times \dfrac{V^{0 \cdot 69}}{D^{0 \cdot 31}}$

where A × 0·70 for two rows ; 0·79 for three rows ; 0·86 for four rows ; 0·91 for five rows ; and 0·99 for ten or more rows.

CONSTRUCTION OF BOILERS.

Boiler Shells.

Mild steel is now almost invariably used for boiler shells. As a rule, in order to provide a margin for wear and tear, plates below $\frac{3}{8}$ in. thick should never be used.

The bending of plates should be done by rolls, and not by hammering. Rivet holes should be drilled after the plates have been bent and fixed together. The plates should then be taken apart and the rough edges removed by a countersinking tool.

Steel for Boilers.

The steel is usually required to be made by the open-hearth acid process. The tensile strength is about 26 to 30 tons per sq. in. for shell plates, and 24 to 28 tons per sq. in. for plates for furnaces, flue tubes, and endplates. An elongation of not less than 23 per cent. is advised.

Strength of Boiler Shells.

Let

P = working pressure in lbs. per sq in.;
T = thickness of plate in inches;
D = diameter (internal) of boiler in inches
E = efficiency of longitudinal joint—i.e. proportionate strength of joint to plate;
F = factor of safety ;
f = tensile strength of plate in lbs. per sq. in.;

then,

$$P = \frac{2E f T}{DF}, \text{ or } T = \frac{PDF}{2Ef}.$$

The factor of safety is usually between 4 and 6. Frequently rules are used in which the safe working stress is substituted for $\frac{f}{F}$ in the above.

For permissible values of f, F, or $\frac{f}{F}$, the rules of the Boiler Survey or Insurance Society concerned should be consulted.

The National Boiler and General Insurance Co. rule is

$$P = \frac{S \times (t - 2) \times K}{D \times 16}$$

where t = thickness of plate in thirty-seconds of an inch, and K = effective area of joint ÷ area of solid plate.

S = 13,100 for double riveted butt joints at longitudinal seams.

S = 12,500 for double or treble riveted lap joints at longitudinal seams.

S = 10,500 for single riveted lap joints at longitudinal seams.

For 'Standard Conditions for Marine Boilers,' see page 34.

The proportionate strength of joint to plate—i.e. the efficiency of the joint—depends upon the type of joint, and also on the pitch and diameter of the rivets, and thickness of plate.

Typical percentage figures for single riveted lap joints are 40 to 58; for double riveted lap 55 to 70; for double butt (a butt strap each side of the plate and double riveted) 72 to 77; for treble riveted butt, each alternate rivet in outer rows being omitted, 82 to 85.

For the method of calculating the efficiency of riveted joints, see page 37.

There is a strong tendency now in favour of butt joints for the longitudinal seams, by which the circular form of the shell is maintained, and there is less liability to grooving. The butt strap also protects the joint from corrosion.

All longitudinal seams break joint, as it is termed—that is, the seam in one ring of plates comes opposite to the solid plate in the next ring.

Furnaces and Flue Tubes.

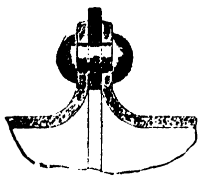

Fig. 5.—Flanged Seam.

For boilers of the Lancashire type, the furnace or flue tubes are usually made with the Adamson flanged seam, with welded longitudinal joints, so that no rivets are exposed to the fire in the furnace.

Increased provision for expansion can be given by making one section of each flue tube of corrugated form.

For proportions of flue sections and thicknesses the rules of the Boiler Insurance Companies should be consulted.

Pressures Required for Riveting and Flanging.

The pressure required for riveting is 75 to 125 tons per sq. in. of rivet area, preferably the lower value. Excessive pressure causes local deformation of the plate. The riveting pressure should be maintained for a short period, so that the rivet may cool down a little, otherwise the spring of the plate may stretch the rivet while it is still hot.

The pressure required for flanging boiler plates may be found from the formula:

$$F = \frac{2\cdot 5\,(L \times t^2)}{L + 10},$$

where,

F = press load in tons; L = length run of flange in feet; t = thickness of plate in sixteenths of an inch. (*Mechanical World Year Book.*)

Welded Pressure Vessels.

In May, 1937, Lloyd's Register of Shipping issued 'Requirements for Fusion Welded Pressure Vessels intended for Land Purposes.' It recognises two classes of welded vessels. The welding of Class I vessels is to be done only by firms which have demonstrated to the Society's surveyors that they are capable of making efficient welds consistently, whilst those of Class II may only be done by firms which satisfy the surveyors that their works are properly equipped for the welding of pressure vessels.

Detection of Fine Cracks in Steel Plates.

A method of detecting cracks in steel plates which are not visible of themselves, is to apply a powerful magnet to the plate, and pour upon its cleaned surface a liquid consisting of a mixture of light oils with finely divided iron in suspension.

The iron dust accumulates along any cracks owing to the change in local distribution of the magnetic flux.

BOILER RULES AND REGULATIONS.

'Standard Conditions for the Design and Construction of Marine Boilers' have been recommended by a committee of representatives of the Board of Trade, British Corporation, Lloyd's Register, and Bureau Veritas. An abstract of the rules drawn up is given in the following pages. For boilers constructed to the requirements of a particular surveying body or boiler insurance company, the rules of the body concerned should be consulted.

Standard Conditions for the Design and Construction of Marine Boilers.*

(Abstract.)

MATERIALS OF CONSTRUCTION.

(Based on British Standards.)

Process of Manufacture.—Structural steel for marine boilers shall be made by the open-hearth process, acid or basic.

Freedom from Defects.—The finished material shall be free from cracks, surface flaws, and lamination. It shall also have a workmanlike finish, and must not have been hammer-dressed.†

Tensile Tests: Plates.—The tensile breaking strength of steel plates for shells and girders, determined from Standard test pieces, shall be between the limits of 28 tons and 35 tons per square inch, but a range of not more than 4 tons per square inch shall be permitted in any one case. For plates intended for flanging or welding, and for combustion chambers and furnaces, the tensile breaking strength shall be between the limits of 26 tons and 30 tons per square inch. The elongation, measured on a Standard test piece having a gauge length of 8 ins., shall be not less than 20 per cent. for material of $\frac{3}{8}$ in. in thickness and upwards, required to have a tensile breaking strength between the limits of 28 tons and 35 tons per square inch; and not less than 23 per cent. for material of $\frac{3}{8}$ in. in thickness and upwards, required to have a tensile breaking strength between the limits of 26 tons and 30 tons per square inch.

Stay Bars.—The tensile breaking strength of longitudinal stays shall be between the limits of 28 tons and 35 tons per square inch, with an elongation of not less than 20 per cent. measured on the Standard Test Piece B, but a range of not more than 4 tons per square inch shall be permitted in any one case. For steel bars for combustion chamber stays the tensile breaking strength shall be between the limits of 26 tons and 30 tons per square inch, with an elongation of not less than 23 per cent. measured on the Standard Test Piece B.

Where stay bars are tested on a gauge length of 4 times the diameter (Test Piece F), the elongation shall be 24 per cent. and 28 per cent. respectively.

The tensile breaking strength of angle and tee bars shall be between the limits of 28 and 32 tons per square inch, with an elongation of not less than 20 per cent. measured on the Standard Test Piece A.

For material under $\frac{3}{8}$ in. in thickness the elongation may be 3 per cent., but not more than 8 per cent., below the above-named elongations.

Wherever practicable the rolled surfaces shall be retained on two opposite sides of the test piece.

Rivet Bars.—The tensile breaking strength of rivet bars shall be between the limits of 26 tons and 30 tons per square inch of section, with an elongation of not less than 25 per cent. measured on the Standard Test Piece B or 30 per cent. measured on the Standard Test Piece F. The bars may be tested the full size as rolled.

Bend Tests: Cold Bends.—Test pieces shall be sheared lengthwise or crosswise from plates or bars, and shall not be less than $1\frac{1}{4}$ ins. wide, but for small bars the whole section may be used. For rivet bars bend tests are not required.

Temper Bends.—The test pieces shall be similar to those used for cold bend tests. For temper bend tests the samples shall be heated to a blood-red colour and quenched in water at a temperature not exceeding 80° F. The colour shall be judged indoors in the shade.

In all cold bend tests, and in temper bend tests on samples 0·5 in. in thickness and above, the rough edge or arris caused by shearing may be removed by filing or grinding, and samples 1 in. in thickness and above may have the edges machined, but the test pieces shall receive no other preparation. The test pieces shall not be annealed unless the material from which they are cut is similarly annealed, in which case the test pieces shall be similarly and simultaneously treated with the material before testing.

For both cold and temper bends the test piece shall withstand, without fracture, being doubled over until the internal radius is equal to $1\frac{1}{2}$ times the thickness of the test piece, and the sides are parallel.

For small sectional material these bend tests may be made from the flattened bar.

Bend tests may be made either by pressure or by blows.

* Published by His Majesty's Stationery Office.

† The Board of Trade has more detailed instructions which it proposes to retain.

Tests for Manufactured Rivets.—**Rivets selected by the Inspector from the bulk shall withstand the following tests:—**

(*a*) The rivet shanks are to be bent cold, and hammered until the two parts of the shank touch, without fracture on the outside of the bend.

(*b*) The rivet heads are to be flattened, while hot, in the usual manner, without cracking at the edges. The heads are to be flattened until their diameter is 2½ times the diameter of the shank.

FORMS OF BRITISH STANDARD TENSILE TEST PIECES.

For Plates and other Structural Material.

TEST PIECE A.

X.—For thicknesses over ⅞ths in.: Maximum width allowed = 1½ ins. Y.—For thicknesses ⅜ths in. to ⅞ths in.: Maximum width allowed = 2 ins. Z.—For thicknesses under ⅜ths in.: Maximum width allowed = 2½ ins.

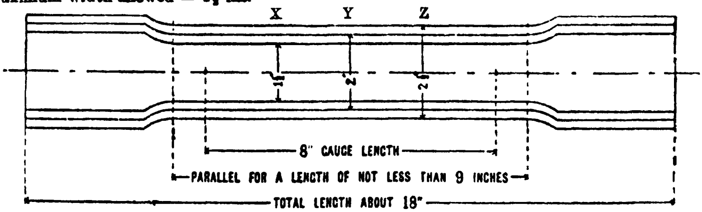

FIG. 6.

NOTE.—It will be observed that the widths given above, being maxima, do not exclude the use of the usual 1½ ins. by 8 ins. test pieces.

TEST PIECE B.

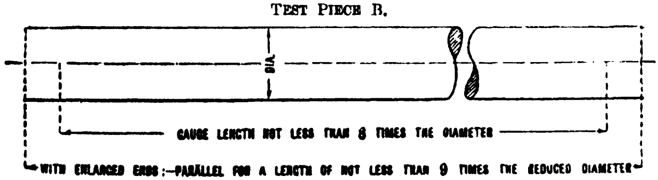

FIG. 7.

TEST PIECE F.

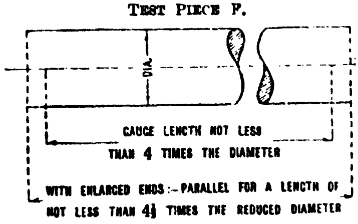

FIG. 8.

SPECIAL IRON FOR SCREW STAYS FOR COMBUSTION CHAMBERS

In order that iron screw stays may be approved of the same size as would be required for mild steel, the iron must withstand the following tests:—

Tensile Tests.—**The tensile breaking strength shall not be less than 21½ tons per square inch, with an elongation of not less than 25 per cent. measured on the Standard Test Piece B, or of 30 per cent. measured on the Standard Test Piece F.**

Bend Tests.—**Test pieces either of the bar as rolled, or turned down to 1 in. diameter, shall stand bending cold until the sides are parallel and the space between the two sides is not greater than the diameter of the test piece.**

Diameters and Thickness of Plain and Stay Tubes.—The following table may be worked to :—

Outside Diameter in Inches.	Standard Thicknesses in L.S.G.				Suitable for Working Pressures of Lbs. per Square Inch.			
Inches.	A	B	C	D	A	B	C	D
2	—	11	10	9	—	155	215	300
2¼	11	10	9	8	140	190	260	315
2½	11	10	9	8	125	175	230	300
2¾	11	10	9	8	110	160	215	275
3	10	9	8	7	140	190	250	300
3¼	10	9	8	7	130	180	230	280
3½	10	9	8	7	120	165	215	260

The minimum thickness of stay tubes measured under the threads shall be ¼ in. for marginal stay tubes, and $\frac{3}{16}$ in. for other stay tubes.

Thickened Ends.—If stay tubes are required to have their thickness increased at the screwed ends, so that the thickness at the bottom of thread is practically the same as in the body of the tube, the thickening is to be attained by upsetting and not by any welding process, and the tubes are to be annealed after the upsetting.

Screwed Threads to be Continuous.—Stay tubes must be screwed at both ends with a continuous thread, which should not be finer than 10 threads per inch. It is desirable, however, that they should be screwed to the standard 9 threads per inch, therefore, after 30th June, 1921, this should be the rule.

MARINE BOILERS, CYLINDRICAL TYPE.

General Conditions as to Design, Workmanship, Hydraulic Test, etc.

In the design and construction of marine boilers the following conditions should be observed :—

Riveting of End Seams.—The riveting of the seams joining the end plates to the cylindrical shell shall be not less than 42 per cent. of that of the solid plate. Where the shell plates exceed ⅝ in. in thickness the seams connecting the shell plates to the end plates are to be double riveted.

Other Circumferential Seams.—The circumferential seam at or near the middle of the length of single-ended boilers should have a strength of joint not less than 60 per cent. of the solid plates. The inner circumferential seams of double-ended boilers should have a strength of joint not less than 62 per cent. of the solid plate. In any case there shall be three rows of rivets when single-ended boilers have shell plates over 1⅜ ins. in thickness, and when double-ended boilers have shell plates over 1$\frac{5}{16}$ ins. in thickness. Where the shell plates exceed ⅞ in. in thickness the intermediate circumferential seams of double-ended boilers are to be at least double riveted.

Welding and other Treatment of Plates.—No steel plates subject to a direct tensional stress are to be welded except where the weld is covered by a butt strap or straps. For small steam domes, by special permission where the welding is done by hammer and the plates do not exceed ⅜ in. in thickness, the straps may be omitted. The strength shall, in such cases, be assumed to be 50 per cent. of that of the solid plate. All steel plates which are welded, dished, flanged, or locally heated, are to be afterwards efficiently annealed.

Butt Straps.—Butt straps must be cut from plates, and not from rolled strip.

Rivet Holes.—All rivet holes must be drilled 'fair,' and as far as possible they should be drilled in place. After drilling the plates the burrs should be removed and the faying surfaces of the plates cleaned, and the sharp outer edges of holes removed also.

Stays not to be Welded. Annealing of Fire-worked Stay Bars.—No steel stays are to be welded. If plus threads are desired, the ends of the stay bars may be upset or the bars may be drawn down in the central portions from bars originally of the size of the ends. In either of these two cases the bars must be subsequently annealed throughout.

In double-ended boilers the through longitudinal stays must be supported at or near the middle of their length.

Threads of Screw and other Stays.—All longitudinal stays and also screw stays should have threads in accordance with the British Standard Specification, and true to pitch, *viz.* :—
All screw stays 1¼ ins. in diameter and upwards should have 9 threads per inch, and all stays 2 ins. in diameter and above passing through plates and secured by nuts on each side of the plate should have not more than 6 threads per inch.

Compensation Rings to Manholes.—Where the cylindrical shell is cut for a manhole, compensation must be provided and must be such that the strength in way of the hole is not less than that required for the longitudinal joint.

Hydraulic Tests of New Boilers.—In all new boilers working at pressures up to 100 lbs. per square inch the hydraulic test must be twice the working pressure. For boilers working at pressures greater than 100 lbs. per square inch the hydraulic test pressure must be $1\frac{1}{2}$ times the working pressure plus 50 lbs. per square inch.

RULES FOR DETERMINING THE WORKING PRESSURE TO BE ALLOWED ON VARIOUS PARTS OF CYLINDRICAL MARINE BOILERS.

CYLINDRICAL SHELLS.

Formula for Working Pressure of the Shell.—For the cylindrical shells of steel marine boilers the maximum working pressure (which is designated by W.P. and is in lbs. per square inch) to be allowed shall be calculated from the following formula :—

Where the thickness of the shell plates does not exceed $1\frac{3}{8}$ ins.,

$$\text{W.P.} = \frac{(t-2) \times S \times J}{C \times D}$$

Where the thickness of the shell plates exceeds $1\frac{3}{8}$ ins. and double butt straps are fitted

$$\text{W.P.} = \frac{t \times S \times J}{2 \cdot 85 \times D}$$

where,

t is the thickness of the shell plates in 32nds of an inch,

S is the minimum tensile strength of the steel shell plates in tons per square inch,

J is the percentage of strength of the longitudinal seams calculated by the methods described below.

C is a coefficient, which is 2·75 when the longitudinal seams are made with double butt straps; 2·83 when the longitudinal seams are made with lap joints and are treble riveted; 2·9 when they are made with lap joints and are double riveted; and 3·3 when they are made with lap joints and are single riveted.

D is the inside diameter of the outer strake of plating of the cylindrical shell measured in inches.

N.B.—The factor of safety must be in no case less than 4.

Methods of Calculating the Strength of Riveted Joints.—The percentage of strength of a riveted joint (J) is found from the following formulæ (I), (II), (III): (I) and (II) are applicable to any type of joint; (III) is applicable only to that type of joint in which the number of rivets in the inner rows is double that in the outer row. The lowest value given by the application of these formulæ is to be taken as the percentage of strength of the joint.

(I) Percentage of strength of plate at joint as compared with solid plate $= \dfrac{100\,(p-d)}{p}$

(II) Percentage of strength of rivets as compared with the solid plate $= \dfrac{100\,(S_2 \times a \times n \times C)}{S_1 \times p \times T}$

(III) Percentage of combined strength of the plate at the inner row of rivet holes and of the rivets in the outer row

$$= \frac{100\,(p-2d)}{p} + \frac{100\,(S_2 \times a \times C)}{S_1 \times p \times T},$$

where,

p = pitch of rivets at outer rows in inches;

d = diameter of rivet holes in inches;

a = sectional area of one rivet in square inches;

n = number of rivets which are fitted in the pitch p;

T = thickness of plate in inches;

C = 1·0 for rivets in single shear as in lap joints;

C = 1·875 for rivets in double shear as in double butt-strapped joints;

S_1 = minimum tensile strength of plates in tons per square inch;

S_2 = shearing strength of rivets, which is taken generally to be 23 tons per square inch, and may be 85 per cent. of the minimum tensile strength of the rivet bar.

Thickness of Butt Straps.—Where the longitudinal seams are fitted with double butt-strapped joints, the outer butt strap should have at least 0·625 of the strength of the plate, and should be of sufficient thickness to permit of efficient caulking of its outer edges. The inner butt strap should be $\frac{4}{32}$ in. thicker than this.

In cases where the number of rivets in the inner rows is double the number in the outer rows this will require the thickness of the outer strap to be

$$t = \frac{5 \times (p-d)}{8 \times (p-2d)} \times T,$$

and that of the inner strap to be at least

$$t_n = \frac{5 \times (p-d)}{8 \times (p-2d)} \times T + \frac{4}{32} \text{ in.}$$

Distances between rows of Rivets and between Rivets and Plate Edges.—In all cases the clear space between a rivet hole and the edge of a plate should not be less than the diameter of the rivet hole—i.e. the centre of the rivet hole should be at least $1\frac{1}{2}$ diameters distant from the edge of the plate.

In joints, whether lapped or fitted with butt straps, in which there are more than one row of rivets and in which there is an equal number of rivets in each row, the distance between the rows of rivets should be not less than $0 \cdot 33p + 0 \cdot 67d$, with zigzag riveting, or $2d$ with chain riveting.

In joints in which the number of rivets in the outer rows is one-half of the number in each of the inner rows, and in which the inner rows are chain riveted, the distance between outer rows and the next rows should be not less than $0 \cdot 33p + 0 \cdot 67d$ or $2d$, whichever is the greater, and the distance between the rows in which there are the full number of rivets should be not less than $2d$.

In joints in which the number of rivets in the outer rows is one-half of the number in each of the inner rows, and in which the inner rows are zigzag, the distance between the outer rows and the next rows should be not less than $0 \cdot 2p + 1 \cdot 15d$, and the distance between the rows in which there are the full number of rivets should be not less than $0 \cdot 165p + 0 \cdot 67d$.

In the above p is the pitch of the rivets in the outer rows.

Maximum Pitch of Rivets in Longitudinal Joints.—The maximum pitch of the rivets in the longitudinal joints of boiler shells is to be—

$$\text{Maximum pitch in inches} = C \times T + 1\tfrac{5}{8} \text{ ins.}$$

where T is the thickness of the plate in inches and C is a coefficient as given in the following table:—

Number of Rivets per Pitch.	Coefficients for Lap Joints.	Coefficients for Double Butt-strapped Joints.
1	1·31	1·75
2	2·62	3·50
3	3·47	4·63
4	4·14	5·52
5	—	6·00

FURNACES.

Plain Furnaces.—The working pressure to be allowed on plain furnaces or furnaces strengthened by Adamson or other joints, and on the cylindrical bottoms of combustion chambers, is to be determined by the following formulæ, the least pressure obtained by either formula being taken:—

$$\text{W.P.} = \frac{C\,(t-1)^2}{(L+24) \times D}, \text{ or W.P.} = \frac{C_1}{D} \times [10\,(t-1) - L].$$

where D is the external diameter of the furnace or combustion chamber bottom in inches;

t is the thickness of the furnace plate in 32nds of an inch;

L is the length of the furnace or of combustion chamber bottom or the length between points of substantial support, in inches, measured from the centres of rivet rows or from the commencement of flange curvature, whichever is applicable;

C = 1,450 where the longitudinal seams are welded, and 1,300 where they are riveted;

C_1 = 50 where the longitudinal seams are welded, and 45 where they are riveted.

W.P. = working pressure in lbs. per square inch.

Corrugated Furnaces.—The working pressure to be allowed on corrugated furnaces is to be determined by the following formula:—

$$\text{W.P.} = \frac{C(t-1)}{D},$$

where D is the external diameter measured at the bottom of the corrugations in inches;

t is the thickness of the furnace plate in 32nds of an inch, measured at the bottom of the corrugation or camber;

C is a coefficient which is 480 for the Fox, Morison, Deighton, Purves, and other similar furnaces, 510 for the Leeds Forge Bulb Suspension furnace.

N.B.—No furnace, plain or corrugated, should exceed $\frac{13}{16}$ in. in thickness.

FLAT PLATES SUPPORTED BY STAYS SECURED IN VARIOUS WAYS.

Flat Plates supported by Screwed Stays.—The working pressure to be allowed on flat plates supported by stays is to be calculated by the following formula:—

$$\text{W.P.} = \frac{(t-1)^2 \times C}{a^2 + b^2},$$

but if steel of less tensile strength than 26 tons per square inch is used the working pressure allowed shall be correspondingly reduced.

In this formula,

W.P. is the working pressure in lbs. per square inch;

t is the thickness of the flat plate in 32nds of an inch;

a is the distance apart of the rows of stays in inches;

b is the pitch of the stays in the rows in inches;

C is a coefficient which varies with the method of fixing the stays as follows:—

Where the plates are exposed to flame and the stays are screwed into the plate and their ends are riveted over, C = 50.

Where the plates are not exposed to flame and the stays are screwed into the plate and their ends are riveted over, C = 57.

In these cases the thickness of the plate must be at least half the diameter of the stay required by the rule.

Where stay tubes are screwed into tube plates and expanded, C = 52. If they are fitted with nuts, C = 72.

Where the plates are exposed to flame and the stays are screwed into the plate and fitted with nuts on the outside, C = 75. Where the plates are not exposed to flame, C = 86.

Where the stays pass through the plates not exposed to flame and are fitted with nuts inside and outside, C = 96.

Where plates are stiffened by flanging, the inner radius of which is not greater than $2\frac{1}{2}$ times the thickness of the plate, for the support thus given C = 110 when the plates are not exposed to flame, and C = 96 where they are exposed to flame. The pitch is to be reckoned from the commencement of the curvature.

GIRDERS.

Girders Supporting Combustion Chamber Tops.—For girders supporting the tops of combustion chambers the following formula is to be used:—

$$\text{W.P.} = \frac{C \times d^2 \times t}{(L-P) \times D \times L} \times \frac{S}{28},$$

where,

d is the depth of the girder at centre in inches;

t is the thickness of the girder at centre, when this is a forging, or the sum of the thicknesses of the plates when the girder is made of two plates, measured in 32nds inch;

L is the length of the girder in inches, measured between the tube plate and back chamber plate inside, or between tube plates in chambers common to two opposite furnaces;

P is the pitch of stays supported by the girder, in inches;

D is the distance apart of the girders, centre to centre, in inches;

S is the minimum tensile strength of the steel plates forming the girder, in tons per square inch. In the case of forged girders S is to be taken as 24 for iron and 28 for steel;

C is a coefficient as follows:—

$$C = \frac{n}{n+1} \times 495,$$

when the number of stays in each girder is odd, and

$$= \frac{n+1}{n+2} \times 495,$$

when the number of stays in each girder is even, n being the number of stays to each girder.

STAYS.

Iron or Steel Screw Stays to Combustion Chambers.—For screw stays with threads not coarser than 9 threads per inch, made of steel or of special wrought iron tested to the requirements, the following formula is to be used:—

$$\text{W.P.} = \frac{(d - 0{\cdot}267)^2 \times 8{,}250}{a},$$

where

d is the diameter of the stay over the thread in inches;

a is the area in square inches supported by one stay.

But in no case must the stress exceed 9,000 lbs. per square inch of section.

Steel Longitudinal Stays.—For steel longitudinal stays with threads not coarser than 6 threads per inch, the working pressure is to be calculated from the following formula:—

$$\text{W.P.} = \frac{(d - 0{\cdot}340)^2 \times 9{,}500}{a} \times \frac{S}{28},$$

where d is the diameter of the stay over the thread in inches;

a is the area in square inches supported by one stay;

S is the minimum tensile strength of the steel in tons per square inch.

But in no case must the stress exceed 11,000 lbs. per square inch of section, when steel of a minimum tensile strength of 28 tons per square inch is used.

In cases where longitudinal stays are made with enlarged ends, and the body of the stay is smaller in diameter than at the bottom of the thread, and in cases where coarser threads than 6 per inch are used, the working pressure is to be calculated from the following formula:—

$$\text{W.P.} = \frac{(d_1 - 0{\cdot}125)^2 \times 9{,}500}{a} + \frac{S}{28},$$

where d is the diameter of the stay at the bottom of the thread or at the smallest part of the body.

Stay Tubes.—On stay tubes, whether of wrought iron or of lap-welded steel, a working stress of 7,500 lbs. per square inch of the net sectional area at the bottom of the thread is permitted.

Dished Ends (Convex Outside).—For ends of steam chests, etc., dished to partial spherical form, the following formula is to be used:—

$$\text{W.P.} = \frac{15 \times S(t-1)}{R},$$

where

W.P. is the working pressure in lbs. per square inch;

t the thickness in 32nds of an inch;

R the inner radius of curvature of the end in inches, which shall not exceed the diameter of shell;

S the minimum tensile strength of plates in tons per square inch.

Safety Valves.—At least two safety valves must be fitted to each boiler. They must be arranged so that the springs and valves are cased in, that the valves cannot be overloaded when steam is up, that they can be lifted by easing gear, and turned round on their seats by hand, and in case of fracture of springs they cannot lift out of their seats.

The easing gear must be arranged to lift all the safety valves on a boiler together, and must be workable from some accessible place free from steam danger.

All the safety valves of each boiler may be fitted in one chest, which must be separate from any other valve chest and which must be connected direct to the boiler by a strong and stiff neck, the passage through which should have a cross-sectional area at least equal to one-half the aggregate area of the safety valves in the chest.

Each safety valve box shall have a means of draining it; the pipe shall lead to the bilge or tank clear of the boiler.

Size of Safety Valves.—The minimum aggregate area of the safety valves of the ordinary type in each boiler, whether coal-fired or oil-fired, and whether working under natural, forced or induced draught, shall be found by the following formula:—

Aggregate area of safety valves in square inches

$$= \text{Total heating surface of boilers in square feet} \times \left(\frac{K}{p + 15}\right),$$

where p is the working pressure in lbs. per square inch.

For coal-fired boilers K is 1·25, for oil-fired boilers and boilers with closed stokehold forced draught K = 1·5.

Accumulation Test of Safety Valves.—All safety valves must be set to the required pressure under steam. During a test of 15 minutes with the stop valves closed, and under full firing conditions, the accumulation of pressure must not exceed 10 per cent. of the loaded pressure. During this test no more feed-water should be supplied than is necessary to maintain a safe working water level.

Superheater Safety Valves and Drains.—Where a superheater is fitted which can be shut off from the boiler it must have a separate safety valve fitted with easing gear, etc. The valve as regards construction must comply with the regulations for ordinary safety valves, but the easing gear may be fitted to be workable from the stokehold only.

The superheater must be fitted with a drain cock or valve to free it from water when necessary.

British Standard Specification for Charcoal Iron Lapwelded Boiler Tubes.*

(No. 43—1927.) (*Abstract.*)

1. The tubes shall be lapwelded and shall be made from genuine charcoal iron of the best quality. 2. The tubes shall be sound, clean, smooth and well finished, free from surface defects, rust and longitudinal grooving, both internally and externally, and the ends shall be clean and square. 3. The tubes shall be carefully annealed at both ends. 6. The tubes or strips cut from the tubes shall show a tensile strength between the limits of 19 and 24 tons per square inch inclusive, with a contraction of area of the metal of not less than 45 per cent. 7. The tubes shall stand bulging both hot and cold with a parallel drift (fig. 9) without showing either crack or flaw, until the diameter of the bulged end exceeds the original diameter of the tube by not less than 15 per cent. when tested hot and by not less than 10 per cent. when tested cold. 8. A piece

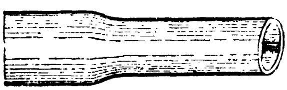

FIG. 9.

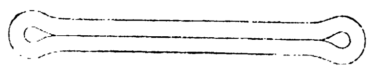

FIG. 10.

of tube 2 ins. long shall be placed on end and shall stand hammering down until it is reduced to 1 3/8 in. high, without showing crack or flaw. 9. The tubes shall, when cold, stand flattening (fig. 10) without showing crack or flaw until the interior surfaces of the tubes meet. 10. Each tube shall be tested by an internal hydraulic pressure of at least 750 lbs. per sq. in., and any tubes failing to stand this test shall be rejected.

British Standard Specification for Cold Drawn Weldless Steel Tubes for Locomotive Boilers.*

(No. 53—1927.) (*Abstract.*)

Quality of Material.

1. The tubes shall be cold drawn and weldless, and shall be manufactured from steel of the best quality made by the Open-Hearth process. They shall not show on analysis more than 0·035 per cent. of sulphur or more than 0·030 per cent. of phosphorus. The manufacturer shall supply an analysis when required to do so.

Freedom from Defects.

2. The tubes shall be perfectly sound, clean, smooth, and well finished, free from surface defects, rust and longitudinal grooving, both internally and externally, and the ends shall be clean and square.

Annealing.

3. The tubes shall be carefully annealed throughout their length after the operation of drawing and the ends shall be carefully annealed after the process of enlarging or decreasing the diameter.

* By permission of the British Standards Institution.

Permissible Variation in Weight.

4. The actual weight of each tube shall not differ from the calculated weight by more than 5 per cent. above or $2\frac{1}{2}$ per cent. below the weight calculated from the specified dimensions, allowing 489·6 lbs. per cubic foot of metal in the tubes.

Tensile Test.

6. The tubes or strips cut from the tubes shall, without further annealing, show a tensile strength of not less than 20 tons per sq. in. nor more than 26 tons per sq. in. with an elongation of not less than 28 per cent. in 8 ins. for tubes, and not less than 22 per cent. in 8 ins. for strips cut from the Tubes. If strips are cut for testing from tubes over $2\frac{1}{2}$ ins. diameter they may be annealed before testing.

Crushing down Test.

8. A piece of tube 2 ins. long shall be placed on end and shall, when cold, stand hammering down until it is reduced to $1\frac{1}{4}$ ins. high, without showing either crack or flaw.

Flattening Test.

9. The tubes shall, when cold, stand flattening (fig. 10), without showing either crack or flaw until the interior surfaces of the tubes meet or, when the tubes are over 11 S.W.G. in thickness, until the interior surfaces are brought to a distance apart equal to the thickness of the wall of the tube.

Hydraulic Test.

10. Every tube shall be tested by an internal hydraulic pressure of at least 1,000 lbs. per sq. in., and any tubes failing to stand this test shall be rejected.

Tubes for Water-Tube Boilers and Superheaters.

The 'Board of Trade Instructions as to the Survey of Passenger Steamships,' 1928, states :—

The minimum thickness of tubes for pressures up to 350 lbs. per sq. in. shall be determined by the following rule :

$$t = \frac{\text{W.P.} \times d}{F} + 7$$

where W.P. = working pressure in lbs. per sq. in.

d = external diameter in ins.

t = thickness in $\frac{1}{100}$ths of an in.

For the two rows of tubes next the fire and round the gaps formed in the nest of tubes for the outflow of hot gases from the fire F = 55. For all the other tubes F = 75.

Superheater tubes.—The mean thickness of the heating tubes shall be determined from the formula $t = \frac{\text{W.P.} \times d}{75} + 5$. The symbols have the meanings given above.

The recent extensions of design to plants to work at very high pressures call for the development of a new formula for high pressure and high temperature combined.

Dorey proposes the following formula for high pressure water-tube boilers for marine purposes :

For fire row tubes $\quad t = \left[\frac{\text{W.P.} \times d_1}{100} + \frac{4000}{\text{W.P.}}\right] \frac{5000}{5000 + \text{W.P.}}$.

For ordinary row tubes $\quad t = \left[\frac{\text{W.P.} \times d_1}{100} + \frac{2000}{\text{W.P.}}\right] \frac{5000}{5000 + \text{W.P.}}$.

where t = thickness in hundredths of an inch,

W.P. = working pressure in lb. per sq. in.

d_1 = external diameter of tube in inches.

The terms $\frac{4000}{\text{W.P.}}$ in the first formula, and $\frac{2000}{\text{W.P.}}$ in the second are not to exceed 11 and 7 respectively.

CHIMNEY AND FLUE DIMENSIONS.

Apart from any consideration of production of draught, the height of a chimney must be such that the smoke and noxious gases are discharged at a level at which they will not be a nuisance. The minimum height is usually fixed by the bye-laws of local authorities.

For relation between draught in inches of water gauge and chimney height see page 22.

The area of the chimney depends on the amount of coal burned per hour on the grates of the boilers which it serves, and on the velocity of the gases in the chimney, and their temperature.

The gas velocity again depends on the draught pressure, and on the frictional resistances in the flues and chimney. Thus the area of the chimney for a given size of boiler or battery of boilers should take into account many factors, some of which are not capable of exact determination. This accounts for the empirical character of the rules given by various authorities, and for the variations in them.

For typical conditions, say about 600° F. chimney temperature, flues not abnormal in length, and of area about 20 to 40 per cent. greater than chimney area, and 25 to 28 lbs. of coal burned per sq. ft. of grate area per hour, the following rules give suitable areas:—

H = height of chimney in feet; A = area at top of chimney in sq. ft.; G = grate area.

$$A = \frac{k\,G}{\sqrt{H}};$$

here $k = 1\cdot5$ for one boiler, $1\cdot0$ for two, $0\cdot8$ for three, $0\cdot7$ for four, $0\cdot5$ for five or more.

At 28 lbs. coal per sq. ft. of grate area per hour this corresponds to

$$A = \frac{k\,W}{28\sqrt{H}};$$

where W = lbs. coal burned per hour.

For a 100-ft. chimney, and $k = 1\cdot4$,

A = 0·5 sq. ft. per 100 lbs. coal burned per hour

Other formulæ are:

(*a*) $$A = \frac{W}{14\sqrt{H}}$$

(evidently for lower rate of combustion than the above, as it would agree with $k = 1\cdot5$ and rate of combustion 21).

(*b*) **Area in sq. in.** $= \dfrac{\text{lbs. coal per hour} \times 12}{\sqrt{H}}$ . . . . . (*Bourne*).

or $A \text{ (sq. ft.)} = \dfrac{W}{12\sqrt{H}}$

(*c*) **Area in sq. ins. = 1·5 per lb. coal per hour** . . . . (*Bourne*).

or $A = \dfrac{1\cdot5}{144}W$

corresponding to $k = 1\cdot5$ if $H = 100$ and combustion rate $= 14\cdot4$).

(*d*) **Area in sq. ins.** $= \dfrac{\text{Area of grate}}{\sqrt{H} \times 1\cdot58}$ . . . . (*Elswick*)

or $A = \dfrac{1}{1\cdot58}\dfrac{G}{\sqrt{H}}$

corresponding to $k = 0\cdot63$).

(*e*) **Kent gives formulæ which correspond to the following:—**

Effective area E = A — 0·6 √A;

$W = 16\cdot65\,E\sqrt{H}$; $\quad D = 13\cdot54\sqrt{E} + 4$;

$E = \dfrac{0\cdot06\,W}{\sqrt{H}}$; $\quad S = 12\sqrt{E} + 4$;

where,

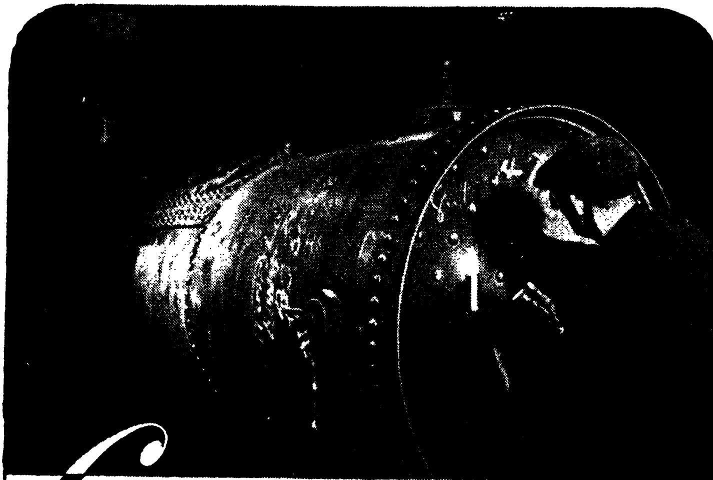
D = diam. of round chimney in inches; S = side of square chimney in inches.

The table on page 1419 has been calculated from the foregoing formulæ of group (*e*).

(*f*) **Sometimes the area of the chimney top is taken as $\frac{1}{8}$ to $\frac{1}{10}$ that of fire grate, the height not being taken into account.**

Flue areas should be about 20–40 per cent. greater than chimney area.

For stability of chimneys see Section XIII, page 464 (Vol. I).



Gainsborough Beauty

THERE'S beauty in a Marshall boiler — not an aesthetic beauty, but a beauty that only an engineer can see — the beauty of fine workmanship — the beauty of precision to the infinite degree. Every plate, every tube, every mounting is made with all the skill which represents the sum total of generations of Marshall craftsmanship.

LANCASHIRE CORNISH AND ECONOMIC BOILERS OF ALL SIZES AND TYPES, LOCO BOILERS AND VERTICAL BOILERS OF VARIOUS TYPES AND FOR ALL CLASSES OF FUEL.

WELDED WORK, DUCTING, KEIRS, PRESSURE VESSELS, AIR RECEIVERS, TANKS.

NOTES.—Under no circumstances must the height of a circular chimney exceed 12 times the diameter of the shaft at ground level. The corbelling at the bottom and below ground level must be at least equal to the thickness of the shaft brick work, and the angle of the corbelling must not be less than 45°. The batter of the chimney must not be less than 2½ ins. in diameter for every 10 ft. of height. The thickness of the brickwork must not be less than that given in the table above, with half-brick offsets every 20 ft. It is advisable that an access door should be placed on the base of each chimney to allow for cleaning.

Notwithstanding the above information, the design of a brick chimney must comply with the local by-laws of the district in which it is to be erected.

THE EMISSION OF DUST AND ASH FROM CHIMNEYS.

The following notes are largely based upon the Report of a Technical Committee appointed by the Electricity Commissioners to study the various methods adopted in Great Britain and on the Continent for the suppression of the dust nuisance from power station chimneys.

Power station chimneys should have a height not less than two and a half times that of the highest point of the station roof, or adjacent building. With this height it is found experimentally that such dust as is discharged will be carried away by an air-stream which will not subsequently come into contact with the ground. Sulphurous gases from the fuel will likewise be rendered harmless. With chimneys of the height stipulated there should be no need for any dust-extraction apparatus in stoker-fired plants provided that the gas velocities and the rate of combustion are moderate. Where these conditions do not exist, or where low-grade fuel is burnt, the most suitable apparatus for eliminating the dust is the multiple cyclone type of extractor. For pulverised fuel installations, some form of dust extraction plant is always necessary, and the most suitable type is the electrostatic precipitator. While 'wet' types of dust extractors are capable of preventing the dust nuisance, they have many practical disadvantages.

THE CONCENTRATION OF GRIT IN FLUE GASES.

A stoker-fired plant burning a fuel with an ash content of 12 per cent. may pass to the chimney 10 per cent. of the ash in the fuel, or about 0·3 grains of dust per cub. ft. of flue gas. A pulverised fuel plant burning similar fuel might pass to the chimney 70 per cent. of the ash or about 2·62 grains per cub. ft. of gas. There are methods of coal cleaning which will reduce the ash content, and therefore the dust emission to a very low figure, but although practically ash-free coal might be advisable for pulverised fuel plants, fuels with a very low ash content are found by experience to make the conditions too severe for mechanical stokers.

The solid particles in the flue gases are usually graded according to their size in microns (0·001 millimeter) as determined by standard sieves. This method, however, is very unsatisfactory as sieve measurements are unreliable below 63 microns, and impossible below 40 microns, while they ignore the most important factor in creating a dust nuisance, namely the specific gravity of the particles. For these reasons grading by means of air-elutriation is preferable. The dust produced by pulverised fuel plant contains about 50 per cent. of particles less than 20 microns in diameter, and as these will remain suspended in the air almost indefinitely they are unlikely to cause a nuisance. An extraction plant should therefore be capable of eliminating practically all particles over this size, besides a good proportion of those smaller. A modern electrostatic plant will remove 90 per cent. of all dust, and 93 per cent. of that which escapes will be less than 30 microns in diameter.

The quantity of dust in flue gases cannot be calculated from the ash content of the fuel as given by analysis because dissociation of the ash takes place at furnace temperature, resulting in a loss of weight that may amount to 10 per cent. The efficiency of a dust extraction plant has therefore to be found by determining the weight of dust per cub. ft. of gas before and after the apparatus. This is done by drawing a sample of the gas through a filter and weighing the dust deposited on the filter.

Types of Dust Extraction Plant.

There are four types of dust extraction plant which may be referred to as (1) the water-film type; (2) the combined spray and water-film type; (3) the electrostatic type, and (4) the cyclone type. The first two depend upon the use of water, while in the others the gases are dry and uncooled throughout. The wet systems are cheaper to instal and operate provided that the effluent can be disposed of without the use of costly filtration plant. They have the effect of reducing the gas temperature to 140° F. or less at the base of the stack, but the induced draught fans cannot take advantage of this as the fans have to be placed at the inlet side of the dust extractor to avoid corrosion from the wet gases, which is more serious than the erosion by the grit in the untreated gases. In the dry systems the fans may be placed at the outlet of the extractor where they only have to handle clean non-erosive gases.

Water Film Type of Dust Extraction Plant.

In one of the best-known designs of this type, the elements consist of hollow four-sided vertical cast iron pipes, arranged in staggered formation in a horizontal flue. Water is supplied to the interior of each pipe and overflows in a continuous trickle down the outsides, which are slightly concave in plan. The gas passes transversely among the set of pipes and the dust collected by their wet sides is washed down to a tank beneath. The draught loss is about 0·75 in. of water, and the gases leave at a temperature of about 120° F.

Combined Water Spray and Film Type of Plant.

In a typical plant of this kind the gases enter a chamber in which they are first subjected to the action of a series of atomising water sprays. They are then turned upwards and backwards through a nest of staggered vertical baffles. The latter are V-shaped in cross-section, and are kept wet by secondary water jets playing on their upper ends. The effluent is in the form of a fine slurry containing about 1·5 per cent. of solid matter. The draught loss is about 1·0 in. w.g. and the outlet temperature of the gases about 140° F.

Electrostatic Type of Dust Extractor.

In electrostatic dust extractors the flue gas is caused to pass through tubes or between planes which form the collecting electrodes. These are maintained at earth potential, and receive the dust extracted from the gas. Down the centre of each pipe, or between adjacent plates, is a discharge electrode, consisting of a wire or rod furnished with discharge points. The discharge electrodes are maintained at a constant negative potential of 60,000 to 70,000 volts. The dust particles in the gas are ionised by the brush discharge from these electrodes and consequently travel across to the surface of the collector electrodes where they give up their charges. The particles then fall by gravity into the hoppers below, any tendency for the dust to adhere to the surfaces being counteracted by a hammer gear which raps the electrodes from time to time. The high negative voltage required for the discharge electrodes is obtained by a transformer and rectifier controlled by a low tension switchboard. The power consumption is very low, amounting only to about 2 kW.h. per million cub. ft. of gas cleaned. The draught loss is about 0·25 in. w.g. and the temperature of the gas is practically unchanged by passing through the apparatus. The draught fans are placed on the outlet side of the plant so that they work with clean gas only and are thus not subjected to erosion. The dust is delivered dry and in very fine particles. It may be removed in this state or carried away by flushing with water, as may be most convenient.

The Cyclone Type of Dust Extractor.

The essential feature of this type of extractor is a casing of volute shape into which the dust-laden gases enter tangentially. Beneath the volute are a number of truncated cones alternating

with cylindrical parts, terminating in a dust outlet at the bottom. The dirty gases travel downwards in a spiral path, throwing out their solid particles by centrifugal force against the inner wall of the casing. The core of clean gas at the centre of the spiral flows upwards to the central outlet at the top. The fan handles the clean gas leaving the apparatus and so works under the best conditions as regards erosion. The draught loss amounts to about 2 ins. w.g. and the heat loss is very small. For dealing with the gases from a 270,000 lb. pulverised fuel boiler, a dozen cyclones may be used in parallel, some of them being shut off during periods of light load.

The Removal of Sulphur from Flue Gases.

Untreated flue gases contain not only grit and dust, but also sulphurous gases derived from the sulphur in the coal burnt, and these gases form acids which have a very deleterious effect upon vegetation and buildings. Although there can be little doubt that by far the greater part of the sulphurous gases in the atmosphere is derived from domestic fires, there is a justifiable demand that power stations in urban areas shall not add to the pollution of the air and many plants have incurred heavy expenses in their efforts to comply with this demand. From the findings of the Committee appointed by the Electricity Commissioners to enquire into the question of dust and grit emission, it would seem that sulphurous gases would not be harmful if discharged from chimneys having a height of at least two and a half times that of the highest point of the nearest roof, as they would then enter a current of air that would not subsequently come into contact with the ground. At certain important power stations, however, such as those at Battersea and Fulham, elaborate flue gas washing apparatus has been installed. At Battersea washing is effected with river water, and also with limed water for the absorption of the sulphur compounds. Thames water is used, and as the liquid effluent is returned to the water, the plant has to include means of rendering this effluent innocuous.

The gases from the boilers pass first through grit arresters, then through 'primary chambers' where they are sprayed with water to remove any dust before they enter the main flue. This flue runs the length of the boiler house, and terminates in large chimney towers at each end. Banks of scrubbers, formed of steel channels are placed in the main flue. The sulphites first obtained are oxidised to sulphates by contact with the iron oxide on the surfaces of the channels, and by the use of aerated wash water, which is re-circulated. From the main flue the gases pass into downtakes in the chimney towers, where they come into contact with limed water and wooden scrubbers. The gases then enter the uptakes leading to the chimneys, passing through more scrubbers supplied with alkaline water, before being finally discharged. The effluent is treated to limit the salts in solution, and also filtered before being sent back to the river. The Battersea flue gas washing plant is described in a paper read by Messrs. Hewson, Pearce, Pollitt and Read before the Society of Chemical Industry in July 1933. During the year 1938 this plant removed 3,680 tons of sulphur from a total of 465,000 tons of coal burnt.

The gaswashing plant at Fulham is of the I.C.I.—Howden type, and is characterised by the absence of any effluent. The gases are scrubbed with an alkaline liquor from which the solids are settled out, and removed as sludge. A plant of this type, installed at the Swansea power station, was described in a paper by Pearson, Nonhebel and Ulander, published in the *Journal of the Institute of Fuel*, 1935.

The Treatment of Boiler Feed Water.

The treatment of raw water to make it fit for boiler feeding is a matter that can only be decided on in the light of a chemical analysis of the water concerned. Expert advice on the subject can always be obtained from the reputable firms who specialise in water-softening, and such firms, moreover, will always be ready to guarantee the results of the treatment they recommend. There are, nevertheless, certain things that all operating engineers should know about water, including a number of simple tests that can be carried out in any plant.

The scale-forming properties of water are due to its hardness The total hardness is made up of the so-called 'temporary hardness' and 'permanent hardness.' The temporary hardness, which can be removed by boiling, is due to the presence of bicarbonates of calcium and magnesium in solution, while the permanent hardness, which cannot be disposed of in this way, is caused mainly by the sulphates, chlorides and nitrates of the same elements. The hardness of water, whether temporary, permanent, or total, is measured by 'Degrees Clark,' one degree denoting a hardness equal to that which would be caused by the presence of one grain of calcium carbonate per gallon. This is equivalent to 14·2 parts per million. The total hardness of the public water supply of 50 British towns has been found to range from 0·80° to 39·18°, the average hardness being 13·20°. As a general rule all waters with more than a few degrees of hardness should be given chemical treatment before being used as feed, even for boilers of the tank type, while extremely soft natural waters should also be looked on with suspicion.

There are on the market innumerable 'boiler compounds' which their makers recommend should be mixed with the raw water with the object of preventing scale, or at least of ensuring that any scale should be of a soft and easily removable nature. These compounds are usually dribbled at a constant rate, into the feed-water in a heater of the open type, in the hope that, on

the average, the right amount will be supplied. Boiler compounds differ greatly in composition, their principal ingredients, apart from water, being usually soda ash, caustic soda, tri-sodium phosphate, and often some organic material such as tannin which has the property of causing the lime salts to be precipitated as a soft sludge. When water requires softening, it is better and cheaper to do it outside the boiler by means of apparatus that can be relied on to dose the water with known chemicals in the exact quantities required to give the correct results. The feeding of chemicals into the boiler is apt to cause foaming and priming as well as involving excessive blowing down.

The Soap Test for Hardness of Water.

The simplest way of testing water for hardness consists of shaking up a sample of the water with increasing quantities of standard soap solution, and noting the quantity of the soap solution required to form a permanent lather. To carry out the test, 70 c.c. of the water are placed in a stoppered bottle, into which the soap solution is run, 1 c.c. at a time, from a graduated burette. The stopper is replaced, and the bottle violently shaken after each addition of soap. The total hardness of the water, in Clark degrees, is given by the number of c.c. of soap solution used to form a permanent lather on the water after shaking up. The standard soap solution can be obtained from any firm of manufacturing chemists, and is standardised by testing with water of standard hardness.

In carrying out the soap test there are two points that need attention. Firstly the addition of soap solution to the sample must be continued until a lather is formed that will last for five minutes. The reason for this is that with some waters a temporary lather may be formed which will quickly disappear, and must not be mistaken for the true lather. The second point of importance is the necessity of taking care that the hands are clean and that the fingers are not used in place of the stopper to close the bottle when it is shaken, for the slightest contamination of the sample with oil or grease will prevent a lather being formed.

The Lime and Soda Water Softening Process.

The commonest method of softening water is by means of the lime and soda process. The treatment is carried out in automatic water softeners which add a properly adjusted mixture of lime and soda solution in proportion to the quantity of water passing through the apparatus. The amounts of lime and soda required are best determined by a previous analysis of the water. The lime serves to destroy the temporary hardness, while the soda destroys the permanent hardness. If the water is treated cold, the softener should be large enough to hold a four hours' supply. The process is very much more rapid when the water is hot. A smaller softener can therefore be used if the water is heated, which is sometimes done by turning exhaust steam into the softener itself.

When the temporary and permanent hardness of the water are known, the approximate quantities of lime and soda needed may be found from the following formula:

Lbs. lime per 1,000 galls. water = 0·096 times the temporary hardness.
Lbs. soda-ash per 1,000 galls. water = 0·159 times the permanent hardness.

Allowances of 20 per cent. in the case of lime and 5 per cent. in the case of soda-ash are included in the formulæ to cover impurities of the commercial materials.

A more accurate way of determining the quantities of lime and soda required, is to calculate them from the analysis of the water. This can be done by the use of the following table, which gives the weight in lbs. of pure calcium hydrate, $Ca(HO)_2$, and of pure carbonate of soda Na_22CO_3, theoretically required per 1,000 gallons of water, to neutralise one grain of the various impurities per gallon.

Impurity.	Lbs. required for 1,000 gallons for each grain of impurity per gallon. Calcium Hydrate.	Sodium Carbonate.
Sulphate of Calcium	—	0·111
Sulphate of Magnesia	0·088	0·126
Nitrate of Magnesia	0·071	0·102
Chloride of Magnesia	0·111	0·159
Nitrate of Calcium	—	0·092
Chloride of Calcium	—	0·136
Free Carbonic Acid	0·240	—
*Carbonate of Calcium	0·105	—
*Carbonate of Magnesia	0·126	—

* These two items are to be disregarded if free CO_2 is listed in the analysis.

The weights of the reagents calculated from the table are the weights of the pure chemicals theoretically required. The totals obtained should be increased by 10 per cent. in order to make sure that the water is fully softened, and is definitely alkaline. When purchasing lime and soda-ash for use in water softeners, guarantees should be obtained as to the actual percentages of calcium hydrate and of sodium carbonate in the respective commercial materials, and these percentages must, of course, be taken into account when deciding on the quantities to be used. The lime should contain not less than 10 per cent. of calcium hydrate, and not more than 3 per cent. of magnesium salts.

When the proper amounts of soda and lime have been decided on, the materials are mixed together with water in the proportion of about 1 lb. of mixture to 1 gallon of water, and it is this solution which is automatically dosed into the raw water by the softener.

A water properly softened by the lime and soda process should have a total hardness not exceeding 2°, and should be of the correct alkalinity. The alkalinity is tested in the following manner. A 70 c.c. sample of the softened water is placed in a white porcelain dish, and two drops of phenolphthalein indicator are added. This should turn the water purple, if it does not do so the water needs more lime and soda. Standard sulphuric acid solution, of strength N/50 is dropped slowly into the purple water from a graduated burette, the water being stirred meanwhile, until the colour vanishes. The number of c.c. of acid used, as read from the burette, is called the alkalinity to phenolphthalein. The same sample of water is now coloured yellow by adding 2 drops of methyl orange indicator, and more acid is dropped in until the yellow colour changes to a faint pink. The number of c.c. of acid required to effect this change is called the alkalinity to methyl orange, and the total number of c.c. of acid used in the two tests is called the total alkalinity. The alkalinity to phenolphthalein should be slightly more than half the total alkalinity. If the alkalinity to phenolphthalein should exceed 3°, *i.e.* if more than 3 c.c. of acid are required to discharge the purple colour, both lime and soda should be reduced. If the methyl orange alkalinity should exceed 2°, the lime should be increased and the soda decreased.

A properly softened water will have a total hardness of between 1 and 2°, an alkalinity to phenolphthalein of about 2·5°, and an alkalinity to methyl orange of a further 2°.

The alkalinity due to sodium hydroxide is called 'Caustic Alkalinity' and is equal to the difference between twice the phenolphthalein alkalinity and the total alkalinity.

Question.—What quantities of lime and soda would be required to soften water having the following analysis.

Silica	0·19
Oxide of Iron	0·15
Sulphate of Lime	4·92
Carbonate of Lime	17·50
Sulphate of Magnesia	3·78
Sulphate of Sodium	3·40
Chloride of Sodium	4·10
	34·04 grains per gallon.

Hardness . . 24·25°.

Answer.—The silica, oxide of iron, chloride of sodium and sulphate of sodium may be disregarded, as they play no part in the hardness of the water. For the other constituents, we see from the table on p. 49 that the quantity of pure calcium hydrate required would be:

For the carbonate of lime	17·50 × 0·105 = 1·817 lb. per 1,000 gallons
For the sulphate of magnesia	3·78 × 0·088 = 0·333 lb. per 1,000 gallons
	2·150

The amount of pure sodium carbonate would be:

For the sulphate of lime	4·92 × 0·111 = 0·546 lb. per 1,000 gallons
For the sulphate of magnesia	3·78 × 0·126 = 0·476 lb. per 1,000 gallons
	1·022

Increasing these quantities by 10 per cent. to ensure complete softening, we find that 2·356 lb. of calcium hydrate, and 1·124 lb. of sodium carbonate are needed for every 1,000 gallons of water.

Supposing that the commercial lime available contains 80 per cent. of pure calcium hydrate, and that the commercial soda-ash contains 98 per cent. of pure sodium carbonate, the final requirements are:

Lime = 2·365/0·80 = 2·95 lb. per 1,000 gallons of water.
Soda = 1·124/0·98 = 1·15 lb. per 1,000 gallons of water.

CAUSTIC EMBRITTLEMENT OF BOILER PLATES.

The failure of boiler plates by cracking between and around rivet holes has been the subject of much investigation during recent years. The cracking has nothing to do with the quality of the plate, and since it takes place between the crystals and not through them, it cannot be attributed to cold working of the metal. The generally accepted explanation is that, when steel under stress is in contact with a concentrated solution of caustic soda at boiler temperature, the soda is decomposed with the evolution of hydrogen which causes the embrittlement of the metal. The caustic soda which gives rise to the mischief, is produced by the decomposition of the soda-ash in the boiler water. The fact that caustic embrittlement only takes place along riveted seams is explained by the possibility of an exceptionally high concentration of caustic soda occurring in conjunction with a high stress at such places.

To prevent caustic embrittlement, it has been recommended that the ratio between sodium sulphate and total alkalinity should be not less than unity for boiler pressures up to 150 lb., than 2 for pressures from 150 to 250 lb., and not less than 3 for higher pressures. It should be noted that the total alkalinity rather than the caustic alkalinity is taken into account because of the conversion of carbonate of soda into caustic soda in the boiler.

The maintenance of the above ratios has proved effective in preventing embrittlement in a large number of cases. Further investigations carried out by the U.S. Bureau of Mines have shown that embrittlement may be prevented by maintaining the concentration of sodium chloride in the boiler water at a value greater than 0·6 times the total alkalinity, and the sodium sulphate concentration in excess of the total alkalinity. For pressures from 500 to 1,400 lb. per sq. in. it appeared necessary to have soluble salts containing iron and aluminium oxides in the water, in concentrations greater than 0·6 times the concentration of sodium silicate present, for sodium silicate had been found to be conducive to embrittlement.

In discussing these results, F. J. Matthews, in *Boiler Feed Water Treatment* (Hutchinson), states that chloride is present in most boiler waters. The requisite sulphate introduction varies according to the method of treatment. The lime-soda process usually requires the soda ash to be carried to slight excess. If the sulphate content is high enough before treatment to keep the required ratio with this excess of soda ash, no additive treatment is necessary. If not, sodium sulphate should be added. Acid treatment should not be adopted in the lime-soda process. The soda ash is carried to excess to facilitate softening, and if sulphuric acid were added this excess would be reduced and softening retarded.

When the sodium-zeolite treatment is used, if the carbonate hardness is higher than the sulphate, the treated water will be higher in sodium carbonate than in sodium sulphate. The usual procedure has been to acid treat the water in such a case. When natural waters, having free sodium carbonate and low sulphate are used, they are usually treated with lime and then sufficient sulphuric acid to maintain the ratio, or by lime and aluminium or iron sulphate. In all cases care must be taken not to overtreat with acid or sulphate salts.

Among other agents which have the power of inhibiting embrittlement, tannic acid has been said to be fifty times as effective as sulphate, and sodium phosphate to be 1,500 times as effective as sulphate. It should be remembered, however, that the only phosphate that counts is that actually present in solution in the boiler water. This must be kept at over 4 parts per 100,000 for boilers working up to 250 lb. pressure, and the same concentration is said to be effective at higher pressures when the alkalinity of the water is kept below 130 parts per 100,000. In view of certain contradictory experiments, however, sodium sulphate is the inhibitor most frequently employed.

DETERMINATION OF CAUSTIC ALKALINITY OF BOILER WATER.

A method of determining the caustic alkalinity of water by means of the phenolphthalein and methyl orange tests has already been given. An alternative method, given by F. H. Mathews, is as follows. Take 100 c.c. of the boiler blow-down sample, and add 25 c.c. of a 10 per cent. solution of barium chloride. Dilute the mixture with water if necessary, so that a pink colour is produced when a few drops of phenolphthalein are added. Add N/10 nitric acid drop by drop from a burette until the pink colour just disappears. The number of c.c. of acid required, multiplied by 5, gives the parts of caustic alkalinity expressed as parts of calcium carbonate per 100,000.

This method may also be used for determining caustic alkalinity in softened water, but in this case the quantity of barium chloride should be reduced to 10 c.c.

DETERMINATION OF TEMPORARY HARDNESS OF RAW WATER.

Take 70 c.c. of the raw water, add a few drops of methyl orange, and drop in N/10 nitric acid drop by drop from a burette, until the colour just changes from yellow to pink. Five times the number of c.c. of acid used gives the temporary hardness in Clark degrees, or in grains of calcium carbonate per gallon.

The Conditioning of Boiler Feed Water.

Conditioning is the term used to denote a supplementary treatment of feed water designed to ensure that such deposits as occur in the boiler shall be of the less troublesome kind, such as calcium carbonate and calcium phosphate which do not cause a hard scale. An excess of sodium carbonate will bring about this state of affairs, but unfortunately at modern boiler pressures the sodium carbonate dissociates and forms sodium hydroxide thus causing an undue amount of caustic alkalinity in the boiler. To avoid this difficulty, sodium phosphate has been used. This salt results in a soft scale, but unless it is pumped directly into the boiler, it is liable to react with the residual hardness in the feed water and form deposits in the feed piping or the economiser. Sodium metaphosphate can be used without any of the disadvantages of the tri-sodium phosphate, and is now extensively employed for water conditioning. It can be added to the feed water without risk of trouble with the feed pipes or economiser, as it delays the precipitation of the calcium salts until the boiler is reached, and then brings them down as sludge. It protects the pipes from corrosion and has the further advantage of dissolving any calcium scale already formed in them, while its action in the boiler is to reduce the alkalinity, and therefore the amount of salts in the water necessary to maintain the required sulphate-alkalinity ratio. The use of 2 parts of sodium metaphosphate per million parts of water is said to be sufficient to prevent deposits in feed-lines, etc.

Water Softening by the Zeolite Process.

The zeolite used for water softening is an artificially prepared hydrated alumino-silicate in granular form. When hard water is passed through it, the calcium and magnesium salts are replaced by corresponding salts of sodium, with the result that the water is completely softened. When the zeolite ceases to be effective, its softening power can be fully restored by flushing with an ordinary brine solution, and washing out the calcium chloride thereby formed.

A zeolite softener is a closed steel cylinder coated with protective enamel. It is half filled with zeolite, and provided with the necessary connections for operating and flushing. The Permutit Company have introduced a completely automatic plant in which regeneration takes place every time a predetermined quantity of water has been treated.

Zeolite softening produces zero hardness. No adjustment is needed for variation in the quality of the raw water, and no chemicals are used except the salt required for regeneration. No precipitate is formed, and the whole apparatus is simple and easy to operate.

On the other hand, the zeolite softened water will actually contain something like five per cent. more solids in solution than the raw water, whereas softening by the lime and soda process effects a great reduction in the dissolved solids. The zeolite method of softening therefore tends to increase the concentration of salts in the boiler, and consequently, the risk of foaming, priming, corrosion due to the CO_2 evolved, and caustic embrittlement.

The zeolite process is not applicable to acid, ferruginous, or turbid waters, and is not advisable for waters with much temporary hardness. To avoid the high alkalinity produced in the latter case, the softened water is sometimes treated with sulphuric acid, and the carbon dioxide formed is removed by steam. A better way still is to do the main part of the softening by the lime and soda process and to use zeolite softening only to remove the residual hardness.

Water Conditions Accepted as Good Practice.

The following conditions are given as representative of good practice by Messrs. Babcock & Wilcox, Ltd.

Low and Medium Pressure Boilers: Feed Water.—Dissolved oxygen should be less than 0·1 c.c. per litre; chlorine not over 0·3 grains per gallon. Alkalinity should be definitely caustic soda alkalinity, but not more than 0·5 grain per gallon, and should have a hydrogen ion concentration *p*H of about 8·4. Total solids should be kept to the minimum possible amount.

Boiler Water Conditions.—Caustic soda alkalinity should be not greater than 50 grains per gallon; total solids not greater than 500 grains per gallon; chloride not over 30 grains per gallon. Hardness as near zero as possible. Oil, no indication of even the slightest trace. In no case should the ratio of sodium sulphate to alkalinity be less than the figures stipulated on p. 51 in the section on 'Caustic Embrittlement.'

For high-pressure boilers (600 lb. per sq. in. and over) feed water conditions:

Dissolved oxygen	0·02 c.c. per litre (maximum value)
Caustic soda alkalinity	0·1 grain per gallon "
Sodium Sulphate	0·4 " " " "
Other salts	0·2 " " " "
Hardness	Nil.
No Oil.	

Boiler water conditions:	600 to 850 lb. per sq. in.	850 to 1,500 lb. per sq. in.
Caustic Soda, grains per gallon maximum	25	15
Sodium Sulphate " " "	100	60
Sodium Phosphate " " "	5 to 10	5 to 10
Other salts " " "	15 to 20	15 to 20
Total maximum	150	100

The Elimination of Oil from Feed Water.

It is of the greatest importance that feed water should be free from oil, the merest trace being a source of danger with modern water-tube boilers. When condensate from reciprocating engines is used as a boiler feed it is always likely to be contaminated by the oil used for the cylinder lubrication. A mechanical oil-separator, which must be of adequate size, placed in the exhaust pipe of the engine will remove a great part of the oil before it reaches the condenser, and such a separator is often relied on in industrial plants. But if the condensate contains oil in emulsion, it must be effectively purified before being used as boiler feed. The oil particles in an emulsion are so minute that the oil will neither settle out, nor can it be removed by any ordinary process of filtration, unless previously coagulated. This can be done by the addition of sulphate of alumina and soda-ash to the water. The effect is to produce a flocculent precipitate which is easily filtered out. A de-oiling apparatus, to supply measured quantities of these reagents automatically to the oily water is often combined with the ordinary lime-soda softening plant. Alternatively, the oil in emulsion may be removed by an electrical process of de-oiling. The water, in this case, is caused to flow slowly between iron plates across which a small difference of potential is maintained. The oil is then deposited on the plates in the form of sludge.

BOILER INSPECTION.

Boilers must be inspected by a competent person at least once in every fourteen months. The owner or user may be made responsible for the effects of an explosion.

To prepare a boiler for inspection the manhole and mudhole doors should be removed, the blow-off cock closed, the steam valve locked to prevent tampering and danger to cleaners and inspectors, the hot feed valve locked, the bars and bridges removed from the furnace, and the flue doors removed and the hearth pit plates lifted away.

The flues and boiler plates in the flues should be swept clean of soot and dust.

The amount and nature of the internal scale should be observed, and the boiler thoroughly cleaned inside and scale removed.

Brickwork must be removed to the extent required by the person making the examination. It should, in any case, be removed to the extent necessary to expose the seams of shell boilers and headers of water-tube boilers, not less frequently than once in every six years in the case of boilers situated in the open or exposed to weather or damp, and not less frequently than once in ten years in the case of every other steam boiler.

The special points to be observed by the inspector are the condition of the plates along the seatings and all points of contact with bricks, the dryness of the flues, the absence of lime mortar near the plates, the dryness of the top covering, leakages at seams, circularity of furnaces, blisters, signs of overheating. Internally: grooving at plate junctions, around the angle irons of shell or furnace tube connection to end plates, at the root of angle irons or flanged seams or other points of stress or flexure, tautness of gusset stays, easy slackness of longitudinal stay bolts if present, condition of plates as to cleanliness, corrosion &c., condition of low-water appliances, scum troughs, feed pipes, gauge openings, and generally all points bearing on the safety of the boiler that may by some unlikely and hard to conceive contretemps lead to mishap of any sort.

In old boilers the openings in the shell should be looked to in order to ascertain the weakening due to removal of so much plate, and the degree of strength given back by added rings or other reinforcements. It is also desirable to note the quality of the attendance and workings of the boiler periodically, and to test the accuracy of the steam gauge and working of the safety valves.

The foregoing remarks apply more particularly to shell boilers. For water-tube boilers, the caps of the water tubes must all be removed, and each tube examined and seen through for scale deposit, and as far as possible externally for blisters. Locomotive-type boilers are not easy to inspect, should never have riveted shell seams below water line, and must be largely judged by the appearance of such parts as are visible. Every few years the shell should be examined internally, the fire tubes being removed for the purpose. The accessibility of a boiler for complete inspection ought to be a considerable factor in determining the choice of a boiler, and more particularly so when the water is dirty or corrosive in quality.

Experience is necessary to make a good inspector. He must possess judgment and sense of proportion, and be able to order a boiler not to be worked until further notice, without it being possible for further enquiry to show that there were not good grounds for his fears.

BOILER LEGISLATION.

The Boiler Explosions Acts, 1882 (45 & 46 Vic. ch. 22) and 1890 (53 & 54 Vic. ch. 35) provide for inquiry into boiler explosions. The Acts extend to the whole of the United Kingdom. The term 'boiler' means any closed vessel used for generating steam, heating any liquid, or receiving steam for heating, steaming or boiling, excepting boilers used exclusively for domestic purposes or in the service of his Majesty. On the occurrence of a boiler explosion, notice must be sent within 24 hours to the Board of Trade by the owner, user, or person acting for him. This notice to state the name of premises or works, postal address, day and hour of explosion, number of persons killed and injured, description of boiler, purpose used for, particulars of failure, working pressure, by whom last inspected, and by whom insured.

The Act of 1890 makes the Act of 1882 applicable to sea and mine boilers.

BOILER FITTINGS.

Valve bodies, tees and other fittings should be of cast steel for superheated steam, and also for saturated steam if the pressure exceeds 120 lb. per sq. in.

Injectors.

To Compute the Diameter of Throat and Volume of Discharge.

d = diameter of throat in millimetres; V = volume of water required per hour in gallons; P = pressure of steam in pounds per sq. in.

$$d = \cdot 709\sqrt{\frac{V}{\sqrt{P}}} \qquad V = 1\cdot 985\, d^2 \sqrt{P}.$$

Example.—The pressure of steam is 200 lbs., and the volume of water required to be delivered per hour is 1,010 gallons.

Then $\cdot 709\sqrt{\frac{V}{\sqrt{P}}} = \cdot 709 \times 8\cdot 45 = 6$ mms.; and $1\cdot 985\, d^2 \sqrt{P} = 1\cdot 985 \times 36 \times 14\cdot 142 = 1{,}010$ gals.

The above particulars apply to all properly proportioned live steam injectors.

Notes on Injectors.

A very frequent cause of trouble is that by one means or another the injector becomes overheated and refuses to lift its water. This may be due to steam leaking past the check valve into the body of the injector, and then passing to the suction pipe, so that the latter becomes too hot. Under these conditions it is impossible to make the injector work. Another cause of overheating is sometimes to be traced to the proximity of the fitting to the hot boiler shell, which allows heat from the latter to pass to it by conduction and radiation. In the first case the remedy is to fit a well-made check valve, combined with a plug cock, between the injector and the boiler. This should be done, even if the former is designed with a self-contained back-pressure valve. Further, the plug cock should be shut off when the injector is not in use. In the second instance, it sometimes happens that an injector is employed which is fitted with its own back-pressure valve, and it is then bolted directly to the boiler. This is very bad practice, as a single valve is not dependable in the first place, and a further point is, that the injector is much too close to the hot boiler. This is a fruitful cause of trouble. Also, should anything go wrong with the injector, it is necessary to blow down the boiler before it can be put in order; whereas, with a combined check valve and plug cock, the latter can be closed, and the injector removed under steam.

An injector will not work satisfactorily if supplied with wet steam; therefore, in order to ensure that this is as dry as possible, it should be taken from the highest available point in the boiler.

Another defect sometimes arises through the check valve not having sufficient lift, or on account of some sort of obstruction in the delivery pipe. The effect of this is that the injector will lift the water, but on account of the greater pressure due to the obstruction against which it has to work, it will be unable to force the water into the boiler, which will consequently find an escape through the overflow instead.

In some cases the water supply to the injector is taken from a tank placed beside the boiler, on the boiler-house floor, the supply to the tank being from an external source, and controlled by a ball cock with a float attached, so that the level of the water in the supply tank is constant. This is a very satisfactory arrangement. In other instances the source of supply may be some little distance away, and connected to the injector by means of pipes. Further, if the water is taken from a well the level may vary between considerable limits. Hence, when purchasing an injector, it is of the utmost importance that the manufacturer should be given all possible data, such as the greatest static head and the length of pipe with the number of bends, so that he can obtain the total suction lift and supply an injector to suit the conditions.

Much trouble will be experienced if the feed-water is allowed to become hot. The lower the temperature the better. There are many so-called hot-water injectors, but even these will not prove very satisfactory if the temperature of the feed-water is allowed to rise too near to the maximum temperature specified by the makers. In order to prevent as much as possible any rise in temperature, it is of the greatest importance that the overflow from the injector should not be allowed to drain back into the feed-tank. An overflow pipe should be fitted that will lead this hot water clear of the feed supply. Such a pipe should not be closed, but should enter an open cup, similar to the overflow of the circulating water in a gas-engine jacket. It is then under constant observation of the man in charge, and if any irregularity occurs it is quickly detected.

Occasionally an injector will refuse to work, due to a leak in the suction pipe. If this defect is present it may be located by fixing a plug in the suction pipe and opening the steam supply to the injector, when the position of the leak will be easily detected.

Lastly, dirt and grit are a source of trouble at times. To prevent this as far as possible, a straining rose should be fitted to the suction pipe. This will not exclude all grit, and occasionally small grains of solid matter suspended in the feed-water will find their way through and lodge on the internal surface of the injector. Also if the water contains soluble salts of magnesium and calcium, it becomes heated on passing through the injector, and some of these salts are deposited, forming incrustations which may cause the injector to refuse to work, either because it has become totally choked up, or else small particles of the incrustations may break away and become lodged under the back-pressure valve or check valve and prevent its closing, when the injector will refuse through overheating.

It is always advisable to keep a spare injector in stock, and if the water contains a considerable amount of impurity, instructions should be given to change the injector at regular periods. The length of time that one should be allowed in continual service must be governed by experience with the particular conditions under consideration. In order to loosen the deposit the injector may be left to soak in diluted hydrochloric acid.

If the above very easily followed points are given attention, injectors will be found most reliable, and few complaints will be heard.

('*Mechanical World.*')

SAFETY VALVES:

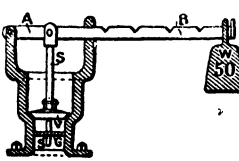

FIG. 11. B, lever; A, short arm of lever; SS, stem; V, valve; G, guide; W, weight.

WEIGHT ON SAFETY VALVES.

If A = area of valve in sq. ins., P = pressure in lbs. per sq. in., l_1 = distance of valve from fulcrum, l_2 = length of lever, w_1 = weight of lever in lbs., l_3 = distance of centre of gravity of lever from fulcrum, w_2 = weight of valve and stem in lbs.

Then W, the weight required at the end of the lever

$$= \frac{P \times A \times l_1 - w_1 \times l_3 - w_2 \times l_1}{l_2}.$$

SAFETY VALVE AREAS.

Since the steam production of a boiler is sensibly the same at all pressures, and since the density of steam increases very nearly as the pressure, and since steam escapes at an outlet at practically constant volume, it appears that safety valves, like boiler stop valves, may be reduced in size as pressure increases. Ordinary valves have a very small lift. Special valves in which the steam reaction is utilised to increase the lift will give a much greater opening. If a valve lift a height equal to a fourth of its diameter the area of opening is equal to the valve area, and no greater lift would give greater output.

It is not sufficiently well known that boilers working at a low pressure require larger safety-valves than boilers at a high pressure. Thus, for example, a boiler working at 15 lbs. by the steam gauge requires three times the area of safety valve opening that is required by a boiler at 75 lbs. This is the more important when it is remembered that in a boiler which is safe only at low pressure, an additional 15 lbs. pressure doubles the strain, whilst in the boiler at 75 lbs. a rise of 15 lbs. adds but a fifth to the stress on the plates. This point as to the safety-valves on old low-pressure boilers is too little known or recognised.

Safety-valve areas should be inversely as the absolute pressure.

In well-proportioned dead-weight safety valves it is usually expected that if a pressure of 60 lbs. per sq. in. opens the valve, a pressure of 70 lbs. will keep it sufficiently open for the escape of all the steam produced.

The former Board of Trade rules are largely followed, and as they are more detailed, bringing out many points of importance, extracts are given below, also extracts from the rules of Lloyd's and Bureau Veritas.

BOARD OF TRADE RULES FOR SAFETY VALVES.

(Extracts from.)

The valve chest should be placed directly on the boiler; the neck, or part between the chest and the flange which is bolted to the boiler, should be as short as possible, and cast in one with the chest.

The minimum aggregate area of the safety valves should not be less than that obtained from the following formula, but in no case should valves less than $1\frac{1}{2}$ ins. in diameter be passed without the special sanction of the Board of Trade.

$$A = \text{THS} \times \frac{k}{p + 15}$$

where A = aggregate valve area in sq. ins.;
THS = total heating surface of the boiler in sq. ft.
p = working pressure in lbs. per sq. in.;

$$k = \begin{cases} 1 \cdot 25 \text{ for coal-fired, cylindrical boilers in open stokeholds.} \\ 1 \cdot 5 \text{ for coal-fired, cylindrical boilers with closed stokehold and forced draught} \\ 1 \cdot 5 \text{ for oil-fired, cylindrical boilers.} \\ 1 \cdot 1 \text{ for coal-fired, water-tube boilers with natural draught.} \\ 1 \cdot 25 \text{ for coal-fired, water-tube boilers with forced draught.} \\ 1 \cdot 25 \text{ for oil-fired, water-tube boilers.} \end{cases}$$

The safety valves should be fitted with lifting gear, so arranged that the two or more valves on any one boiler can at all times be used together, without interfering with the valves on any other boiler. The gear should be arranged so that it can be worked by hand from some accessible place free from steam danger, and the arrangement should permit of the valves being turned round on their seats by hand.

Care should be taken that the safety valves have a lift equal to one-fourth of their diameter; that the opening for the passage of steam to and from the valves, including the waste-steam pipe, have each an area not less than 1·1 A, and the area of the main waste-steam pipe should not be smaller than the combined area of the branch pipes. Each valve box should have a drain-pipe fitted at its lowest part.

In the case of lever valves, if the holes in the lever are not bushed with brass, the pins must be of brass; iron and iron working together must not be used.

Too much care cannot be devoted to seeing that there is proper lift, also that free means of escape for the waste steam are provided, as it is obvious that unless the means for escape of the waste steam are ample, the effect is the same as reducing the area of the valves or putting an extra load upon them. The valve seats should be secured by studs and nuts.

The valves should have a clearance in the seats of at least $\frac{1}{32}$ in. on the diameter, and should not project below.

For spring loaded safety valves, (1) at least two valves are to be fitted to each boiler, (2) the valves are to be of the prescribed size, (3) the springs and valves are to be so cased in and locked up that they cannot be tampered with, (4) provision is to be made to prevent the valves lifting out of their seats in the event of the springs breaking, (5) screw lifting gear is to be provided to ease all the valves, (6) the size of the steel of which the springs are made is to be in accordance with the formula $d = \sqrt[3]{\frac{S \times D}{C}}$, where S = load on spring in lbs., D = diameter of spring (from centre to centre of wire) in inches, d = diameter, or side of square, of wire in inches, C = 8,000 for round steel, 11,000 for square steel, (7) the springs are to be protected from the steam and impurities issuing from the valves, (8) when valves are loaded by direct springs, the compressing screws are to abut against metal stops or washers when the loads sanctioned by the Surveyor are

on the valves, (9) the springs are to have a sufficient number of coils to require a compression under the working load of at least one-quarter of the diameter of the valve.

The valves are to be tested under full steam, and full firing, with the feed water shut off and stop valve closed. The duration of the tests for accumulation of pressure shall be, on cylindrical boilers, 15 mins., on water-tube boilers, for as long as the water supply in the boiler permits, with a maximum of 7 mins.

Lloyd's Rules for Safety Valves.

(Abridged.)

At least two safety valves are to be fitted to each boiler, arranged so that springs and valves are cased in, that valves cannot be overloaded while steam is up, that the valves can be lifted by easing gear and turned round on their seats, and that valves cannot lift out of their seats if the springs break.

Vertical boilers with 100 square feet or more of heating surface to have two safety valves each not less than 1·5 in. diameter; those with less than 100 square feet heating surface one valve not less than 2 ins. diameter.

All safety valves of one boiler may be fitted in one chest connected direct to boiler by passage having cross-sectional area not less than half the aggregate area of the valves. Valve chest to be drained. The minimum aggregate area of safety valves of a boiler, coal- or oil-fired, in square inches

$$= \text{total heating surface of boiler in square feet} \times \frac{C}{p+15},$$

where

p = pressure in lbs. per square inch;
C = 1·25 for boilers using coal;
C = 1·5 for boilers using oil and for those with closed stokehold forced draught.

Waste-steam pipe to have area not less than 1·1 times area given by above formula.

Safety valves to be set under steam. During test of fifteen minutes with stop valve closed and full firing conditions accumulation of pressure is not to exceed 10 lbs. per square inch.

Bureau Veritas Rules and Regulations for Safety Valves.

At least two spring safety valves of an approved design must be fitted to each main boiler The total area of the safety valves is given by the formula

$$A = \frac{8{\cdot}7}{\sqrt[4]{(P-18)^3}},$$

where

A = sectional area of safety valve in sq. ins. per sq. ft. of grate surface; P = working pressure in lbs. per sq. in. No safety valve to be less in diameter than 1¼ in.

When forced draught or oil fuel is provided for, the area is to be increased in proportion to the increased evaporative power of the boilers.

Suitable arrangements and gear to be fitted in connection with the safety valves, whereby they may be lifted from the deck as well as from the stoke-hole floor.

Defects in Water Gauges.

As ordinarily fitted, the gauge is usually attached directly to the boiler and provided with three taps, one connecting to the steam space, the second to the water space, and the third controlling the discharge to atmosphere. The latter should always discharge inside the boiler-house, where the effluent can be seen, and not be as it sometimes is, with a mistaken idea of cleanliness, coupled to a waste pipe, led outside, where the evidence of its action is not visible when the attendant opens the tap. It is of value to have duplicate gauges, as the cost is comparatively trifling, and one gauge serves as a check on the other. All three taps should be tested independently, that is to say, the bottom tap should be shut while the top one is opened and *vice versâ*, the top one shut while the bottom is opened, so as to give a thorough 'blow through' of the steam and water connections to the boiler. Unless this is done there is no certainty of the gauge being in working order, while there is risk of the top and bottom connections becoming choked and causing a false reading. More than one serious accident has been traced to defects in the taps themselves, owing to the holes in the plugs of the taps not coinciding with the thoroughfare of the fitting, so that when the position of the handle suggests the tap is open it is in reality nearly closed. Another cause of false readings is the blocking of the passage in the glass tube through the indiarubber packing ring working over the ends of the glass, owing to the glass being cut too short and the gauge not being provided with a nipple in the bottom of the gland to protect the glass against this risk. Having regard to the serious results which may attend overheating from shortness of water, it is advisable whenever possible to supplement the water gauge with a fusible plug, and if the boiler is a large one, with a low-water safety-valve as well. (*Mechanical World.*)

GAUGE GLASSES.

It is important to have the fittings exactly in line with each other, and to have them large enough so as not to cause the glass to bind or to be cramped in the least. When the fittings are not in line the glass is apt to be cramped either when putting it into the sockets in the fittings or when tightening the packing nuts. Wrenches should not be used for tightening the packing nuts around the gauge glass. When a glass is packed with the proper kind of packing and the nuts have been screwed up just tight enough to prevent leakage when both the glass and the packing have been warmed, the glass may readily be turned around in the fittings with merely the thumb and forefinger.

After putting in a new glass turn on a very little steam, leaving the drip at the bottom of the glass open so that the steam will gradually fill the glass and escape through the drip-cock. The glass is thus warmed thoroughly before the water is let into it and before it is subjected to pressure. When the glass has become thoroughly hot, open the steam valve wider, then open the water valve a like amount, and continuing to open both valves alike until fully open, then slowly close the drip at the bottom. This method not only allows the fittings to be thoroughly blown out, but enables the operator to increase the pressure on a new glass and new packing more gradually. It is best to anneal all the glasses before using them. This is generally accomplished by means of a water and steam bath, the water and the glasses being heated by steam. It is cheaper in the long run to cut glasses with a gauge-glass cutter than

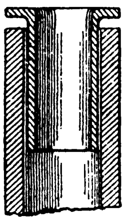

FIG. 12.

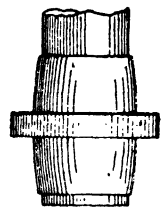

FIG. 13.

to attempt to cut or break them off with a broken file, or by similar means, because a slight nick in the glass at the wrong place may mean the early destruction of the glass when subjected to pressure and varying temperature. Some engineers fit a thin brass or copper thimble into the upper end of the tube, as shown in fig. 12, which prevents scale and water from coming in contact with the glass when blowing out the latter, and hence it reduces the eroded and pitted appearance commonly seen at the upper end of unprotected glasses. Tubes made of aluminium may be obtained of dealers in engineers' supplies which accomplish the same result.

These tubes and thimbles, it will be seen, protect the inner surfaces of the glass only, and as the glass is liable to be crowded to one side or the other in the packing nut as well as in the fitting itself, it is a good plan to also protect the glass on the outside.

A simple means of protecting the glass on the outside is also obtained from dealers in gauge glasses. The arrangement consists of a rubber sleeve adapted to slide over the end of the glass, as shown in fig. 13. The glass cannot come in contact with the socket in the fitting, neither can the packing nut touch the glass when the packing is screwed up. The combination of the thimble and the latter device prevents the rapid wear of the glass at the top, and also retains the glass clear of all metallic contacts, which has been found to be very desirable where glasses are subjected to high pressure and temperature and sudden changes in the latter.

When the rubber protector is employed, separate packing rings are not needed, because the packing forms a part of the sleeve, as shown. Annealed gauge glasses protected inside and out by this or similar means will last as long under any circumstances as it is possible to make them by any means thus far made known.

If packing 'rings' are used, then in order to secure a tight joint with the least possible pressure, thus avoiding any tendency to break or to cramp the glass due to the packing, it is necessary to obtain a form of packing that will fit snugly in the space in the nut.

(*H. B. Waverly*, '*Mechanical World.*')

The following arrangement, fig. 14, for packing is said to give very satisfactory results:— A fibre washer $\frac{1}{16}$ in. thick with an outside diameter to allow an easy fit into the gauge-cock nut,

and an inside diameter equal to that of the glass, is put into each nut before the rubber gasket. The fibre washer so fitted prevents the rubber gasket being pushed out between the glass and

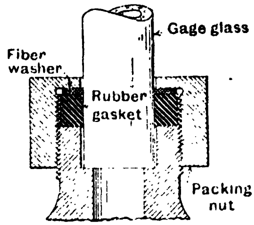

FIG. 14.

hole in the nut. The fibre does not scratch the glass, and therefore will not cause the latter to crack and break, as would a metal washer or a nut with too snug a hole in it.

(*F. R. Rawson*, *Power*.)

Superheated water acts on most varieties of glass as a violently corrosive agent, and for gauge glasses ordinary glass cannot be used. A special glass, under the brand 'Hercules,' to resist high-pressure steam, is made by Joseph Tomey & Sons, Ltd., Birmingham. It is specially constructed of boro-silicate, and is made after the 'Jena' formula. The glass is practically white in colour and has withstood the following remarkable tests:—

> After the glass had been submerged in iced water for five minutes it was plunged into molten lead, and showed no signs of fracture. It has withstood 4000 lbs. hydraulic pressure, and 750 lbs. steam pressure.

Although the glass was specially manufactured to meet the requirements of high-pressure and superheated boilers, it has been used for a great number of low-pressure boilers, because at low pressure the material is practically unbreakable and is considerably cheaper in the long run than the ordinary quality gauge glass.

Cutting Gauge Glasses.

A simple and reliable method of cutting gauge glasses to any desired length consists in filing a notch, then wrapping the tube with a strip of wet filter paper or paper towel on each side of the notch, leaving the space between the strips $\frac{1}{16}$ to $\frac{1}{8}$ in. wide. The strips of paper may be $\frac{1}{4}$ to $\frac{3}{8}$ in. wide and wrapped on about three layers deep. The fine flame of a blast burner is directed against the tube between the papers and at the notch for a second or two when the tube is slowly rotated in the flame. The tube should be turned rapidly enough to avoid burning the wet paper. At the completion of the revolution the tube will break off with a clean and even cut. Short tubes for oil-sight feeds may be cut with ease by this method when it would be impossible to break them off from just a file notch. Bottles and large tubes are equally easy to cut.

In breaking a tube from a file notch, which is the universal method for small-diameter tube and rod, much depends on the nature of the file mark. Just as in cutting window glass, what is wanted is a cut and not a scratch, and in filing a notch completely around the tube, even the inexperienced is likely to make a real cut at some point on the circumference, while in his hands the single file notch may not register the cut necessary for the clean break.

REDUCING VALVES.

These are very needful fittings in connection with steam appliances when steam has to be reduced from a high to a uniform low pressure. It is a common mistake to order reducing valves too large, which leads to their excessive wear. No reducing valve should be implicitly trusted; but wherever a rise in steam-reduced pressure is liable to bring about serious results a relief valve should follow the reducing valve.

Reducing valves which are too large for the amount of steam they are to pass are usually unsatisfactory; either they will open and close continually and chatter violently, or will stand in a position nearly closed and become steam-cut and leaky. It is more satisfactory to use two small valves in parallel, one set slightly heavier than the other, so that one will supply steam up to its maximum capacity before the other opens. Another way is to use one reducing valve equal to about one-half the maximum demand, and a by-pass of about the same capacity with a hand-operated valve in it, so that when the reducing valve reaches its capacity the by-pass valve may be opened wide and the reducing valve be closed down and make up the shortage. This, of course, requires that an attendant shall observe the pressure gauge occasionally.

STEAM PIPES.

Steam pipes should be made of mild steel, preferably weldless. The steel should be of boiler plate quality. For pressures up to 250 lb. per sq. in. the following are suitable minimum thicknesses:

Bore of pipe, inches .	2	$2\frac{1}{2}$	3	4	5	6	7	8	9	10	12
Thickness, inches .	$\frac{3}{16}$	$\frac{3}{16}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{5}{16}$	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{3}{8}$	$\frac{7}{16}$

Bends for pipes 6 ins. and larger should be $\frac{1}{16}$ in. thicker. Flanges for pipes up to 6 ins. may be screwed on, but for larger sizes, flanges should be welded or riveted on.

Flanges should be of wrought steel forged from the solid. The ends of the pipes should be expanded into screwed flanges.

It is essential in steam pipe arrangements to make adequate provision for (*a*) drainage, and (*b*) expansion.

The pipes if possible should not rise from the valve on the boiler to the main steam pipe, as this causes a water pocket.

If the junction valve has to be below the level of the main steam range, suitable drain connections must be fitted. These drains should be tested by blowing to atmosphere at least twice a day.

The best steam pipe arrangement between engine and boiler is that the boiler stop valve should stand at the top of a vertical pipe on the boiler and there should be a steady slope in the direction of flow of about $\frac{3}{8}$ in. per 100 ft., and a drop-leg or separator should be provided at the end of the range.

Rupture from water hammer occurs from failure of pipe drains, or from neglect in their use. If possible, pipe lines should be so designed as to render drains unnecessary except at drop-legs or separators.

The closing of no valve should be able to cause water to accumulate against it. Where it is impossible to avoid drainage points, these should be carefully arranged, and unduly small drain pipes must be avoided lest they choke with rust or dirt.

Long lengths of drain piping, from steam mains to traps, should be avoided; they are a continual source of waste, and with superheated steam the water they drain away has largely been formed by condensation in the drain piping itself. Therefore the pipes from steam main to traps should be as efficiently lagged as the main steam line.

Idle parts of the steam range should be isolated when not in use, and carefully drained, as valves often leak when shut, through scoring of faces and grit wedging in, preventing tight closing.

All live steam drains should be returned to the feed tanks.

The coefficient of expansion of steel being 0·000006 per °F. (at moderate temperatures), the expansion at a pressure of 190 lb. per sq. in. or a temperature of 384° F., from an initial temperature of 60° F. is about 2·33 in. per 100 ft.

At higher temperatures the coefficient of expansion increases: at 800° F. it is about 20 per cent. greater than at 200° F. This is taken into account in calculating the expansion of pipe lines. Pipes should be arranged so that about 2·8 inches for saturated, or about 4·2 in. for superheated steam per 100 ft. of length can be allowed for without straining the pipes or their connections. Flexibility should be obtained by the use of steel bends or spring legs, rather than by expansion joints.

In erecting pipe lines, the pipes are frequently cold sprung in a direction opposite to that of expansion to about half the expected expansion so as to minimise the expansion stresses, the bends being then equally stressed in opposite directions when hot and when cold.

The pipes should be marked when cold opposite marks on the walls, and again when hot. Anchors should be at the points where least movement is shown. Pipes are best carried on brackets. Where they rest they should have rubbing pieces firmly attached, and they should not rest on rollers as the friction helps to check vibration.

The centre of a main steam pipe should be anchored, to divide the longitudinal expansion. Where engine and boiler room are in line and steam mains are of considerable length, a ∩ or Ω-shaped bend should be inserted between the engine and boiler-room. Anchor-plates should then be fixed in the centre of the engine-room main and in centre of boiler-room main.

Expansion bends are best arranged to project horizontally from the line of pipe, in order to allow a free passage for water. If they stand vertically upwards they prevent water flowing, and if hung downwards they form water pockets. In both cases they necessitate careful drainage.

When erecting new steam pipes, attention should be given to the thorough cleaning of the pipes, as otherwise fine particles of grit, driven by the steam into the faces of the valves, cut into the seats, causing considerable trouble and expense.

New pipes and drains should be well blown through to remove scale and dirt before traps are fixed.

Pipes may be best bent by filling with thoroughly dry sand and plugging the ends. They will then bend without buckling.

Copper pipes are bent by being filled with melted resin, or with solder, the pipe bent cold, and the filling then melted out.

The radius of bends in steel steam pipes measured to the centre line of the pipe should not be less than three and a half or preferably four times the diameter of the pipe.

While main steam pipes should have flanged joints, small pipes, if the pressures are moderate, say up to 80 lb. per sq. in., may be screwed into fittings or branch pieces. The screw threads should be tapered.

For dimensions of pipe flanges, and bolting, see pages 108–110, Section V (I), Vol. I.

Steam Pipes for High Pressure and Temperature.

An excessively thick pipe is not necessarily a strong pipe; it is very stiff, and therefore subject to heavy expansion stresses.

For 0·17 carbon steel the following are suitable maximum working stresses: at 900° F., 4,500 lb. per sq. in.; at 850°, 5,500 lb.; at 800°, 6,500 lb.; at 750°, 7,500 lb.; at 700°, 8,400 lb. These are below the stresses that will produce a creep rate of one-hundredth of one millionth inch per inch per hour, or one tenth of 1 per cent. during a working life of 100,000 hours.

The maker of weldless, hot-finish tubes requires a tolerance of 12½ per cent. Pipes must be specified 12½ per cent. thicker than the minimum required, and may come out 12½ per cent. thicker than that specification—i.e., a pipe required to be not less than ⅞ in. must be ordered 1 in., and accepted if 1⅛ in. This increase does not affect the strength, for as stress due to expansion goes up, that due to internal pressure comes down, but it does increase the thrust on the fixed points to which the pipes connect.

Under modern conditions the only satisfactory method of joining pipes is by welding. The best joint has the pipes butt welded, and a heavy sleeve passed over the joint and welded to both pipes, but it is not easy to erect and weld on site and can only be broken with difficulty. The usual method is to combine flanges and welding. Collars are formed on the ends of the pipes, integral with the pipes, and are backed by heavy loose flanges, which are bolted together and take all mechanical and expansion stresses. The joint is made steam tight by a weld round the junction of the collars. This type of joint can be made to connect to valves and fittings and can be easily broken. The bolts are of nickel-chrome-molybdenum steel, of ultimate stress (cold) 69 tons, screwed with five threads all the way, and with nuts at each end.

The tolerance up to and including 12 in. nominal bore is plus/minus 12½ per cent. as stated, but over 12 in. bore the tolerance is plus/minus 15 per cent.

Creased and Corrugated Iron Bends. (*Aiton.*)

With thick tubes, the inner wall does not appreciably thicken in bending, almost the entire difference in length of the inner and outer walls of the bend has to be accommodated by thinning of the outer wall. To avoid excessive thinning, the radius of a bend must be large, but this reduces the flexibility of the pipe. This difficulty can be overcome by forming creases on the inner wall which vanish at about two-thirds of the circumference. Bends can be made in a thick creased pipe to a smaller radius than in a plain pipe, giving at the same time less thinning of the outer wall and more flexibility. Another method of achieving the same object is to corrugate the pipes.

The bends have a series of corrugations which in themselves strengthen the tube, especially as the process of manufacture thickens the wall of the tube. The corrugated pipe is formed into a bend in the usual way, and there can be no thinning of the wall in bending as all that happens is that the corrugations are somewhat opened out on the outside of the bend and are closed up on the inside.

These corrugated pipes can be bent to a much smaller radius than plain pipe—in extreme cases they can be bent to the same radius as an elbow. In all cases, to stand corrugating, the tubes must be of a good soft quality of steel and must be well made, free from variations of thickness; they are usually solid drawn tubes, hot finish, 24 tons to 28 tons tensile, 25 per cent. elongation in 8 ins.

The comparative flexibility of different types of pipe bend is shown by the following examples of bends, 10-in. internal diameter, ⅞-in. thick, at 700 lb. per sq. in. pressure, 900° F., the bends measuring 45 ins. from centre line of one leg to flange of other leg.

Description of Pipe.	Radius of Curved Portion.	Thrust in Lb.	Stress Lb. per Sq. In.
Plain	30 in.	14,980	13,640
Creased at bend . . .	10 in.	6,070	7,250
Corrugated at bend . .	10 in.	4,400	6,140
Creased at bend and corrugated on straights for 10 in. . . .	10 in.	3,480	3,420
Corrugated at bend and on straights .	10 in.	2,345	2,505

An expansion bend of the lyre type made from plain tube 10 ins. bore and 138 ins. high from the centre of the main to the centre of the pipe at the crown of the bend, allows for a movement of 2¼ ins. out or in; a bend made from corrugated pipe of the same bore can be made 55 ins. high, and gives 2¼ ins. out or in, and a similar bend 72 ins. high gives 3⅜ ins. out or in, or 50 per cent. more than the much larger plain bend.

The severest test of the behaviour of the bends under heavy vibration has been on steam hammers. A 5-ton hammer when first started to work had connected to it a plain 5-in. steel bend and subsequently a copper bend, but this did not last more than a month, and the steam joints had to be remade, on an average, once a day. A 5-in. corrugated bend 24 ins. × 20 ins. made from stock solid-drawn hot-finish tube, $\frac{7}{32}$ in. thick, was fitted, and after working for two years was microscopically examined and showed no signs of deterioration.

Roughly speaking, the pitch of the corrugations is 2¼ ins. and each curve of the corrugation 1¼ ins. The steam friction is about double that of a plain bend.

There are no records of a corrugated pipe ever having failed in service.

See 'Strength and Flexibility of Corrugated Piping' by R. L. Dennison, John Hopkins University, *The Engineer*, 20th Sept. 1935, et seq.

Lloyd's Rules for Steam Pipes.

The following is abstracted and abridged from Lloyd's Rules:

Pipes made from electro-deposition of copper on a mandril are not to be used for steam.

Copper pipes are to be properly annealed.

Copper pipes for pressures over 75 lbs. per square inch are to be solid drawn.

Pipes for pressures above 180 lbs. per square inch are not to be of copper if the diameter exceeds 5 ins.

Copper pipes are not to be used for superheated steam.

Permissible working pressures (W.P.) are as follows:

where,

t = thickness in hundredths of an inch; d = diameter of pipe in inches.

For brazed copper	$\text{W.P.} = \frac{45(t-3)}{d}$
For solid-drawn copper	$\text{W.P.} = \frac{60(t-3)}{d}$
For solid-drawn cold-finished steel . .	$\text{W.P.} = \frac{120(t-10)}{d}$
For solid-drawn hot-finished steel . . .	$\text{W.P.} = \frac{120(t-12)}{d}$
For lap-welded iron or steel with or without covering straps	$\text{W.P.} = \frac{90(t-12)}{d}$

(*Power.*)

Exhaust Pipes.

These may be of cast iron and should be free from blow holes. The flanges should be faced and jointed with soft rubber rings. Exhaust pipes should be painted while under vacuum, preferably with several coats of red lead paint well brushed in until all the pores are filled.

Joints for Steam Pipes.

Flanged steam pipes for low or moderate pressures are jointed with jointing pastes or special insertions, such as asbestos millboard.

For high pressures, corrugated metal joint rings (of brass, for example), inside the bolt circle, are used. They should be coated with jointing paste, of which there are special brands on the market, or with pipe cement, graphite and boiled oil. The joint should be bolted up before the paste has set.

To prevent joints adhering to flanges, they should be painted with black lead, mixed to a thin paste with water. Joints so treated can be used over again. Covering the bolt threads with graphite and tallow facilitates the removal of the nuts when joints are to be broken.

For very high pressures, a successful joint-ring is one of soft steel, fitting inside the bolt circle and thickened for a radial width of about ⅝ in., the inner diameter of the thickened ring being equal to the pipe bore. This thickened ring has narrow circular grooves with sharp edges which bear on the flanges or the ends of the pipes when the joint is bolted up.

Size of Steam Pipes.

The diameter of a steam pipe is usually in practice chosen to give a certain steam velocity in the pipe, 100 feet per sec. being a customary velocity for steam at ordinary pressures.

Many engineers use this speed for both saturated and superheated steam. Others vary the velocity as in the following table:

Diameter of Pipe.	Velocity, Feet per sec. Saturated.	Superheated.
Up to 3 ins.	75	100
3½ ins. to 9 ins.	90	120
10 ins. and over	90	140

For superheated steam in long, straight pipe lines 180 ft. per sec. may be used.

It should be remembered that the higher the velocity the smaller is the pipe diameter, and hence the external radiating surface is less.

Pressure Drop in Pipe Lines.

The formula (known as the Babcock formula) usually employed to relate the flow, pressure drop, and pipe diameter is

$$W = 87{\cdot}5\sqrt{\frac{D\,(p_1 - p_2)\,d^5}{L\left(1 + \frac{3{\cdot}6}{d}\right)}},$$

where W = weight in pounds per minute; d = diameter in inches; D = density or weight per cubic foot; p_1 = initial pressure; p_2 = pressure at end of pipe; L = length in feet.

This formula corresponds to $p_1 - p_2 = 0{\cdot}0001306\,\dfrac{W^2L\left(1 + \frac{3{\cdot}6}{d}\right)}{Dd^5}$ and also to $h = f\,\dfrac{v^2}{2g}\cdot\dfrac{4L}{d_1}$

where h = loss of head in feet, d_1 = diameter in feet, f = coefficient of friction of the steam in the pipe, f being equal to $0{\cdot}0027\left(1 + \frac{3}{10d_1}\right)$; this coefficient is due to R. C. Carpenter, and is accepted by Unwin.

The following table gives, approximately, the weight of steam per minute which will flow from various initial pressures, with one pound loss of pressure, through straight, smooth pipes, each having a length of 240 times its own diameter. The table is calculated from the above formula.

TABLE OF FLOW OF STEAM THROUGH PIPES.

Initial Pressure by Gauge. Lbs. per Sq. In.	Internal Diameter of Pipe in Inches. Length = 240 diameters.													
	½	1	1½	2	2½	3	4	5	6	8	10	12	15	18

(*Morley.*)

The foregoing table is based on saturated steam. For any other loss of pressure multiply by the square root of the given loss. For any other length of pipe *divide* 240 *by the given length expressed in diameters, and multiply the figures in the table by the square root of this quotient*, which will give the flow for 1 lb. loss of pressure. Conversely, dividing the given length in diameters by 240 will give the loss of pressure for the flow given in the table.

For superheated steam multiply the values in the table by $\sqrt{\dfrac{\text{density of superheated steam}}{\text{density of saturated steam}}}$

—or *approximately* $\dfrac{1}{\sqrt{1 + {\cdot}0015\,t_s}}$, where t_s = degrees of superheat.

The loss of head due to getting up the velocity, to the friction of the steam entering the pipe, and passing elbows and valves, will reduce the flow given in the table. The resistance at the opening, and that at a globe valve, are each about the same as that for a length of pipe

equal to 114 diameters divided by a number represented by 1 + (3·6 ÷ diameter). For the sizes of pipes given in the table these corresponding lengths are, approximately:—

·¾	1	1½	2	2½	3	4	5	6	8	10	12	15	18
20	25	34	41	47	52	60	66	71	79	84	88	92	95

The resistance at an elbow is equal to two-thirds that of a globe valve. These equivalents—for opening, for elbows, and for valves—must be added in each instance to the actual length of pipe. Thus a 4-in. pipe, 120 diameters (40 ft.) long, with a globe valve and three elbows, would be equivalent to 120 + 60 + 60 + (3 × 40) = 360 diameters long; and 360 ÷ 240 = 1½. It would therefore have 1½ lbs. loss of pressure at the flow given in the table, or deliver (1 ÷ $\sqrt{1\cdot 5}$ = ·816), 81·6 per cent. of the steam with the same (1 lb.) loss of pressure.

In place of the calculations on the table given in the preceding paragraphs, the following nomographic chart (based on the formula, p. 64) may be used, and provides a very convenient and sufficiently accurate method of determining pipe sizes, pressure drops, etc.

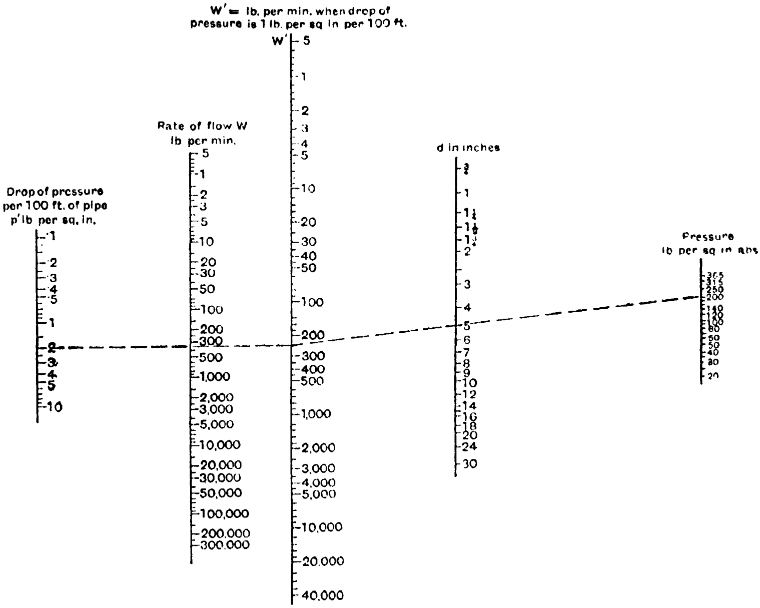

FIG. 16.

Method of use of chart:

(a) To find diameter for given quantity and pressure drop, join W and p' and produce to cut scale of W', join point so found to pressure scale at right, read required diameter at intersection with scale of d.

(b) To find quantity for given pipe and pressure drop, reverse above process, finding first W' and then W.

(c) To find pressure drop for given pipe and flow, join points on scales of pressure and d, produce to find W', join W' to W and produce to cut scale of p' at required value.

Flow of Air and Steam in Pipes.

The conclusions of subsequent investigations made by McAdams and Sherwood are that for air the best formula is:

$$P_1 - P_2 = \frac{0{\cdot}13 f L Q^2 P^2}{P_a D^5 T}$$

$$\text{or } Q_1 = 2{\cdot}77 \sqrt{\frac{D^5 (P_1 - P_2)\, T\, P_a}{f L P_1^2}}$$

and for steam

$$P_1 - P_2 = 0{\cdot}0484 \frac{f L G^2}{D^5 w_a}$$

$$\text{or } G = 4{\cdot}54 \sqrt{\frac{D^5 w_a (P_1 - P_2)}{f L}}$$

where

- P = absolute pressure in lbs. per sq. in.;
- P_1, P_2 = initial and final pressures in lbs. per sq. in.;
- P_a = average pressure, lbs. per sq. in. abs.;
- Q_1, Q = cub. ft. air per minute at P_1, P, respectively;
- D = inside diameter of pipe in inches;
- L = equivalent frictional length of pipe in feet = length of straight pipe + $2{\cdot}5\ D \times$ number of elbows;
- T = air temperature, ° Fah., abs.;
- G = lbs. steam per minute;
- w_a = lbs. per cub. ft. of fluid flowing at average temperature and pressure;
- f = friction coefficient,

in accordance with the values in the following table:

Values of $\frac{G}{D}$ for Steam, or $\frac{QP}{DT}$ for Air.	Steam.	Air.

Loss of Heat from Uncovered Steam Pipes.

The large amount of heat lost from bare steam pipes, and the consequent waste of coal, is frequently not fully appreciated. One square foot of uncovered pipe surface, the pipe containing steam at 100 lbs. per sq. in., will dissipate about 3 B.Th.U. per hour per degree of temperature difference between the steam and the atmosphere, or about 850 B.Th.U. per hour at ordinary

atmospheric temperatures. The steam condensed per hour due to this square foot of bare pipe will be 0·96 lb. In a year of 3,000 working hours the steam wasted will amount to 2,880 lbs., corresponding to a coal consumption of about 410 lbs.

A single 9-ft. length of 6-in. pipe, if uncovered, will waste by heat loss about 2·5 tons of coal per year.

80 to 90 per cent. of this loss may be avoided by the use of suitable coverings, the expense of which is amply counterbalanced by the saving in coal.

It is important that flanges, valves, etc., as well as the body of the pipe lengths, should be covered.

The loss of heat per hour per sq. ft. of surface, in the case of bare pipes, depends principally upon the difference of temperature between the pipe—*i.e.* practically, that of the steam in the pipe—and the surrounding atmosphere, but also is influenced to some extent by the diameter of the pipe, its position—whether horizontal or vertical—the presence of air currents about the pipe, the nature of the pipe surface, and the velocity of the steam in the pipe.

Complete data on all these factors are lacking.

It is usually assumed that the loss is proportional to the difference of temperature, but careful experiments show that the rate of loss, B.Th.U. per sq. ft. per degree F., increases at the higher temperature differences. Thus from 1·95 at 50° difference, it becomes 2·4 at 150°, 3·26 at 300°, 4 at 400°, and 5·26 at 460°. (*McMillan.*)

There is little experimental data on the effect of pipe diameter, but it appears that the loss per sq. ft. decreases as the diameter increases, and this is in accordance with theory.

The following table shows the heat loss from pipes covered with various thicknesses of 85 per cent. magnesia composition and the approximate loss from uncovered pipes is given for comparison.

LOSS OF HEAT FROM STEAM PIPES, WITH STEAM 300° F. ABOVE ATMOSPHERIC TEMPERATURE.
LOSS IN B.TH.U. PER HOUR PER SQUARE FOOT OF PIPE SURFACE.

(*McMillan.*)

The 'efficiency' of the covering in preventing loss of heat is taken as the ratio (heat loss from bare pipe − loss from covered pipe) ÷ heat loss from bare pipe. The table shows that this 'efficiency' varies with the thickness and the pipe diameter, hence to compare different covering materials, the comparison must be made under the same conditions of thickness, etc., if the comparison is to show the relative insulating properties.

The coverings may also be compared on the basis of cost per foot run—*i.e.* taking a greater thickness in the case of the cheaper materials.

The relative properties of various pipe coverings are shown in the following table, the thickness being about 1·4 ins., diameter of test pipe 1 in., steam pressures in pipe 50, 100, and 200 lbs per sq. in.

RELATIVE VALUE OF PIPE COVERINGS.

BOXES FOR PIPE FLANGES.

In estimating the loss of heat from covered pipe lines, the effect of the boxes covering the flanges in adding to the total area of radiating surface must be allowed for.

For typical flange boxes, assuming one box at each 10 feet of pipe line, the additional area may be taken as about 7 per cent. *i.e.* to find the heat radiated, calculate the pipe surface in square feet, as if there were no flanges, add 7 per cent., and multiply by the appropriate figure from the table on page 67.

NOTES ON COVERINGS FOR PIPES AND BOILERS.

As well as having good heat insulating properties, it is important that pipe coverings be durable. A material which easily disintegrates under vibration will not long remain an efficient insulator, nor will a material which cannot stand high temperature. For example, hair felt is a good insulator, but will not stand contact with pipes carrying high pressure or superheated steam.

Tests with locomotive-type boilers, first uncovered and then covered with 2 ins. of 85 per cent. magnesia, showed in the second case 2·5 per cent. additional evaporation for 13·8 per cent. less coal, or a total coal saving of 16 per cent.

Recent tests at the National Physical Laboratory have shown that 85 per cent. magnesia (that is, 85 per cent. hydrated magnesium carbonate and 15 per cent. asbestos) begins to calcine at 450° F., and that at 600° F. the decomposition is considerable. At the high steam temperatures now coming into use in large power stations (pressures up to 375 lbs. per sq. in. and temperatures up to 700° F.) it is necessary to place next the pipe a material unaffected by heat. About ½ in. of slag wool or of special composition may be used, then a layer of 85 per cent. magnesia or other good non-conductor, and then an outer layer, ½ in. thick, of hard-setting composition to bind the whole together.

Aluminium Foil for Heat Insulation.

Thin aluminium foil crumpled so as to form irregular ridges and include air spaces has been successfully applied as a heat-insulating medium for pipes or for flat surfaces.

In spite of the high conductivity of aluminium the flow of heat through the crumpled foil is low owing to the smallness of the contact areas. The bright surface also reduces radiation loss. The foil is crumpled and wrapped round the pipe or other object to be insulated in layers until a

sufficient thickness is obtained. The covering is held in position by spacing wedges and a thin sheet steel covering attached by spot welding.

It is claimed that the heat loss through the foil is considerably less than that through an equal thickness of 85 per cent. magnesia.

Notes on Lagging.

The holding of slag wool to pipes or boilers (to which asbestos composition has been applied) is best effected by means of wire-bound split laths, so spaced that the finishing overlay of cement may not only be keyed in between them but may also afford a means of locating any leakages, in addition to preserving a favourable density estimated at from 10 to 12 lbs. per cubic foot.

A cheaper but decidedly less effective way of holding slag wool together is by means of wire netting in the meshes of which an overlay of plastic cement is impacted. When, therefore, disintegration takes place and the wool settles down by its own gravity, the upper surface is reduced to a mere shell of wire and cement by which the bulk is held in suspension.

Glass Silk, a fairly recent introduction, has been ascertained by the N.P.L. to have very high insulating properties.

Hair-felt is one of the finest non-conductors known, but is quickly consumed by direct contact with heated surfaces.

STEAM SEPARATORS.

The function of a steam separator, or as it would be more correctly called a water-separator is to extract the water particles carried in suspension by wet steam. Apparatus of this kind served a very useful purpose before the use of superheated steam became general, but are now much less commonly employed. They act by causing a change of direction in the flow of the steam, either giving it a definite whirling path, when the water particles are thrown out by centrifugal force, or by causing the steam to pass round baffles to which the water adheres. To be at all efficient, a steam separator must have ample volume, so that the steam passes through it comparatively slowly and the water has time to settle out and is not picked up again by the rush of the steam past the edge of any baffles. Separators should be well lagged, and the larger they are the better.

STEAM TRAPS.

Steam traps are indispensable adjuncts to apparatus from which water of condensation has to be drained off with regularity and certainty, and without loss of steam.

Steam traps fall into two main classes; (*a*) Float or Bucket traps which are operated by the difference in density between water and steam, and (*b*) Expansion traps which depend on a difference of temperature. The varieties of each kind are almost innumerable, and great care should be taken in selecting the design which will be best suited to the duty to be performed.

In the simple float trap, a hollow metallic float on the end of a pivotted lever rises as the water accumulates in the trap, and opens a discharge valve until the water has fallen to its normal level. Such traps can be designed so that the whole of the working parts can be inspected or removed without interference with the pipe connections. The conditions that the float must be strong enough to resist collapse under the steam pressure, and yet light enough to have the necessary buoyancy and power to open the discharge valve, impose a limit on the valve size and discharging capacity of traps of this type. The discharge of such traps should theoretically be continuous. In practice it is generally intermittent at small loads, which is an advantage as it is less severe on the valve and seating.

When the amount of water to be handled varies greatly, or when the trap may have to work in a tilted position as on shipboard, the float trap is provided with a trip mechanism which ensures that it either discharges at full flow or not at all. This intermittent action enables the trap to be heard working, which is a good feature when it is not a nuisance. The trip mechanism detracts, somewhat of course, from the simplicity of the trap.

In traps of the ordinary bucket type, the discharge valve is kept shut by the upward pressure due to the buoyancy of a hinged open bucket around which the water gradually rises. In time the water overflows into the bucket, causing the latter to sink and thereby to open the valve which is situated at the end of a fixed pipe projecting downwards nearly to the bottom of the bucket. The latter is therefore emptied by the steam pressure and its buoyancy restored. The discharge is necessarily intermittent. This kind of trap is long-lived and reliable. It has no float to collapse or to leak, and can be designed for high pressures.

The inverted bucket trap is equally simple in construction. In this trap the bucket, which is upside down, is usually suspended from a hinge at the side. It is completely immersed, and the condensate enters it through an upturned pipe projecting into its interior. Air can escape through

a small hole in the top of the bucket, so that the trap can never become air-locked. This gives it an advantage over the open bucket type. Should the hole, however, get stopped up, the trap will be put out of action. Furthermore, if the trap gets hot enough to evaporate the water it contains, it will blow steam full bore and will not be able to re-set itself. Traps of this kind should always be left bare on top, and it may be desirable to connect them to the apparatus they serve by means of a length of unlagged pipe when the steam is very hot. Another precaution often advisable is a non-return valve to prevent loss of water from the trap.

Inverted bucket traps can be made in very small sizes. The bucket of these small traps is not hinged, but operates the valve directly by its rise and fall.

Expansion traps rely for their action on the fact that water of condensation can be, and practically always is, colder than the steam from which it was derived. The discharge valves of such traps are controlled by the expansion and contraction of some substance according to whether it is in contact with steam or water. This principle ensures that the trap shall always be full open when cold, so that it is not liable to be injured or put out of action by frost, and it will discharge all air from the system at starting up.

In the simplest form of expansion trap, a straight copper tube fixed at one end, expands and keeps the discharge valve closed so long as it is subjected to steam temperature. If water is present the tube contracts and opens the valve. Traps of this kind are somewhat lengthy, though this is often no drawback. The length of the trap can be much reduced by employing the expansion of a liquid such as oil sealed in a corrugated bellows piece to operate the valve. In both metallic and liquid expansion traps it is necessary to limit the closing pressure by some kind of spring device, otherwise the valve or its seating might be injured when the trap was exposed to steam at a higher temperature than normal.

As an alternative to oil, a volatile liquid may be used in the bellows. This permits of the construction of a very small and cheap trap which can also serve usefully as an automatic air-vent. Such traps, however, must not be used with superheated steam, nor in situations where they are subject to water hammer.

Traps draining any apparatus working with steam at more than atmospheric pressure can be used to discharge the condensate to an elevated tank whence it can flow to the inlet of the feed-pumps. This is a practically necessary arrangement for the pump when the condensate is at all hot. When traps are used for raising the discharged water to a higher level, a non-return valve should be placed at the outlet of the trap. The practical limit of lift can be taken as 2 ft. per pound of gauge pressure of the steam at the trap. Special forms of trap are manufactured by Messrs. Hopkinson Ltd. and other firms to deliver the water of condensation directly into the boiler.

General Notes on Steam-Trap Practice.

Steam traps should always be placed at the lowest point of the apparatus to be drained, and care must be taken that the water of condensation has a free flow to them, without the possibility of air-locks. When draining a steam main it is important to ensure that the connection to the trap does not project into the main and thus prevent the last drop of water being taken away. It is good practice to drain from a pocket welded to the underside of the main. A length of bare pipe on the upstream side of the trap will facilitate the action of the latter by cooling the condensate, but of course, only at the expense of a loss of heat.

It is good practice to every steam trap with a by-pass, but only on the condition that the by-pass is never improperly used. Its presence enables the trap to be examined or adjusted while the plant is working, and it also contributes to safety at starting up if opened for a short time to clear all water and air out of the system. On the other hand, unless it is properly closed at normal times, it is so wasteful a fitting that some engineers prefer to dispense with it altogether.

When a trap discharges into a sealed drain, it is convenient to have a three-way cock at the trap outlet, so that the trap can be adjusted with the cock open to atmosphere. Also turning the cock to this position enables the fact that the trap is working properly to be verified at any time.

The appearance of steam at the outlet of a trap is not necessarily a proof that the discharge valve is leaking, for whenever water under pressure and at a temperature greater than 212° F. is released to the atmosphere, some of the water will automatically flash into steam.

All traps should be situated where they are readily accessible for routine inspection and servicing, and no trap of the float or bucket type must be placed where it is liable to become frozen.

In general the greatest trouble with steam traps is due to dirt, scale, grit or some other foreign substance getting into them. Before they are installed the pipe work should be blown through with steam, and every care taken that it is thoroughly clean. Whenever there is any danger of

dirt being carried into a trap of the float or expansion type, a strainer of wire gauze must always be fitted ahead of the trap. With bucket traps a strainer is less necessary. Suitable strainers are supplied by the trap makers, and they must be regularly inspected and cleaned.

In purchasing traps, the makers should be informed of the maximum and minimum pressures at which the trap will have to work, and the rate at which it will be required to discharge. The size of the pipe connections to a trap is no guarantee of its discharging capacity. A good trap is well worth what it may cost, for traps of cheap and shoddy design are a perpetual nuisance and usually a source of serious waste.

Expansion of Steam.

It is found in practice that in engines using saturated steam the expansion line follows closely the hyperbolic law :—

absolute pressure × volume = a constant.

Hence it is usual to compute indicator diagrams on the assumption that the expansion is hyperbolic. With highly superheated steam the pressure falls more rapidly than the hyperbolic curve indicates.

Referring to fig. 1, the theoretical indicator diagram is A B C D O, there being no clearance and a perfect vacuum. Steam is cut off at B and exhausted at C.

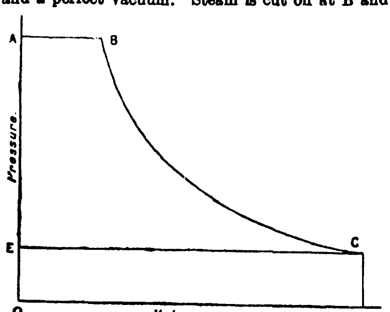

FIG. 1.

The referred M.E.P. of compound engines is the equivalent M.E.P. if the entire expansion were to take place in the low-pressure cylinder.

The nominal ratio of expansion is the stroke volume of the L.P. cylinder ÷ volume swept by H.P. piston up to point of cut-off, or

$$R = \frac{V_L}{a\,V_H} = \frac{\text{cylinder ratio}}{a}$$

where V_H, V_L are stroke volumes of H.P. and L.P. cylinders, and a is proportion of stroke at which cut-off takes place in the H.P. cylinder.

If O_H and O_L are the clearance volumes at each end of the H.P. and L.P. cylinders, the real ratio of expansion is

$$\frac{V_L + O_L}{a\,(V_H + O_H)}$$

To determine the probable actual mean pressure (referred to the low-pressure cylinder in the case of a multiple-expansion engine) multiply the initial pressure (absolute) by K, deduct the back pressure, and multiply by a suitable 'diagram factor.'

Diagram factors depend on the type of engine, type of valves and valve gear, jacketing, superheating, speed, etc. Approximate typical values are as follows:—

TABLE OF DIAGRAM FACTORS.

Triple-expansion	·65–·75
Compound condensing, superheated	·65–·75
" " saturated	·7– ·8
" non-condensing	·8–·85
Simple condensing, trip gears	·9–·95
" " slide valves	·85– ·9
" non-condensing	·9–·95

Note.—In calculating the M.E.P. the clearance is ignored. If the clearance is allowed for, the ratio of expansion for a given cut-off is lower and the theoretical M.E.P. higher, necessitating a lower diagram factor, particularly for simple and compound engines. Thus, some authorities give from 0·7 to 0·9 for simple engines.

Low revolutions, large clearance, jackets, reheaters, and low compression increase the diagram factor. These special conditions must be allowed for, as in slow-speed pumping engines.

Usual Expansions in Various Types of Engines.

Single Condensing Engines	from 2 to 5 times
Two-cylinder Compound Engines	" 10 " 20 "
Triple-expansion Engines	" 12 " 25 "
Quadruple-expansion Engines	" 16 " 30 "
Uniflow Engines	" 7 " 12 "

INDICATED HORSE-POWER OF STEAM ENGINES.

P = Mean effective pressure, in pounds per square inch;
A = Area of cylinder in square inches;
L = Stroke in feet;
N = Revolutions per minute;

then I.H.P. (for a double-acting engine) $= \frac{2\,PLAN}{33{,}000}$

The I.H.P. of a compound or multiple expansion engine is the sum of the powers of the individual cylinders, each calculated as above. For such engines, the 'referred M.E.P.' or 'M.E.P. referred to the L.P. cylinder' is frequently spoken of and used in designing. It means that M.E.P. which, if it acted in a single cylinder of the same dimensions as the L.P. cylinder of the compound engine and working at the same speed, would produce the same power.

The '*referred M.E.P.*' is thus equal to M.E.P. of H.P. cylinder $\times \frac{\text{H.P. cylinder area}}{\text{L.P. cylinder area}}$

$+$ M.E.P. of I.P. cylinder $\times \frac{\text{I.P. cylinder area}}{\text{L.P. cylinder area}}$ $+$ M.E.P. of L.P.

For a two-cylinder compound engine the middle term disappears.

Brake Horse-Power (B.H.P.).

'Brake' or 'Effective' or 'Actual' horse-power is the horse-power delivered by the engine to whatever it is driving. If the engine shaft is coupled to the driven machine—such as a generator for electric power, or a rolling mill, or whatever it may be—the B.H.P. is the power transmitted at the coupling. For a rope drive it is the power at the engine rope pulley. In all cases the B.H.P. is the indicated H.P. less the power absorbed in the running of the engine itself. This latter power—the frictional H.P.—is about 10 per cent. in good modern engines, 8 per cent. in those of the highest class, but may be as much as 20 per cent. in small engines of crude design.

Mechanical Efficiency.

The 'mechanical efficiency' is the ratio of B.H.P. to I.H.P. For high-class engines of, say, 100 H.P. and upwards, typical values of the mechanical efficiency at various loads are as follows:—

Load	Full	¾	½	¼
Mechanical efficiency, per cent.	92	90·5	88	80

Theoretical Steam Consumption.

The theoretical steam consumption of an engine is the weight of steam per h.p. hour which would be required by an ideally perfect engine working on the Rankine cycle with the given live steam and exhaust conditions. This can be most readily calculated by the following formula when, as is practically always the case, the exhaust steam is not in a superheated condition.

$$\text{Theor. lbs. of steam per h.p. hour} = \frac{2{,}545}{H_1 - H_2 + T_2(\phi_2 - \phi_1)}$$

where H_1 = B.Th.U. per lb. of live steam,
H_2 = ,, ,, ,, saturated steam at exhaust pressure.
T_2 = Absolute temp. in deg. Fahr. of saturated steam at exhaust pressure.
ϕ_1 = Entropy per lb. of live steam.
ϕ_2 = ,, ,, ,, saturated steam at exhaust pressure.

When the steam is superheated at exhaust, the formula becomes simply—

$$\text{Theor. lbs. of steam per h.p. hour} = \frac{2545}{H_1 - H_3}$$

where H_3 = B.Th.U. per lb. of steam at exhaust pressure and temperature.

Values H and ϕ are to be found in Callendar's Steam Tables. (See also p. 3 *et seq.*)

EFFICIENCY OF ENGINES.

The thermal efficiency—of the engine alone, exclusive of boiler plant—is the ratio of the work done per lb. of steam (in B.Th.U.) to the heat required to generate 1 lb. of steam, at the pressure and temperature, at the engine stop valve from feed water at the temperature of the engine exhaust.

$$\text{Thermal efficiency } e = \frac{\text{I.H.P.} \times 42 \cdot 42}{w(H_1 - h_3)} = \frac{\text{I.H.P.} \times 2545}{W(H_1 - h_3)},$$

where,

w = steam used, lbs. per minute; W = do., lbs. per hour;
H = total heat at pressure and temperature at boiler side of engine stop valve;
h_3 = water heat at temperature of exhaust.

It is customary to express the performance of engines in steam consumption per h.p. hour, but since the heat required to generate the steam increases with pressure and temperature the steam-consumption figure alone is not a complete criterion of the merit of the engine.

EFFICIENCY RATIO.

The ratio of the thermal efficiency of the actual engine to that of the Rankine cycle—or of the steam consumption of the Rankine cycle to the actual steam consumption (both having the same pressure, superheat, and vacuum or back pressure)—is the 'efficiency ratio.'

The efficiency ratio varies with the pressure, superheat, and vacuum, as well as with the merit of the engine as regards freedom from condensation, leakage, and other losses.

Nevertheless the 'efficiency ratio' is useful in comparing engine test results and in predicting steam consumptions.

Economy of High-pressure Working.

The consumption of steam in pounds per horse-power per hour decreases as the pressure rises. The actual steam consumptions vary according to the size and type of engine.

Steam Saving by Superheating.

Superheating improves the efficiency ratio, so that in practice the saving due to superheating is much greater than that calculated for the Rankine cycle.

Superheating reduces the steam consumption of engines approximately at the rate of 1 per cent. for each 10° F. of superheat, but the rate is rather greater for the lower grades of superheat and less for higher grades.

The practical steam and fuel economy due to the use of superheated steam are about as follows, all superheats being measured at the engine stop valves :—

Approximate Percentage Reduction in Steam Consumption by Superheating, for Compound and Uniflow Engines.

Superheat, deg. Fahr.	50	100	150	200
Common Steam and Exhaust Ports	12	20	26	30
Separate " " " "	10	16	21	25
Uniflow, about	8	12	17	21

(*Foster.*)

Superheat reduces the steam consumption most in simple engines.
For superheat in steam turbines see Part IV, page 140.
The advantages of superheating in general are chiefly :—

1. **Greater thermal efficiency of the engine, due to reduced condensation loss.**
2. **If the boiler plant is not provided with very ample heating surface the addition of a superheater increases the boiler plant efficiency and capacity apart from the engine effect.**
3. **As compared with saturated steam, higher steam velocities in the pipes may be used with superheated steam, and consequently the pipes may be smaller. For this reason, the percentage loss of heat in the pipe system is lower, in spite of the higher temperature.**
4. **Reduction in size of auxiliary plant owing to smaller weight of feed water and coal.**

Degree of Superheat.

In modern practice the following are usual :—

General engine practice: superheat at boilers 150° F., or, say, 120° to 130° at engine. Up to 650° F. total temperature, say 260° F. of superheat at 200 lbs. pressure, can be used if the engine is designed for it.

In general, with flat slide or Corliss valves on the high-pressure cylinder (about 550° F. total temperature) must not be exceeded.

For turbine practice, see Part IV. page 143.

Characteristics of Superheat.

Condensed steam is a slight lubricant. The absence of this must be met by adequate lubrication when using superheated steam. The high temperature requires a special oil of high flashpoint. Pipe friction losses are reduced by superheating.

In reciprocating engines a later cut-off is required to develop the same horse-power. Hence the maximum power which can be developed is slightly reduced by superheating.

Moderate superheat, about 50° or 100° F., is desirable for evaporating and similar heating purposes, especially with long pipe mains, but very high superheats are undesirable, as the steam should have little, if any, superheat by the time it reaches the heating surfaces of the evaporators.

Throttling slightly raises the superheat in steam; expansion, as in a turbine nozzle, very greatly reduces it.

Except for very moderate superheat, cast-iron and copper must not be used for pipes and valves in contact with the steam.

STEAM JACKETS.

Steam jackets are rarely adopted to-day except for slow-running engines. There is no doubt that a well-arranged jacket leads to considerable economy when the engine is supplied with saturated steam. The economy is much less marked with superheated steam, especially as jackets are usually arranged. Having regard to the extra first cost and complication, jackets are not to be recommended with superheated steam unless the conditions are exceptional.

The usual arrangement of steam supply is defective; the steam is supplied to the jacket and a trap fitted to drain away the condensed steam, but there is no through flow. Usually, on intermediate and low-pressure cylinders the jacket steam pressure is reduced to a few pounds above the steam chest pressure; except to relieve the cylinder barrels and liners of mechanical stress, there is no justification for such an arrangement; from the point of view of steam economy it is ridiculous and largely nullifies the value of the jackets. Wherever possible, the jacket steam should have a through-flow. With saturated steam the engine steam should pass through the jackets and then through a water separator before entering the cylinders.

When jackets are used with steam superheated 100° F. or more, they are unnecessary on the high-pressure cylinder.

Small and slow-running engines benefit most from jackets.

Reheaters, *i.e.* appliances for heating the steam in the receivers between the cylinders, do not appear to be useful with saturated steam.

With good initial superheat, say over 150° F., reheaters give good results.

Steam Consumption

Typical steam consumptions, with the corresponding efficiency ratios, are shown in the following table:—

TYPICAL STEAM CONSUMPTIONS AND EFFICIENCY RATIOS.

Type of Engine.	Pressure at Stop Valve. Lbs. per Sq. In. (Gauge.)	Superheat °F.	Condensing. Steam. Lbs. per I.H.P. Hour.	Condensing. Efficiency Ratio.	Non-Condensing. Steam. Lbs. per I.H.P. Hour.	Non-Condensing. Efficiency Ratio.
Simple	160	—	17 to 17·5	51 to 49	21 to 22	67 to 64
	160	150	12 to 13	65 to 61	16 to 17	78 to 74
	120	—	18·5 to 19·5	49 to 47	24 to 25	65 to 62
	120	150	14·5 to 15	57 to 55	19 to 20	73 to 70
	80	—	22 to 23	45 to 43	30 to 33	62 to 56
	80	150	16 to 17	56 to 53	24 to 26	69 to 64
Compound	200	—	12·5 to 13	66 to 64	—	—
	200	150	10 to 10·5	74 to 71	—	—
	160	—	13 to 13·5	66 to 64	17·5 to 18·5	80 to 75
	160	150	10·5 to 11	74 to 71	14·5 to 15	86 to 83
	120	—	14 to 15	65 to 61	19·5 to 20·5	79 to 75
	120	150	11·5 to 12·5	72 to 67	16 to 17	86 to 83
	80	—	—	—	25 to 26	74 to 71
	80	150	—	—	20·5 to 21·5	81 to 77
Triple	200	—	11·5 to 12	72 to 69	—	—
	200	150	10 to 10·5	75 to 71	—	—
	180	—	12 to 12·5	70 to 67	—	—
	180	150	10·2 to 11	75 to 70	—	—
Uniflow	200	—	11·8 to 12·3	70 to 67	—	—
	200	150	10 to 10·5	75 to 71	—	—
	160	—	12·5 to 13	69 to 66	19 to 20	74 to 70
	160	150	10·5 to 11	75 to 71	16 to 17	78 to 74
	120	—	13·5 to 14·5	68 to 63	21·5 to 22·5	73 to 69
	120	150	11·5 to 12·5	72 to 67	18 to 19	78 to 73

The particulars in the table refer to high-class modern engines with Corliss or drop valves and of about 600 i.h.p. or upwards working at normal full load.

In the case of condensing engines, the vacuum has been taken as 26 ins.

The non-condensing uniflow values are subject to considerable variations.

The figures given being for engines of the highest class, for good average practice add from 5 to 10 per cent. For badly clothed or defective engines add 20 per cent. or more. For small engines add from 5 per cent. upwards according to size. The superheat is measured at the engine stop valve. The loss of temperature between superheater and engine may be from 20 to 100 degrees, according to steam-pipe conditions. Simple (alternating-flow single-cylinder) engines vary a good deal according to the cut-off. In general, a uniflow has a rather lower steam consumption than a good compound engine.

Duty of Engines.

The duty of an engine is rarely spoken of except for pumping engines, and is then expressed in terms of the work done in lifting the water per 1,120 lbs. of steam used, or some other basis. Sometimes 1,000 lbs. of steam is used, especially in America; and sometimes coal or heat units is the basis.

Example.—Pumping engine consumes 14 lbs. of steam and 1·8 lbs. of coal per water, or pump h.p. hour. The total heat added per lb. of steam is 1,125 B.Th.U.

Duty per 1,120 lbs. steam is $\frac{1,120}{14} \times 33,000 \times 60$ . . . = 158,400,000 ft. lbs.

Duty per 112 lbs. coal is $\frac{112}{1 \cdot 8} \times 33,000 \times 60$ . . . . = 123,200,000 „

Duty per 1,000,000 B.Th.U. in steam is $\frac{1,000,000}{1,125} \times \frac{158,400,000}{1,120} = 125,700,000$ „

The steam consumption of high-class slow-speed triple-expansion pumping engines is very low.

The duty of Winding Engines is rarely measured, but is sometimes stated in terms of steam used per shaft h.p. hour, or per h.p. hour in the coal hoisted. This steam consumption increases greatly when the cages are not fully loaded and the number of winds is below maximum. Under favourable conditions compound non-condensing engines use from 30 to 50 lbs. of steam per shaft h.p. (in the coal raised) per hour. For high pressure engines and unfavourable conditions the consumption increases to about 100 or 120 lbs., and occasionally more.

Tests of a cross-compound non-condensing engine at Sherwood colliery gave a steam consumption of 40 lbs. per S.H.P. hour. The engine cylinders were 32 ins. and 53 ins., stroke 66 ins., pressure 125 lbs. per sq. in., superheat 65° F.

For the steam consumption of turbines *see* Part IV, Steam Turbines, p. 143.

THE INDICATOR DIAGRAM

General Definitions.

The Atmospheric Line, AB, fig. 2, is a line drawn by the pencil of the indicator when the connections with the engine are closed and both sides of the piston are open to the atmosphere. This line represents on the card the pressure of the atmosphere, or zero gauge pressure.

*The Line of **Absolute Zero Pressure***, OX, is a reference line usually drawn about 14·7 lbs. by scale below the atmospheric line. It represents a perfect vacuum, or absence of all pressure.

At any considerable height above sea level the line OX becomes nearer the line AB.

The Clearance Line, OY, is another reference line drawn at a distance from the end of the diagram equal to the same percentage of its length as the clearance volume is of the piston displacement. The distance between the clearance line and the end of the diagram **represents the volume of the clearance and of the ports and passages at the end of the cylinder.**

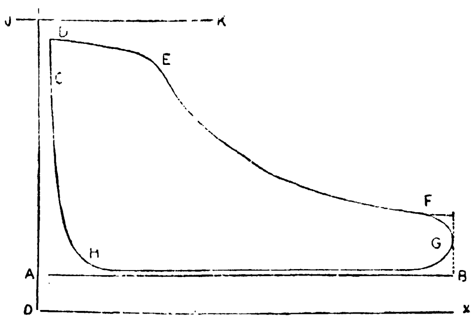

Fig. 2.

The Line of Boiler Pressure, JK, is drawn parallel to the atmospheric line, and at a **distance from it by scale equal to the boiler pressure shown by the gauge. The difference in pounds between it and DE shows the loss of pressure due to the steam pipe and the ports and passages in the engine.**

***The Admission Line* is in two parts. CD, which show the rise of pressure due to the admission of steam to the cylinder by opening the steam valve (if the steam is admitted quickly when the engine is about on the dead centre this line will be nearly vertical), and**

DE, which is drawn when the steam valve is open and steam is being admitted to the cylinder.

***The Point of Cut-off*, E, is the point where the admission of steam is stopped by the closing of the valve. It is difficult to determine the exact point at which the cut-off takes place. It is usually located where the outline of the diagram changes its curvature from convex to concave.**

***The Expansion Curve*, EF, shows the fall in pressure as the steam in the cylinder expands and does work.**

The Point of Release, F, shows when the exhaust valve opens.

FG represents the change in pressure that takes place when the exhaust valve opens; exhaust continues to the point H.

The Back Pressure Line, GH, shows the pressure against which the piston acts during its return stroke. On diagrams taken from non-condensing engines it is either coincident with or above the atmospheric line, as in fig. 2. On cards taken from a condensing engine, however, it is found below the atmospheric line, and at a distance greater or less according to the vacuum obtained in the cylinder.

The Point of Compression, H, is the point where the exhaust valve closes. It cannot be located very definitely, as the change in pressure is at first due to the gradual closing of the valve.

The Compression Curve, HO, shows the rise in pressure due to the compression of the steam remaining in the cylinder after the exhaust valve has closed.

The Mean Effective Pressure (M.E.P.) is the mean net pressure urging the piston forward.

The Initial Pressure is the pressure acting on the piston at the beginning of the stroke.

The Terminal Pressure is the pressure above the line of perfect vacuum that would exist at the end of the stroke if the steam had not been released earlier. It is found by continuing the expansion curve to the end of the diagram, as in fig. 2.

Defects in Diagrams.

A very common and serious defect in diagrams arises from the stretching of the indicator cord. If two diagrams taken from the same engine at the same time show noticeably unequal lengths the cords are probably inaccurate. As a rule the stretch is greatest when the drum is pulled open. Thus one end of the diagram is widened and the other narrowed, giving incorrect M.E.P. and points of valve action.

The cord used should be as short and as inextensible as possible.

The reducing gear should give an accurate copy of the motion of the engine crosshead, and the cord from the reducing gear should run in a direction parallel to the line of motion of the crosshead.

If the diagram is very much to one side of the card, and if the near end is quite straight and vertical, the drum is probably hitting its stop at one end of its travel. Alter the length of the indicator cord.

If the expansion line is stepped in rough terraces the indicator piston is probably sticking and the calculated M.E.P. will be too high.

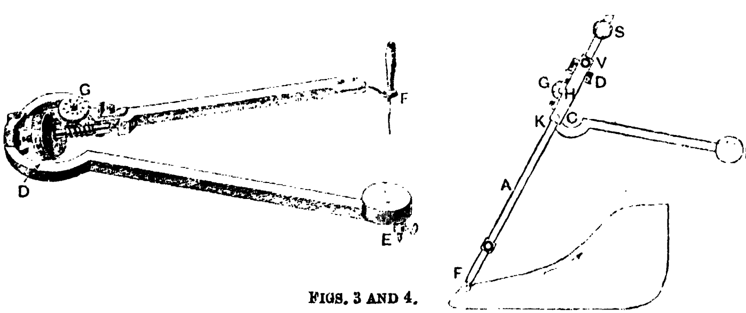
If the expansion is wavy the spring is too light and should be replaced by a stiffer one.

Mean Effective Pressure.

This is best determined by finding the area of the indicator diagram; dividing this by the length, so obtaining the mean height; then, multiplying the mean height by the pressure scale the mean effective pressure is the result.

The best method of measuring the area of the diagram is to use a planimeter, which if carefully handled gives results accurate to hundredths of a square inch.

The most commonly used planimeter is of the Amsler type, and is shown by figs. 3 and 4.



FIGS. 3 AND 4.

It consists of two arms hinged together; one is constrained to swing round a fixed pivot, the other carries a tracing point which is made to follow the outline of the diagram. This arm also carries a roller, with its axis in the centre line of the arm, and provided with a scale and vernier

by which its rotary movements can be accurately measured. As the tracing point moves round the diagram the roller partly slides and partly rolls over the paper or board on which the diagram is drawn or to which it is pinned. The readings of the scale before and after each exact circuit of the diagram are noted; their difference measures the area of the diagram on a scale determined by the proportions of the instrument.

The roller should be pivoted so as to rotate freely, but without endshake, and the surface on which it moves should be flat and unglazed. The position of the pivot point should be chosen so that the tracing point can reach freely all parts of the outline. The pivot point has a needle which can then be pressed into the paper or board.

It is advisable to check the planimeter occasionally by running it round a simple figure, such as a square or circle the area of which can be easily calculated independently.

To Interpret the Indicator Diagram.

Besides the calculation of horse-power and the rough estimate of steam consumption, from the diagram, other important information can be learned from a study of the diagram, as follows:—

The diagram will show the opening and closing of the valves, as explained on p. 79, fig. 2. If the point of cut-off is fixed, as with most slide and piston valve engines, the depth of the steam admission line DE below the boiler pressure line YK is a measure of the loss by throttling. If this is invariably considerable, it may pay to shift the eccentric so as to give an earlier cut off. With a simple slide or piston valve this would make the exhaust open earlier and the compression commence earlier. These, and particularly the latter, must be watched, as too early compression sends the compression pressure above the steam chest pressure. This is not good; although the compression line should rise nearly to the admission pressure. In the case of a reversing engine having a Stephenson, Joy, or similar link motion, the point of cut-off is varied by shifting the equivalent eccentric; and thus at early cut-off the exhaust and compression are both early, but at late cut-off the exhaust and compression both become late. Hence when studying such diagrams these changes of exhaust and compression with cut-off must always be kept in mind. The points of valve action can also be altered by changing the lap. Thus if the exhaust edge of the valve is chipped the exhaust takes place earlier and the compression later. Similarly chipping some of the lap off the steam edge of the valve makes the cut-off later and lead earlier.

If the admission line DE falls rapidly, the valve is too small or the valve travel too small.

In a multiple-cylinder engine the diagrams give the distribution of power and forces among the several cylinders. As a rule these should be roughly equal for the several cranks, but need not be equal for the two cylinders of a tandem engine. Indeed, in the latter case, the h.p. cylinder may with advantage take rather more than half the load if the steam is superheated.

Valve setting should always be checked by actual indicator cards after an engine is first started to work.

It is found in practice that the expansion line (fig. 2, p. 79) is closely hyperbolic when using saturated steam, the two axes of the hyperbola being the absolute zero line OX and a vertical touching the diagram at CD. Hyperbolic curves can be purchased printed on transparent paper for placing over indicator diagrams. If the expansion line rises above the hyperbola as the pressure falls it indicates leakage past the steam valve into the cylinder. Similarly, if the expansion line falls more rapidly than the hyperbola it indicates either leakage past the exhaust valve out of the cylinder, excessive condensation of steam in the cylinder, or the use of initially superheated steam. If superheated steam is used, the vertical axis of the hyperbola should be about the clearance line OY in fig. 2; but the exact position depends on the degree of superheat.

The hyperbola is easily drawn more or less completely as desired when it is remembered that the absolute pressure multiplied by the volume has the same value at all points on the same hyperbolic curve.

ENGINE TYPES FOR VARIOUS DUTIES.

Each type of engine has a field, not sharply defined, in which it shows to best advantage.

Elaborate and expensive types are least desirable when coal is very cheap, the working hours few, labour unskilled, or the working conditions very rough.

Non-condensing engines consume from 20 to 50 per cent. more steam and coal than condensing engines.

Unless floor space is limited or very high speeds are desired, a horizontal engine is generally more satisfactory than a vertical. It is more accessible for running and overhauling.

Steam turbines are relatively uneconomical in very small units. In the neighbourhood of 1,000 to 1,500 horse-power they surpass the best reciprocating engines, and for very large units—unless for some special purpose, as driving a reversing rolling-mill—are without serious rival. To show to advantage a turbine must be run condensing, with a good vacuum.

Where economy is at all important the ordinary simple (single-expansion) engine is at a marked disadvantage, which, however, is least with steam superheated 120° or 150°F. For most purposes the compound is the standard type, although the uniflow (a special form of single-expansion engine) is widely adopted. Triple and quadruple expansion engines are more economical than compound, but are more costly and complex. They are therefore chiefly employed on

ships, for towns pumping, flour mills, and other situations where coal consumption is specially important. Their superiority over the compound engine is reduced if the steam is superheated.

The class of engine is frequently designated by the valve gear. Thus the plain slide valve gives the cheapest engine and also, other things being equal, the least economical.

The piston valve is really a circular slide valve, and gives an engine of similar characteristics. For the highest economy and class of engine Corliss or drop valves are desirable. The Corliss valve is really a circular slide valve of small diameter which rotates to and fro through a small angle in its valve chamber. The drop valve may be of the double-beat seating type or of the double-beat piston type. As a rule Corliss and drop valves are operated by a trip valve gear or other form of valve mechanism enabling the cut-off to be automatically varied to suit the load. Slide and piston valves, on the other hand, are not so suitable for cut-off governing and are not usually so arranged, but rely on throttling the steam to meet changes of load. High-speed engines almost invariably have piston or slide valves, because trip and other cut-off gears are unsuitable at high speeds of revolution.

Cut-off, or expansion, governing gives the best economy for variable loads, except at very light loads, when throttling is superior. The difference is least with highly superheated steam, which tends to equalise the steam consumptions at different loads (measured per horse-power, of course).

The superior economy of Corliss and drop valve engines is often believed to be due to the superior qualities of trip valve gears. Actually this is a very minor factor. The chief gain arises from the fact that the inlet and exhaust ports and valves are usually quite separate.

The following list shows the engine types frequently adopted for various duties :—

Duty.	*Type of Engine.*
Agriculture, occasional service	Simple, slide or piston, N.C.
,, regular service	Compound, slide or uniflow, N.C.
Cement works	Compound, Corliss or drop, uniflow, turbine, S.
Electric generating, small	Compound, high-speed vertical, turbine, S.
,, ,, large	Turbine, S.
Factories, cotton mills, etc.	Compound, Corliss or drop, uniflow, geared turbine, S.
Flour mills	Compound or triple, Corliss or drop, uniflow, S.
Paper mills	Compound, Corliss or drop; uniflow, turbine, also with steam extraction, S.
Portable	Same as agriculture.
Pumping, centrifugal	Compound, usually high-speed vertical, also uniflow if at moderate speed, S.
,, hydraulic and town water	Triple three-crank vertical, slow-speed, Corliss or drop, S.
,, well pumps	Compound or triple, Corliss or drop, S.
Rolling mills, not reversing	Horizontal compound, Corliss or drop, uniflow, S.
,, ,, reversing	Two- or three-crank, piston valves, simple or tandem compound, often N.C., S.
Winding	Two-crank simple or compound (tandem usually), N.C., S.

Note.—N.C. indicates non-condensing. S. indicates superheated steam.

Back Pressure and Extraction Engines.

Increasing attention is now being paid to the saving of fuel, which is rendered possible by the combination of power supply and heating services, the heating being effected by using exhaust steam or steam taken from the engine at an intermediate pressure. Factories using steam for heating in their own industrial processes offer special opportunities in this direction, though schemes have also been successfully carried out in which the heating of adjoining offices and houses has been effected in addition to the heating required in the factory processes.

For example, in a factory requiring 200 i.h.p. for driving machinery, and 3,200 lbs. of steam per hour at about 15 lbs. per sq. in. gauge pressure for heating purposes, the methods of independent and combined supply may be compared as follows. In the independent method an economical condensing engine would be used, taking, say, 11 lbs. steam per i.h.p. hour, or 11 × 200 = 2,200 lbs. steam per hour. The total steam is thus 2,200 + 3,400 = 5,600 lbs. per hour.

In the combined system, a back pressure engine would be used, exhausting at the pressure required for the heating steam. It would require, say, 18 lbs. steam per i.h.p. hour, or 3,600 lbs. per hour. Allowing 10 per cent. for loss by condensation, 3,240 lbs. exhaust steam per hour are available for heating. Thus the steam to be generated for all purposes is 3,600 lbs., at

against 5,600 lbs. in the former case, and even though the whole of this steam has to be generated at high pressure and (preferably) superheated, the fuel consumption at the boiler is reduced in nearly the same proportion. The saving in fuel is thus $\frac{5,600 - 3,600}{5,600} \times 100 = 35 \cdot 6$ per cent. approximately.

By means of such systems the large proportion of heat carried away and lost in the condensing water of even highly economical power plants is greatly reduced; cases are on record in which the heat utilised as work in the engine, together with heat made available for heating purposes, amounts to 77 per cent. of the heat in the steam delivered by the boiler.

In the 'intermediate steam extraction' system, which is adapted for fluctuating power and heating requirements, a compound engine is used, the heating steam is taken from the receiver between the cylinders, and only a part of the steam used in the h.p. cylinder passes to the l.p. cylinder, and thence to the condenser. By means of a pressure regulator, the intermediate pressure is allowed to vary only between fixed limits. With an increased demand for heating steam, the pressure falls slightly, the pressure regulator makes the l.p. cut-off take place earlier, and, if the load on the engine remains unchanged, the speed governor makes the h.p. cut-off correspondingly later; thus more steam passes through the h.p. cylinder and less through the l.p. Provision is usually made for supplementing the 'extraction' steam, when necessary, by steam taken directly through a reducing valve from the live steam main; this additional supply is also controlled automatically. The l.p. cylinder may with advantage be of the 'uniflow' type.

On account of the variations in the distribution of the power between the two cylinders with varying demands for extracting steam, the extraction engine usually has its cylinders arranged in tandem.

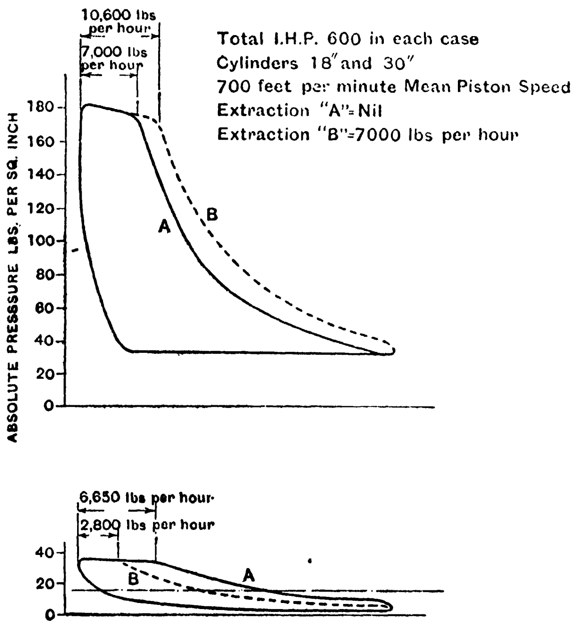


FIG. 5.

This is not, however, absolutely essential, and, particularly if the extraction steam is comparatively small in quantity, the engine may be of the cross compound arrangement.

Typical indicator diagrams for an extraction engine are shown in fig. 5.

The steam quantities in each cylinder with and without extraction are marked on the diagrams, the total load being the same in both cases.

Oil in Exhaust Steam.

The objection is often raised that steam exhausted from, or extracted from, a reciprocating engine is unsuitable for use in contact with textile fabrics on account of its contamination with lubricating oil.

Vertical engines may be operated with bronze piston rings and no cylinder oil in order to avoid this objection.

The risk of trouble due to oil is, however, much exaggerated. The experience obtained in using exhaust steam from oil-lubricated cylinders in bleaching and dyeing works where it comes into contact with all sorts of fabrics and all sorts of dyes justifies the conclusion that no trouble due to oil need be feared. Not the slightest effect of oil on the fabrics has been detected in many years of working under such conditions.

An oil separator should, of course, be provided, although it will not remove absolutely the whole of the oil.

ENGINE DESIGN.

The type of engine is first settled from a consideration of duty, steam consumption, price of fuel, space available, working conditions, water supply, first cost, etc.

Cylinder proportions, stroke and speed of revolution are then fixed. Typical British cylinder ratios and mean effective pressures are given in the tables below. On the European Continent the cylinder ratios adopted are usually considerably below the tabular values. That is, a larger high-pressure cylinder is adopted. This makes for economy with superheated steam, but for a two-crank engine tends towards unequal distribution of load on the two cranks which is not altogether desirable. This objection does not apply in the case of tandem engines.

TYPICAL MEAN EFFECTIVE PRESSURES AT NORMAL FULL LOAD IN LBS. PER SQ. IN.

Boiler Pressure—Gauge	80	100	120	140	160	180	200
Simple Condensing, about	30	34	37	—	—	—	—

Having fixed the cylinder sizes the probable steam pressures on the pistons are put down, and from these the total piston loads are obtained. From these, by allowing suitable stresses and bearing pressures, the principal sizes are fixed.

Usual stresses in high-class engines are as follows :—

USUAL ENGINE STRESSES.

Crank and crosshead pins, up to	9,000 lbs. sq. in.
Crankshaft journals	7,000–9,000 „
Piston rod, net tension at cotter hole	5,000–6,000 „
Piston rod, gross tension (direct plus bending in body)	9,000 „
Connecting rod bolts	4,000–6.000 lbs. sq. in.
Main studs and bolts	5,000 „
Lesser „ „	4,000–6,000 „
Connecting rod body, small end	3,000–6,000 „
Shear on cotters	3,000–5,000 „
Bending on cotters	up to 7,000 „
General forgings	4,000–8,000 „

Cast Iron in Tension.

Simple frames, direct pull	700–900 lbs. sq. in.
Frames, with some bending	500–800 „
Complex frames, with bending	500–600 „
Flywheel arms (C.F.)	1,500–2,500 lbs. sq. in.
Cylinder barrels, new	1,200–2,000 „
„ „ usual	1,500 „

For engines, such as rolling mill engines, subject to shocks, the stresses calculated on the steady load should be less—e.g., a 9-in. crank-pin of good material failed, although the stress calculated from steady load conditions was 5,650 lb. per sq. in.

(*From an Insurance Co. Report*, 1930–31.)

It should be noted that in calculating the above frame tensions only the direct pull is included. If bending is calculated separately and added on, very high figures are sometimes reached.

HORIZONTAL ENGINE BEARING PRESSURES.

Bearing.	Lbs. per Sq. In.	Bearing.	Lbs. per Sq. In.
Crosshead pins	1,200–1,300	Second motion bearings	100–200
Crank pins	800– 950	Crosshead slides	40– 50
Crankshaft journals (steam load)	100– 150	Intermediate piston rod slides	20– 40
Crankshaft journals (combined loads)	150– 200		

USUAL BEARING PRESSURES FOR VERTICAL HIGH-SPEED ENGINES.

Bearing.	Lbs. per Sq. In.	Bearing.	Lbs. per Sq. In.
Main bearings	200– 300	Crosshead slippers	40–50
Crank pins	400– 550	Eccentric straps	60–70
Crosshead pins	1,000–1,200		

For journals with steady loading running at high speeds, see p. 134.

ENGINE DESIGN.

As an example, take the case of a cotton mill engine of 1,500 i.h.p. normal load, the engine to be of the cross-compound condensing type ; boiler pressure 160 lbs.

The cylinder ratio we take to be 4 nominal, piston rods being ignored. We aim at equal loading on the two cranks so that of the total drop in pressure from stop valve to condenser one-fifth will take place in the low-pressure (l.p.) cylinder. Allowing 12 lbs. vacuum and losses of 5 lbs. and 8 lbs. at the steam pipe and intermediate receiver respectively, the total effective pressure drop is 159 lbs., of which 32 takes place in the l.p. cyl. and 127 in the h.p. If the engine has a stroke of 5 ft. and runs at 66 r.p.m. (higher speeds are coming into favour), the piston speed is 660 ft. per min., and the area of the l.p. cylinder for a m.e.p. of 30 lbs.

$$= \frac{1{,}500 \times 33{,}000}{660 \times 30} = 2{,}500 \text{ sq. ins.}$$

This is taken as the gross piston area, giving a diameter of 56·5 inches. The actual m.e.p. would therefore be about 31 lbs. The h.p. cylinder should then be 28·25 ins. diam., but odd dimensions are unsatisfactory, and the cylinders will be fixed at 28 and 56 inches, giving a nominal m.e.p. of 30·5 lbs., which is rather below modern practice, which tends rather to higher m.e.p. than given in the table above.

Ignoring the piston rods, the gross load on the l.p. piston is 32 × 2,500 = 80,000 lbs. The load on the h.p. piston is the same. Owing to the effect of the rods this value is rather high, but the difference may be ignored, and 5 per cent. added to cover variations in the load distribution, making the total piston load 84,000 lbs. Taking bearing pressures of 1,250 and 850 lbs. per sq. in. on the crosshead pin and crank pin, the projected areas of these become 67·2 and 98·8 sq. ins. respectively. We may thus fix the pin bearings (diam. × length) as 6·75 × 10 and 10 × 10 ins.

We now turn to the size of the crankshaft neck. The bending 'arm' from centre of crank pin to centre of main crankshaft neck, we estimate at about 26 ins., so that the bending moment is M = 84,000 × 26 = 2,180,000 inch lbs. The twisting moment is

$$T = 84{,}000 \times 30 = 2{,}520{,}000 \text{ inch lbs.}$$

The equivalent bending moment is

$$M_e = \tfrac{1}{2}\left[M + \sqrt{M^2 + T^2}\right] = 2{,}755{,}000.$$

Adopting a stress of 8,000 lbs. per sq. in., the modulus of the neck section is

$$Z = \frac{2{,}755{,}000}{8{,}000} = 344.$$

For a solid neck of diam. d, $Z = 0{\cdot}0982d^3$. Hence $d = 15{\cdot}2$ ins., say 15·5 ins. The length of the neck must be determined to give a suitable bearing pressure from dead weight and steam load.

The piston rod diam. is next fixed, and partly from it and partly directly from the load the proportions of the connecting rod. The piston rod is proportioned so that the stress round the cotter hole at the crosshead is about 5,000 to 5,500 lbs., whilst the total direct tension plus tension due to bending (assuming a tail support to the rod) does not exceed about 9,000 lbs. The net section of the frame will lie between about 100 and 170 sq. ins. according to type, the highest stresses being allowed where there is least bending.

The size of the crosshead slipper is determined as follows:—If the connecting rod is 5 cranks long, centre to centre, divide the total piston load by 5. The result, 16,800 lbs. in this case, is approximately equal to the maximum load on the slide due to piston pressure. To this should be added the dead weight in the case of a horizontal or inclined engine, giving, say, about 18,000 lbs. in all. Taking a pressure of 45 lbs. per square inch (less if the pressure is steady and not highly variable), gives a slipper area of 400 sq. ins.

FRAMES.

Bedplates and other frames are either of strong cast iron or of fabricated steel. They should be so formed as to reduce bending to a minimum consistent with convenience for the engine attendant and reasonable cost. To secure this they should be as nearly as possible symmetrical on both sides, and also above and below the centre line. This does not mean strict geometrical symmetry, as this is very rarely attainable except as regards the two sides; but it implies an approximately equal distribution of stress. Circular bores and turned joints make for truth in alignment and often for cheapness in manufacture. Ample bearing surface on the foundations must also be allowed.

CYLINDERS.

Cylinders should be hard and strong. Apart from questions of strength, for information on which see the table of stresses on page 85, the following important points should not be overlooked:—

(1) The clearance volume should be as small as reasonably possible.

(2) The clearance surface should be reduced to a minimum.

(3) The exhaust and inlet ports are better separated.

(4) The ports should be short, direct, and not too large. Large ports involve increased clearance surface.

(5) The covers which, however, are closely influenced by the piston details, should be free from recesses and curves.

(6) Where there are jackets the steam should be arranged to have a decided through flow, the more rapid the better.

(7) Proper relief valves and drainage should be provided.

(8) Metal bosses and projections connecting to the frames or atmosphere facilitate heat radiation, and should be kept small.

The port sizes are based on a steam velocity of 100 to 125 feet per second for inlet ports, and 90 to 120 feet per second for exhaust ports when using saturated steam. With superheated steam these speeds are increased to 130 or even 150 feet per second.

Area of Steam Passages and Valves.

The area is usually calculated from the mean piston speed. Thus if the pipe or valve area is one-tenth the piston area and the piston speed is 600 ft. min. or 10 ft. sec. the steam speed through the pipe or valve is 100 ft. sec.

Usual values for steam and exhaust valves, ports, and pipes:—

Saturated steam	100 ft. per sec.
Superheated steam	125 ,,

For drop-seated valves add about 50 per cent. at high speeds, and up to 100 and 150 per cent. for uniflow engines.

For steam turbines base on actual weight of steam, but assumed saturated, and allow 90 ft. per sec. This is equal to about 120 ft. sec. for steam superheated about 150° Fah. at the turbine. A rough rule is 1000 lbs. of steam per hour at rated load per sq. in. of pipe area.

For the main steam range, unless this is very short, base on actual volume, assumed saturated, flowing at about 90 ft. per sec.; rather less, say, 75 to 80 ft. per sec., for reciprocating engines or pipes below 4 ins. in diameter.

BEARINGS.

With very rare exceptions oil is dragged into a bearing by the relative movement of the two so-called rubbing surfaces by a kind of wiping or dragging action. To prevent loss of lubrication the oil must not be allowed to escape from the bearing except at the proper place. Ordinary crosshead pin bearings work mostly by suction. The slight pulsation of the pin in the bearing draws in oil on alternate strokes. On the return of the pressure the oil has not time to escape.

Oil grooves should be looked upon as local supply reservoirs.

Bearing clearances should not increase so rapidly as the diameter of the journal. They vary according to the class of work.

The use of white metal bearings (see page 1242 Vol. I) is a safety precaution in case of overheating. It also has constructive merits.

Usual bearing pressures are given on page 85.

For the Michell bearing see page 302.

CRANK CONNECTING-ROD MECHANISM.

If r = crank radius; l = length of connecting rod; n = R.P.M.; θ = crank angle (measured from inner dead centre); x = per cent. stroke of piston (measured from end of stroke remote from crank),

then the following relationships are nearly exact:

$$x = \frac{1 - \cos\theta}{2} + \frac{r}{8\,l}\left(1 - \cos 2\,\theta\right);$$

$$\text{piston velocity} = 2\,\pi\,n r\left(\sin\theta + \frac{r}{2\,l}\sin 2\,\theta\right) = 2\,\pi\,n\,r \times k_1$$

$$\text{piston acceleration} = 4\,\pi^2\,n^2\,r\left(\cos\theta + \frac{r}{l}\cos 2\,\theta\right) = 4\,\pi^2\,n^2\,r \times k_2.$$

TABLE OF CRANK ANGLES AND FACTORS FOR PISTON VELOCITY AND ACCELERATION.

θ = angle of crank for out-stroke.
Angle for in-stroke = 180 − θ, measured from outer dead centre.

Stroke per cent.		$\frac{l}{r}$ = infinity.			$\frac{l}{r} = 5$			$\frac{l}{r} = 4$

100	0	180·0	0	−1·00	180·0	0	−0·80	180·0	0	−0·75

The positions of piston and crank for zero piston acceleration are as follows:

	$\frac{l}{r} = \infty$	$\frac{l}{r} = 6$	$\frac{l}{r} = 5$	$\frac{l}{r} = 4$	$\frac{l}{r} = 3$	$\frac{l}{r} = 2$
Stroke per cent.	50	46·1	45·4	44·4	43·2	41·7
Crank angle (degrees)	90	80·8	79·1	76·7	73·2	67·7

Crank Effort and Turning Moment.

The crank effort is the force exerted by the connecting rod on the crank pin in the direction of motion of the pin.

The turning moment (at a particular crank) is the crank effort multiplied by the crank radius.

The total turning moment of an engine is the sum of the moments at all the cranks.

To find the crank effort: From the indicator diagram (the assumed probable diagram in the case of design) and the cylinder area, the total force exerted on each side of the piston by the steam is found for any point of the stroke, and hence also the nett steam force on the piston.

To this must be added, with due regard to algebraic sign, the inertia force, *i.e.* the force required to accelerate (or retard) the reciprocating masses. If the engine is vertical, the weight of the moving parts must also be allowed for.

Thus the force P, say, acting at the crosshead in the direction of motion is found.

To find the inertia force at any position of the piston, it is usually sufficient to find the inertia at the ends of the stroke and to find the position at which the inertia is zero, thus fixing three points on the diagram, fig. 6. A fair curve drawn through these points gives the inertia line RRR.

At the inner dead centre, the acceleration $a = 4\pi^2 n^2 r\left(1 + \frac{r}{l}\right)$; at the outer dead centre $a = 4\pi^2 n^2 r\left(1 - \frac{r}{l}\right)$, and $a = 0$ at a position depending on the ratio $\frac{l}{r}$ (see table, p. 88).

The inertia force = weight of reciprocating parts $\times \frac{a}{g}$.

Fig. 6 shows the form of a typical diagram of forces. AB is the stroke, A the inner and B the outer end. PPP represents the resultant force of the steam on the piston during the out-stroke and QQQ that during the in-stroke. RRR is the inertia line. Ordinates measured from RRR represent the forces at the crossheads in the direction of motion (For a vertical engine, the line RRR is lowered by an amount representing the weight of the parts.)

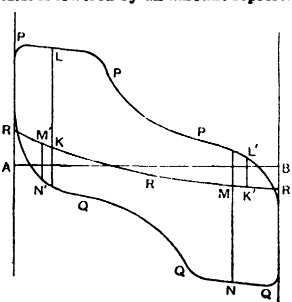

Fig. 6.

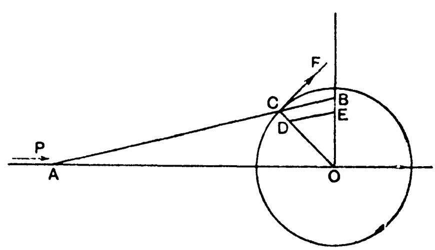

Fig. 7.

E.g. for the out-stroke, ordinates such as KL or K'L', and for the in-stroke, such as MN or M'N', represent the crosshead forces P.

Fig. 7 shows the crank-connecting rod mechanism diagrammatically. If AC (the connecting rod) is produced to meet the perpendicular from O at B, and if OD is measured along OC (the crank) to represent the crosshead force P, and DE drawn parallel to CB, then OE represents the crank effort F.

The ratio OB : OC or OE : OD also represents the ratio of the velocity of the piston to that of the crank pin. Thus the table of piston positions and velocity ratios k_1, may conveniently be used to find the crank effort in place of the graphical method of fig. 7.

That is: Find P as in fig. 7, find k_1 from the table, then the crank effort = force P $\times k_1$.

Starting Torque of Two-Crank Engines.

Engines which have to start against load, such as locomotive engines, winding engines, etc., have usually two cranks at right angles. They should be large enough to start from any crank position with full steam pressure in the cylinders. The starting torque has minimum values at four points in the revolution occurring just after one crank has passed the position of cut-off. At these points, when the steam stop-valve or throttle-valve is opened, only one of the cylinders receives steam and its crank may be in a very unfavourable position.

The four positions of minimum torque are shown in Fig. 8. In position (1) crank A has just passed the cut-off position on the out-stroke; in (2), B has just passed cut-off on the in-stroke; in (3), A, and in (4), B have just passed cut-off. The worst position is (1).

The ratio of the minimum starting torque to the torque produced by the steam load in one cylinder acting at full crank radius, or as it is often termed 'the equivalent crank ratio,' depends

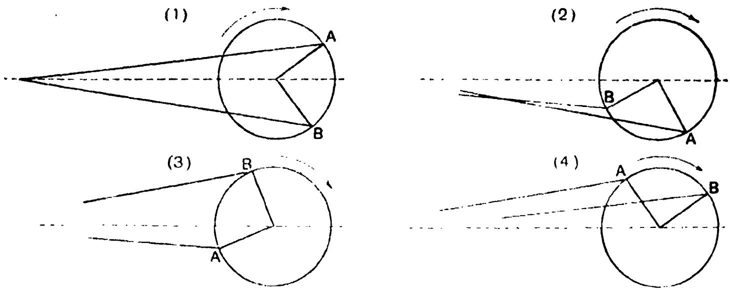

FIG. 8.

on the point of cut-off. For an engine in which the connecting-rod crank ratio is 5, its values are shown in the following table:

Cut-off per cent.	Position 1.	Position 2.	Position 3.	Position 4.
70	0·25	0·39	0·56	0·37
75	0·34	0·475	0·66	0·49
80	0·44	0·56	0·755	0·62
85	0·54	0·645	0·845	0·74
90	0·66	0·74	0·92	0·855
95	0·79	0·84	0·99	0·96

For estimating stresses in the shaft, etc., the maximum torque must also be known.

The combined torque due to two cranks at late cut-off reaches maximum values at four points in the revolution. Two of these points are when the cranks are both above the centre line and at 45°, and when both are below at 45°. The ratio of the torque to that due to one cylinder at full crank radius is then 1·414. Another maximum position is when crank A is at 135° from the inner and B at 45° from the outer dead centre, the ratio being then 1·214. The fourth position is with A at 135° from the outer and B at 45° from the inner dead centre, and this gives the largest ratio of all, namely 1·614.

If the cut-off is sufficiently early, the steam valve of one cylinder will close before the above positions are reached, and the steam pressure in that cylinder will have fallen due to partial expansion; the torque will thus be reduced somewhat as compared with late cut-off.

FLYWHEELS.

D = diameter, measured to centre of gravity of section of rim, in ft.

W_r = weight of rim, in lbs.

W_a = weight of arms and boss, in lbs.

W_e = 'Equivalent weight' at centre of rim section = approximately ($W_r + \frac{1}{3} W_a$)

N = R.P.M.

E = stored energy in ft. lbs.

$= 0\cdot0000425\ W_e D^2 N^2$

or $= 0\cdot00017 W_e R^2 N^2$, where R = radius to centre of rim.

For a specified limiting speed fluctuation, the equivalent weight of the flywheel depends on the irregularity of turning moment of the engine.

A = work done per revolution in ft. lbs. = area of turning moment diagram.

a = max. excess or deficit of area of turning moment curve over curve of resisting moment (which is usually taken as uniform).

k = coefficient of energy fluctuation $= \dfrac{a}{A}$.

NOTE.—Sometimes k is taken as excess energy ÷ work done per stroke instead of work per revolution, and some reference books therefore have values of k twice those given below.

K = flywheel coefficient = $\dfrac{\text{stored energy in flywheel}}{\text{work done per revolution}}$.

X = coefficient of speed fluctuation, or irregularity.

Then, if suffixes 1, 0, 2 refer to maximum, mean and minimum respectively,

$$X = \frac{N_1 - N_2}{N_0} = \frac{k}{2K} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$K = \frac{k}{2X} = \frac{a}{2AX} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Let Y = angular deviation from position of uniform turning,

„ C = number of complete turning moment cycles per revolution,

then $$Y_1 - Y_2 = 28 \cdot 65 \frac{X}{C} \text{ in geometrical degrees} \quad . \quad . \quad . \quad . \quad (3)$$

For engines driving electrical alternators,

let F = frequency of (electrical) cycles per sec.

p = number of poles in alternator field magnets,

then $$Y_1 - Y_2 = 14 \cdot 32 \frac{pX}{C} \text{ in electrical degrees} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

$$= 1719 \frac{FX}{NC} \text{ in electrical degrees} \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

The formulæ (3), (4), and (5) are based on sine curves for the turning moment, and are rarely strictly correct as regards the angular deviation $Y_1 - Y_2$, but formulæ (1) and (2) are always correct if the value of a is properly determined.

Considerable uncertainty arises as to the value of a in the case of multi-crank engines.

It is usual to specify that for alternators the angular displacement must not exceed 2½ electrical degrees. In that case, we obtain from equation (4) the relationship

$$\text{coefficient of irregularity } X = \frac{1}{5 \cdot 73} \frac{C}{p} \quad . \quad . \quad . \quad . \quad (6)$$

In the B.E.A.M.A. standardisation rules for electrical machinery, the rule is given

$$\text{cyclic speed irregularity} = \frac{k}{6p} \quad . \quad . \quad . \quad (7)$$

where

k = engine impulses per revolution ; p = number of poles.

This formula differs from (6) only in replacing 5·73 by 6, but, as already pointed out, these formulæ depend upon the form assumed for the turning moment curve, and variations are therefore not unlikely and do not indicate any error in principle.

Certain flywheel data are given in the three following tables. It will be understood that these are typical values, and that considerable variations occur in practice.

Typical Values of Energy Coefficients, k.

NOTE.—The values of *k* are based on the assumption of a uniform engine load, and do not apply accurately to engines driving pumps, blowers, or even electric alternators. (*Foster.*)

For engines driving alternators, the flywheel effect should be such that the displacement Y_1-Y_0 does not exceed 2·5 electrical degrees, nor should X as a rule exceed $\frac{1}{250}$. Where several units have to work in parallel the flywheel effect must also be such as to avoid resonance, i.e. the natural period of oscillation of the rotor about the position of uniform turning must not coincide with the period of any periodic impulses due to the engine. The determination of the oscillation period requires knowledge of the electrical characteristics of the alternators.

Alternator builders commonly state the flywheel quantity of their alternators in terms of GD^2, which is short for weight multiplied by the square of the diameter of gyration. If the units employed are kilogrammes and metres, the corresponding GD^2 in lbs. and feet can be obtained by multiplying by 23·7.

$$\text{Stored energy} = GD^2 \times \left(\frac{\pi N}{60}\right)^2 \times \frac{1}{2g} = \frac{GD^2 \times N^2}{23{,}500}.$$

If G, D are in lbs. and feet, the stored energy is in ft.-lbs.

The stored energy may be expressed in terms of any radius (or diameter) if the weight corresponding to that radius is stated. Thus, the flywheel effect is sometimes stated as T tons (or lbs.) at 1 ft. radius. The GD^2 is then T × 4 in tons (or lbs.) × feet². The actual diameter need not be known, which is a convenience of this method of expression.

The proportions of flywheels vary, but approximately for a typical engine flywheel the rim weight is about two-thirds of the total weight; the diameter of gyration is about 0·77 × diameter of rim; and the equivalent weight if assumed concentrated at the extreme diameter is about 0·60 × total weight. Thus, if the equivalent weight at the extreme diameter is calculated, the total weight is obtained by multiplying it by $\frac{1}{0·6}$, i.e. by 1·66.

Frequently the calculation is based upon the equivalent weight W_e reduced to the radius at the centre of gravity of the rim section. The actual rim weight is about $0 \cdot 9\ W_e$.

Example.—Tandem compound engine of 1,200 i.h.p. normal load at 94 r.p.m., driving an alternator of 50 cycles. The deviation must not exceed two electrical degrees on either side of the mean position.

From the tables we see that k is about 0·13, and $C = 2$.

In formula (5) we have

$$C = 2,\ Y_1 - Y_0 = 2,\ F = 50,\ N = 94$$

Hence $$X = 0{\cdot}00437 = \frac{1}{229}.$$

Inserting the value of X in formula (2) we obtain $K = 14{\cdot}9$.

The work done per revolution is

$$A = \frac{1{,}200 \times 33{,}000}{94} = 421{,}000 \text{ ft.-lbs.}$$

The stored energy in the flywheel is KA or 6,280,000 ft.-lbs.

If the flywheel is 18 ft. diam., the rim velocity is 88·6 ft. per sec., and the equivalent weight at this diameter is, therefore, 51,500 lbs. The actual flywheel weight should be about 66 per cent. in excess of this, say 86,000 lbs. This makes no allowance for the flywheel effect of the alternator rotor, which is usually considerable and need not be ignored.

The diameter measured to the centre of gravity of the rim section in the example may be about 16 ft., the rim being about 2 ft. in radial thickness.

$$W_e \text{ is then } 51{,}500 \times 18^2 \div 16^2 = 65{,}000 \text{ lbs.}$$

and the rim weight about $65{,}000 \times 0 \cdot 9 = 58{,}500$ lbs., which is a little more than two-thirds of the total weight.

SPEED OF FLYWHEELS.

The rim of a flywheel is subjected to stress on account of centrifugal force, and this stress is independent of the cross-section. For a particular material it depends only on the linear speed of the rim.

For cast-iron wheels the safe rim speed is customarily taken as 6,000 ft. per minute. For a given r.p.m. this fixes the wheel diameter.

Where higher speeds are desired with consequently lighter wheels for the same amount of stored energy, cast steel may be used, or the wheel may be made with discs of steel plate.

A steel plate wheel with wire-wound rim has been run at 15,000 ft. per minute.

GOVERNORS.

It is the function of the governor to adjust the quantity of steam to the load on the engine. The sensitiveness of the governor should depend on the nature of the load, but in all cases the governor should be as free from friction (which also applies to all the valve mechanism operated by the governor) as possible. Friction tends to coarse governing and hunting. On the other hand, a very sensitive governor, especially if of great power on an engine with insufficient flywheel, tends to produce hunting, which should be corrected by an oil dashpot on the governor mechanism. In governor design attention must be paid to the levers and connections so as to give a reasonably equal ratio of governor movement to speed variation at all loads.

The plain Watt fly-ball governor is rarely used, being deficient in power. When loaded with a central weight (Porter governor) it is satisfactory on typical factory engines, especially if carried on ball-bearings and knife edges throughout. The centre weight makes it somewhat sluggish in following changes of speed, and springs replace the weight in many modern governors. The springs need not be vertical.

If the governor is mounted on the crankshaft it may become bulky owing to its slow speed, but has some merits where eccentrics or valve rods have to be moved directly. Shaft governors, owing to their bulk, tend to be sluggish and to lag behind the engine when the speed changes. This inertia effect has been utilised in the inertia shaft governor, in which it is the falling behind of the governor weights due to inertia and not their outward movement under centrifugal force which operates the valve gear.

Relay Governors.

In relay governors the movement of the valve gear is effected by a motor, usually taking the form of a cylinder and piston operated by oil pressure. The movement of the piston is controlled by a small sensitive governor, usually of the centrifugal type. This governor has only to move the oil valve and can be relatively small, whilst the force exerted by the relay piston may be anything desired. The oil is supplied by a reciprocating or, more usually, a rotary pump. A simple

drum or toothed-gear pump is entirely satisfactory. Any pressure can be obtained, but 50 or 60 lbs. sq. in. is a convenient value. In calculating the pump capacity allow for the maximum reasonable movement of the relay piston, and for 25 to 50 per cent. slip at the pump according to the speed, size, and pressure of the pump. These governors are common on large turbines and growing in favour for large oil, gas, and steam engines. Unlike the ordinary centrifugal governor insufficient power shows itself chiefly by slow action and not very much by a large difference in the rising and falling speeds. In short, the relay governor is, under these conditions, slow but accurate.

Governors are best driven by gears, but chains may be used and even belts or ropes if the last two are in duplicate or triplicate to minimise trouble in case of one belt or rope breaking.

Governors are best arranged to knock off at over speed, but this function may be arranged for by a simple separate governor.

Governors are often termed 'expansion' or 'throttle' governors, but these expressions refer to the valve gear rather than the governor. Expansion control is the more economical in most cases, but more difficult to arrange for except in the case of engines having Corliss or drop valves and running at moderate speeds only.

SLIDE VALVE GEAR.

(*W. C. Popplewell, M.Sc., A.M.I.C.E.*)

The movements of an ordinary eccentric driven slide valve are shown by A, fig. 10, S and S_1 are ports leading from the steam chest to the back and front of the piston respectively; E is the port leading to exhaust. The valve itself is shown sliding on the port face. As shown by A, the valve is in mid-position; *ef* is the outside lap, and *gh* the inside lap. As the valve is moved upwards by the eccentric, it reaches a position B where *e* has come opposite *b*, and the steam port S_1 is opening to the steam chest; the amount by which the valve is open at the beginning of the piston stroke is the 'lead.' In position C the steam port is fully open; the valve then returns to D, thus shutting off the supply of steam to the cylinder. This point is 'cut off.' The movement continues until *h* reaches *c*, as at E, when communication is effected between S_1 and E. This point is called 'exhaust.' After opening S_1 fully to exhaust, the valve returns to F, where the exhaust is closed and the point 'compression' reached. This completes the cycle for one end of the valve.

The movements of slide and other eccentric driven valves are analysed by such diagrams as the 'Valve Ellipse' (II, fig. 9), 'Zeuner's Valve Diagram' (fig. 12), and several others designed for the same use. Of these the Valve Ellipse can be made to take account of obliquity of both connecting rod and valve rod, and so yield accurate results. Zeuner's Diagram makes no allowance for obliquity, and in consequence is only approximately accurate, but for purposes of design, where existing data are not available, the Zeuner is the more useful, as it enables the principal dimensions to be approximately fixed. In such a case final adjustments may be completed by using the Valve Ellipse.

Valve Ellipse.

To set this out, begin by drawing the crank circle as at I, fig. 9, and dividing it into a number of equal angles (in this case 8), the crank-pin points being 0, 1, 2, 3, 4, 5, 6, 7. Take the connecting-rod length 1. 1_1, and set it off successively from the crank-pin positions, marking off points on the stroke line 0_1, 1_1, 2_1, 3_1, 4_1. These are positions of the piston corresponding to 0, 1, 2, 3, 4, of the crank-pin, and are seen at II. A similar construction is followed out for the eccentric circle at III (fig. 11). This is turned through a right angle as compared with I, and the 'angle of advance' is marked $\theta°$. The distances of the valve from its mid-position, corresponding to the successive positions of the piston, are shown below the eccentric circle. These are set up as ordinates from the horizontal points on II, and a smooth curve drawn through the points so found. Thus from 1_1 on the line of piston travel at II is plotted an ordinate which represents the distance of the valve from its central position when the piston is at 1_1; this is the distance from ZZ to the line marked 1 at III. Next draw a horizontal line at distance l above 0_1, 4_1, in II, this is the 'lap' line; also a second line at a distance p beyond the lap line, which is the 'port opening.' Similarly below 0_1, 4_1, are two further lines at l_1, 'inside lap,' and p_1, 'exhaust opening.' The points where the ellipse cuts these lines represent the chief incidents in the cycle. They are B (admission), where the valve is just opening to steam; C (full port); D (cut-off); E (release); F (compression).

In the case of the back plate of a gear of the Meyer type, separate ellipses must be drawn for the edge of the plate, and the points where these cut the main ellipse noted.

ZEUNER DIAGRAM.

A few of the principal cases are given in what follows. The results are not strictly accurate, because they are vitiated by the angularity of the eccentric rod. But with reasonable proportions a design will be sufficiently near what the diagram shows. Fuller information may be found in Zeuner's treatise, or in the small book of Cowling Welch, who reduced Zeuner's methods to practice.

SLIDE VALVE GEAR.

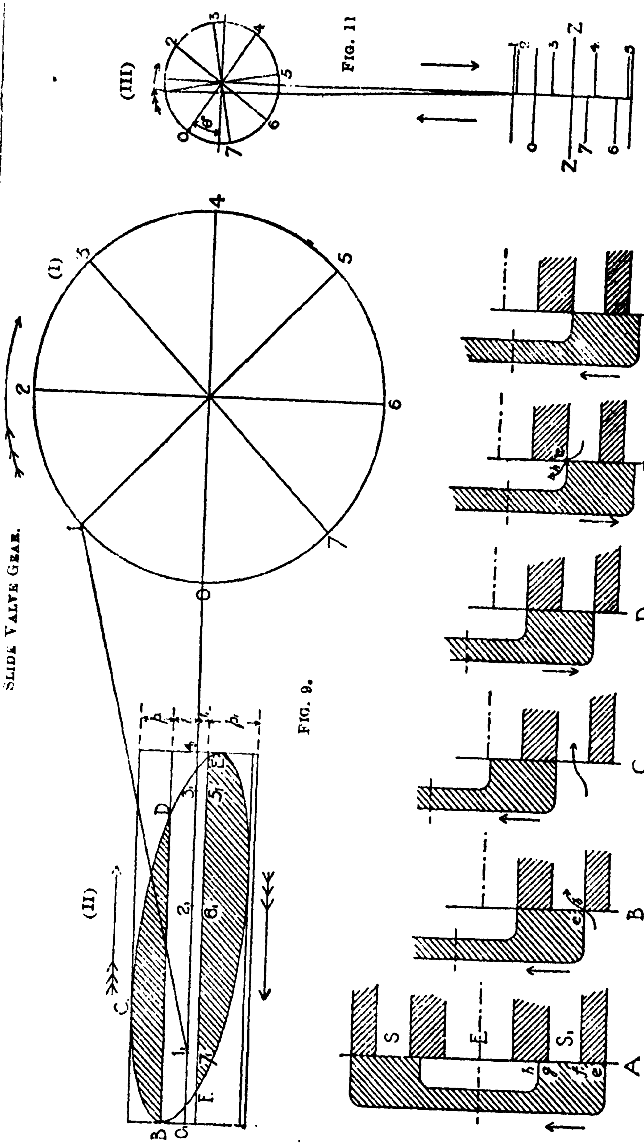

FIG. 9.

FIG. 10.

FIG. 11

Reversing gears which do not employ two eccentrics usually derive motion from some point on the connecting rod. Such are the Joy gear and others, for all of which special advantages are claimed under certain conditions, though as valve movements it is doubtful if any give better results than plain link gears. The newer motions often involve considerable sliding movement of a block in an inclined link, this link being pivoted so as to reverse its inclination, whereby the valve, driven by the block which slides up and down in the inclined link, has its movement reversed or varied according to the degree of inclination either way of the link. Such valve movements are best studied by the aid of models, with variable dimensions made from flat bars of cedar or baywood.

Simple Slide Valve.

Fig. 12 shows Zeuner's diagram of slide valve motions, simple case.

Draw NM and PR at right angles; NM = piston stroke.

OP = OR = valve travel each side of centre point; OA = crank when steam is admitted; OB = crank at cut-off.

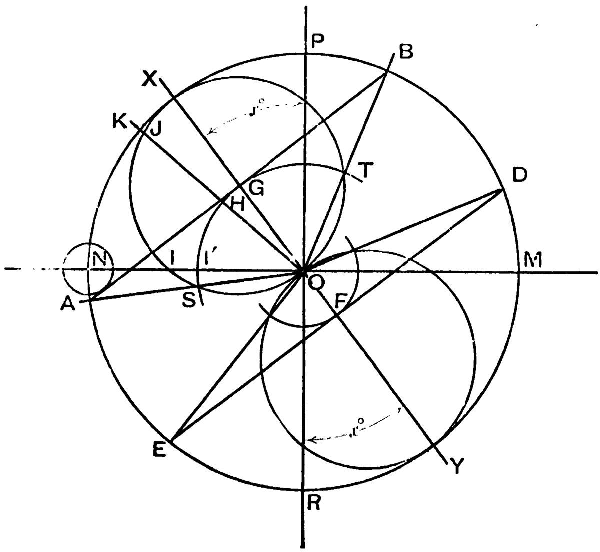

Fig. 12.

Bisect AB. Join OX, OY perpendicular to AB.

$x° + 90°$ = angular advance of eccentric; SGT = outside lap circle; cuts 'valve' circle at ST; OS = position of valve from centre when admitting steam; OT = position of valve from centre when cutting off steam; OF = inside lap; OD = crank when exhaust commences; OE = crank when exhaust closes.

The intercept of any radius from O, cut off by valve circles, shows distance of valve from its midstroke for that crank angle. Thus when crank is at OK valve has moved a distance OJ from its centre and steam port is open a width HJ.

DY = YE. AX = BX. Lead = small circle N = 2I.I.

Double Back-Plate Cut-off.

Figs. 13 and 14 show Zenner's expansion valve diagram with Meyer valve.

Draw AB, XY at right angles, OD at angular advance $\phi°$ = half travel of main valve; OR = crank at admission: ON = lap circle. Draw OP slightly in advance of latest opening of main valve as shown by point *t*. This gives a miminum cover *ts*. Join PD, and draw OE parallel to it and DE parallel to OP. Then OE = half travel and position of the cut-off eccentric which will cut off steam when the crank, OR, reaches the position OP. It need not cut off later than this, for then the main valve has already acted.

The radius Oa or any other vector of the cut-off valve circle shows the movement of the cut-off valve from its middle position, OE being the half throw of the cut-off eccentric, and $\theta°$ its angular advance. Any radius vector of the auxiliary circle OP will show the relative displacements of the main and cut-off valves from each other. At the crank position OP the cut-off plates are drawn close together. Draw the large circle APDM through P. Then for any position OV of

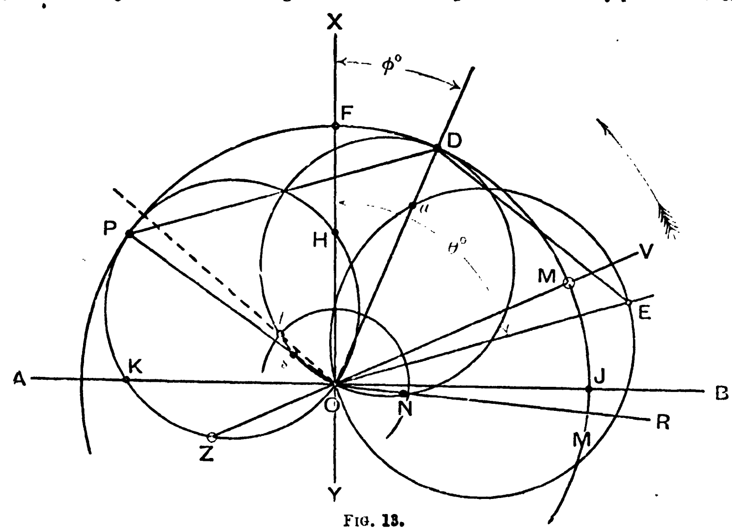

FIG. 13.

desired cut-off the length of the cut-off valve must be increased by separating the two cut-off plates of the right and left screw to the amount MZ. To cut off at OX of the crank would demand the movement FH, while to cut off at the dead point OB the movement of the plates would be JK. The length over the steam ports in the back of the main valve will be equal to the sum of the length of the cut-off plates plus twice OP. The edges of the cut-off plates when fully extended have a maximum distance from the main valve centre of JK (or MZ if OM is the earliest desired

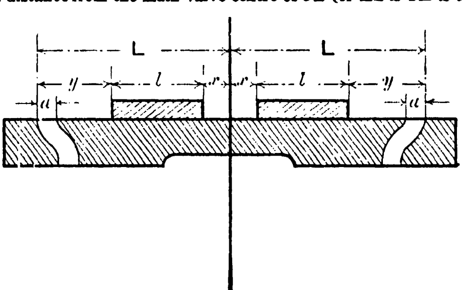

FIG. 14.

cut-off). But at no moment must the inside edges of the cut-off plates uncover the inside edges of the ports in the main valve. These ports have a width a. At the latest cut-off, viz at OP, the cut-off plates will be drawn together so that x = nil.

To find movement of cut-off plates from centre for any point of cut-off, as with crank at OV, the plates must be screwed out a distance x = MZ. If cut-off is at OF position of crank, then x = FH.

Taking the position of earliest cut-off at OV, to find the proportions L and l of valves which will be a maximum :—

Calling FE $= y = L - l - x$ for earliest cut-off, the maximum relative movement of the valve centres by the eccentrics is OP. Since at the position OV the valve centres are the opposite way removed from cut-off by the amount OZ and that OP is the maximum relative movement, we have $L - l = OP$ when $x =$nil and x must be $OP + OZ = MZ$ for earliest cut-off. When the crank reaches OP the cut-off valve is moved out already a distance $x = MZ$ and it is moved a further distance OP by the eccentric, so that the outer edge of the cut-off plate is a distance OP+OP+OZ from the middle of the main valve. And when so far the inner edge of the cut-off plate must not overrun the inner edge of the back port a. Therefore $L - a = 2OP + OZ$ ∴ $L = OP + OP + OZ + a$ and $L - l = OP$ ∴ $l = OP + OZ + a$. Since the main valve has cut-off at the position Ot there is safety lap of ts on the main port below, even if the inner edge of the cut-off plate then reaches the port a.

In the figure the main valve travels $4\frac{1}{2}$ ins. and the cut-off valve $5\frac{1}{2}$ ins. The cut-off plates are each moved out by screws at earliest cut-off $x = 3\frac{1}{4}$ ins., and by eccentric movement $2\frac{1}{4}$ ins. relative to main valve, or a total of $5\frac{1}{2}$ ins. The main valve has a length $L = 5\frac{3}{4} + a$ and the cut-off plate (or $L - OP = l$) a length of $3\frac{1}{2}$ ins. $+ a$.

If $a = 1$ in. then $L = 6\frac{3}{4}$ ins.; $l = 4\frac{1}{2}$; $x = 2\frac{1}{4}$ ins. maximum plus $3\frac{1}{4}$ screw-out.

If early cut-off is desired in the general working of the engine with quick action the auxiliary circle OP should be near to 90° from the cut-off position of the crank. Thus at the position OD the two valves are moving at high relative speed. It is usual to give the greater travel to the cut-off valve.

LOCOMOTIVE LINK MOTIONS.

These may be investigated also by the Zeuner method. A link motion is simply built up with two eccentrics, either of which may be made to bear fully and directly on the valve spindle and cause an engine to run forwards or backwards. This is accomplished by connecting the two eccentric rods by a link in which the end of the valve spindle is carried. At the extreme end position the spindle is wholly driven by one eccentric, while at intermediate positions the two eccentrics combine to give a gradually shorter movement to the valve.

There are three general link gears. 'Stephenson's,' in which the link is raised or lowered to give the desired position of the spindle block or link block; and the link is concave to the axle and has a radius equal to the length of the eccentric rods.

'Gooch's,' with link convex to the axle and not movable up and down; movement of the block being effected by a radius rod and the link having this radius of curvature.

'Allen's,' in which the link is straight and both link and radius rod are raised and lowered in opposite directions.

All three forms are made with open or crossed rods, the former giving greater lead of the valve near the middle position of the link block, and the latter giving less lead towards the middle position. In Gooch's motion the lead is of course always constant.

STEPHENSON LINK MOTION.

Open Rod Design.

In fig. 15, AE=link. BD=link block in forward and backward gear. OJ=virtual single centrics to give requisite travel to B or D in full gear. Join OB, cutting valve circle on OJ at K.

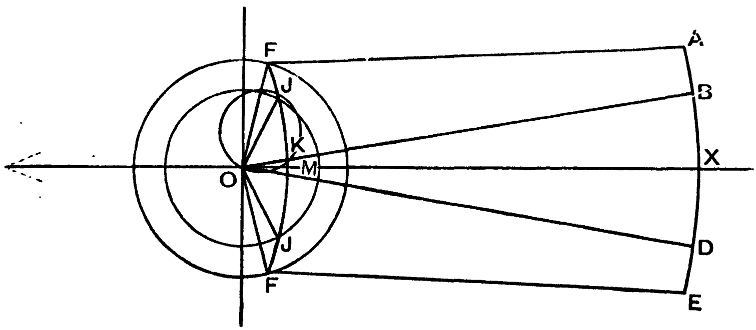

FIG. 15.

Join JM through K. Then the arc struck from c through JMJ will contain the ends of all the eccentric radii or valve circle diameters for all positions of the slider B or D. Dividing this arc

in the same ratio as B divides the link AE will give the ends of the valve circles for each point of the link. And the real eccentrics will have the position and half travel OF, OF just as the ends of the link lie beyond B and D. If the link end-pin comes opposite the extreme positions BD of the block then OJ become the real eccentrics in position and in half throw, i.e. XB : XA : : MJ : MF. Rods are said to be *open* when they are as FA, FE when the eccentric arms point towards the link. With open rods the valve lead increases with the expansion.

Crossed Rod Design.

In fig. 16, AE=link. BD=link block in full forward or backward gear. OJ=virtual single eccentric that would give requisite valve travel in full gear. Join OD, cutting upper valve circle on OJ at L. Join JN through L. N is on the line OX. Then the arc struck from O through JNJ contains the ends of all the valve circles for every position of the slide block, the arc JNJ being divided for each diameter in the same ratio as the slide block divides the link AE. Thus OG, OG become the actual eccentric arms, and NJ : NG : : XB : XA. Rods are said to be *crossed* when they are as GA, GE, the eccentric arms pointing towards the link. With

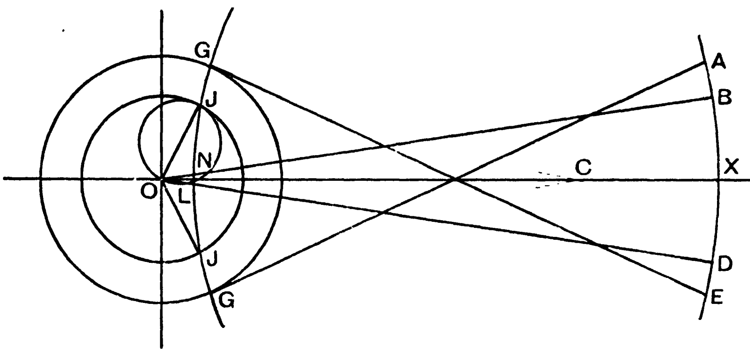

FIG. 16.

crossed rods the lead of the valve decreases with increased expansion. Specially note that OD cutting the valve circle at L is employed in this construction, whereas OB is the line used in the open-rod diagram.

GOOCH'S LINK MOTION.

In this motion, fig. 17, the 'curve' of valve circle centres is a straight line *aa* distant from O an amount $f = \frac{r}{2}\left(\sin \delta^\circ + \frac{c}{l} \cos \delta^\circ\right)$ for the open rod design and $\frac{r}{2}\left(\sin \delta^\circ - \frac{c}{l} \cos \delta^\circ\right)$ for the crossed rod design, where

r = eccentricity of eccentric or OE ;

m is the point from which the link is hung and is a fixed point ;

the versed sine of the link arc is $\frac{c^2}{2l_1}$;

m is distant from O a length $S = -\frac{c^2}{2l_1}$;

n is the point from which the radius rod is hung.

$On = l + l_1 - l_0 - \frac{c^2(l + l_1)}{2l\,l_1}$.

The point n should move in a parabola whose parameter $= 2l_1$ or a circular arc of radius l_1.

The co-ordinates of any point on the curve of centres are as per fig. 18, where

for open rods, $OB = \frac{r}{2}\left(\sin\delta^\circ + \frac{c}{l}\cos\delta^\circ\right)$;

for crossed rods, $OB = \frac{r}{2}\left(\sin\delta^\circ - \frac{c}{l}\cos\delta^\circ\right)$.

$BC = \frac{ru}{2c}\left(\cos\delta^\circ \pm \frac{c}{l}\cos\delta^\circ\right)$, according as the rods are open for − or crossed for + signs, where c = half length of the link and u = the variable position distance of the slider block from the middle of the link.

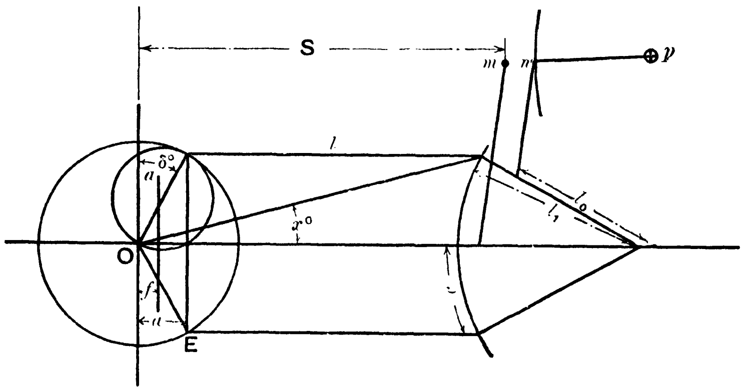

FIG. 17.

The lead is constant at all grades of expansion. The link is so hung that its middle point moves to and fro horizontally by the combined effect of the arc of swing and the cant due to slope of the link, the suspension link being pinned at the centre of the chord of the link.

The radius rod l_0 is so hung that its to-and-fro motion produces a minimum of sliding of the link block in the link. The extreme positions of n being known the actual arc in which it moves

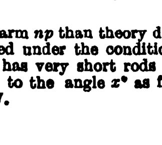

FIG. 18.

is arranged in practice with a shorter arm np than theory demands, the best compromise possible being accepted which can be arranged under the conditions. The Gooch gear, for any given distance between axle and cylinder, has very short rods compared with the Stephenson gear. Also the angle δ° in fig. 18 is equal to the angle x° as found in fig. 12, p. 96, for the simple slide valve, plus the angle δ° in fig. 17.

ALLEN'S STRAIGHT LINK MOTION.

$$\frac{b}{a} = \frac{l_0}{l}\left(1 + \sqrt{1 + \frac{l}{l_1}}\right);\quad n = 1 + \left(\frac{l_1}{l_0}\ \frac{b}{a}\right).$$

Curve of centres is a parabola whose vertex is distant from $O = \frac{r}{2}\left(\sin\delta + \frac{c}{l}\cos\delta\right)$ for open

rods, and $\frac{r}{2}\left(\sin\ \delta - \frac{c}{l}\cos\ \delta\right)$ for crossed rods, and is concave towards O for open rods, and convex for crossed rods. Parameter for both open and cross rods $= \frac{nlr}{2c\cos\delta}\cos\delta \mp \left(\frac{c(n-1)}{nl}\sin\delta\right)^2$ for which a circular arc may be substituted of one half the parameter.

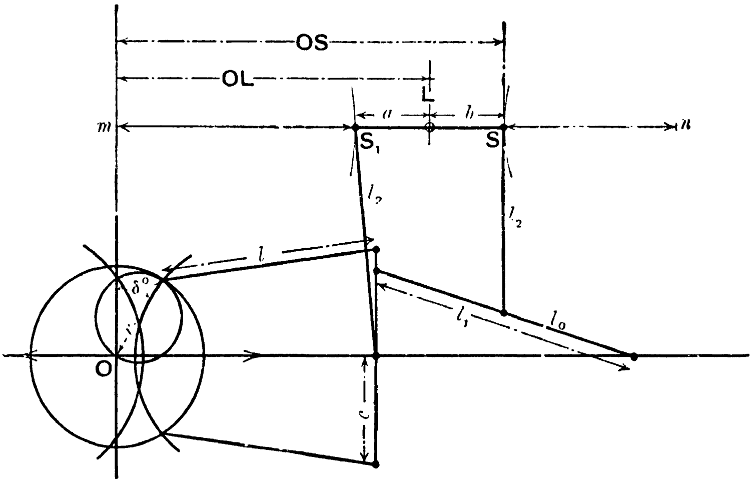

FIG. 19.

S and S_1 should move in parabolas of $2l_1$ and $2l$, or in arcs of l_1 and l radius.

As arranged in practice $a + b = (l_1 - l_0) +$ a little extra l_2; as long as possible.

$$Os_1 = \left(l - \frac{c^2}{2l}\right);\ OL = l + a - \frac{c^2}{2};\ ms_1 = l;\ ns = l_1;\ Os = l + l_1 - l_0 - \frac{c^2(l + l_1)}{2ll_1}.$$

Lead increases with expansion with open rods and decreases with crossed rods.

In this section the following symbols have been used in the indicated significance, except where otherwise stated :—

c = absolute velocity in ft. per sec.
g = constant of gravitation = 32·2 ft. per sec.^{2}
H.h. = heat drop in B.Th.U.
N = speed in r.p.m.
P = pressure in lbs. per sq. ft.
p = pressure in lbs. per sq. in.
t = temperature °F.
T = absolute temperature °F = $(460+t)$.
U = peripheral velocity in ft. per sec.
v = specific volume in cubic ft. per lb.
W = weight of steam in lbs. per sec.
w = relative velocity in ft. per sec.
λ = ratio of the specific heats of a gas.
ω = angular velocity in radians per sec.
J = Joule's Equivalent = 778 ft. lbs. per B.Th.U.

FLOW OF STEAM.

When steam flows through a simple orifice from a chamber (denoted by suffix 1) into a space (denoted by suffix 2) the velocity with which discharge takes place is always dependent on the steam conditions existing before the orifice, and sometimes dependent upon those existing on the discharge side.

If the pressure, P_1, in the chamber is maintained constant, while that beyond the orifice is gradually reduced from an initial value equal to P_1, the velocity and quantity of discharge gradually increase and depend on the pressure drop over the orifice, until a critical value is reached corresponding to a definite value of the ratio $\frac{P_2}{P_1}$.

* See also Marine Steam Turbines, Section XXIX.

Dr. Zeuner * has shown theoretically, and the result is borne out by experiment, that the critical drop is reached when

$$\frac{P_2}{P_1} = \left(\frac{2}{\lambda + 1}\right)^{\frac{\lambda}{\lambda - 1}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

For saturated steam $\lambda = 1{\cdot}135$, and $\frac{P_2}{P_1} = 0{\cdot}577$.

For superheated steam $\lambda = 1{\cdot}3$, and $\frac{P_2}{P_1} = 0{\cdot}546$.

After this *Critical Pressure Drop* has been reached, the quantity and velocity of discharge remain constant for smaller values of P_2, the discharge being accompanied by strong acoustic vibrations.

Dr. de Laval was able to obtain—and used in his turbine—much higher velocities than the critical velocity, by adding a conically divergent nozzle to the orifice. In this way the vibrations are eliminated, and although the velocity of exit from the nozzle may be considerably greater than the critical velocity, the velocity at the minimum section or throat of the nozzle and the weight of steam discharged remain unchanged from the values which would exist in a simple orifice.

From this it will be apparent that there is a discontinuity in the phenomena accompanying discharge of steam through an orifice or nozzle, and that the equations existing between the various terms entering into the formulæ of steam flow must be considered in two groups.

(*a*) *When the Pressure Drop is less than the Critical Drop.*

i.e., when $P_2 > 0{\cdot}577\ P_1$, for saturated steam ; $P_2 > 0{\cdot}546\ P_1$, for superheated steam.

The theoretical velocity c_1 with which discharge takes place, can be calculated from the formula due to Wantzel and St. Venant,

$$c_1 = \sqrt{2g\frac{\lambda}{\lambda - 1}(P_1 v_1 - P_2 v_2)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The actual velocity of discharge c_2 is less than c_1, on account of the friction and eddy losses in the orifice, and is given by

$$c_2 = \phi\, c_1,$$

$$\text{where } \phi = \text{velocity coefficient} = \frac{\text{Actual velocity of discharge}}{\text{Theoretical velocity of discharge}}.$$

The value of ϕ for various cases is given in Table I., page 108.

The weight of steam discharged per second is given by the relation

$$W = k\,S\frac{c_2}{v_2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where,

v_2 = specific volume of the steam in the lower state, in cubic ft. per lb.
S = the sectional area in sq. ft. of the smallest section or throat of the orifice.
k = coefficient of discharge (see Table I.).

The expansion takes place with very great rapidity and for purposes of calculation it may be assumed to be adiabatic without serious error. The validity of this assumption has been questioned, but Dr. A. Loschge† has proved its approximate correctness by obtaining equal discharge through duplicate nozzles made of metal and of porcelain, and it need only be added that formulæ deduced from this basis agree very closely with experimental results.

For adiabatic expansion—

$$P_1 V_1^{\lambda} = P_2 V_2^{\lambda} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

from which, by combination with (2) and (3), we get

$$W = k\,S\sqrt{2g\frac{\lambda}{\lambda - 1}\frac{P_1}{v_1}\left[\left(\frac{P_2}{P_1}\right)^{\frac{2}{\lambda}} - \left(\frac{P_2}{P_1}\right)^{\frac{\lambda+1}{\lambda}}\right]} \quad . \quad . \quad . \quad . \quad (5)$$

* *Technical Thermodynamics*, Dr. Zeuner.
† *Engineering*, October 17, 1913.

Alternative Method.

The following method of dealing with such problems, due to Dr. Zeuner, is often more simply manipulated than that already given, especially when used in conjunction with the Mollier or other entropy diagram.

If

H_1 = total heat of 1 lb. of the steam in the higher condition in B.Th.U.;

H_2 = total heat of 1 lb. of steam in the lower condition in B.Th.U.;

h_a = the heat drop available for adiabatic expansion = $H_1 - H_2$.

Then

$$e_1 = \sqrt{2g \cdot J \cdot h_a} \quad . \quad . \quad . \quad (6), \quad \text{and } e_2 = \phi \cdot e_1.$$

W can be calculated as before from (3); h_a can either be measured directly off a Mollier diagram or calculated from steam tables in the following manner :—

If $t°$ = degrees of superheat; L_1 = latent heat corresponding to P_1; T_1 = absolute temperature corresponding to P_1; h_1 = sensible heat corresponding to P_1; X_1 = dryness fraction of the steam in the higher state; T_2 = absolute temperature corresponding to P_2; h_2 = sensible heat corresponding to P_2; X_2 = dryness fraction of the steam in lower state; ϕ_1 = entropy of the liquid in the higher state; ϕ_2 = entropy of the liquid in the lower state;

then

$$X_2 = \frac{T_2}{L_2}\left[\frac{X_1 L_1}{T_1} + C_p \log_e \left(\frac{T_1 + t}{T_1}\right) + \phi_1 - \phi_2\right],$$

and

$$h_a = X_1 L_1 + C_p \cdot t \cdot + h_1 - X_2 L_2 - h_2.$$

In these formulæ the mean value of the specific heat of superheated steam at constant pressure C_p for the range of the superheat should be taken.

Nozzles which are designed for a smaller pressure drop than the critical are wholly convergent and must be sized according to the methods given in this section.

Simple orifices, the nozzles of Rateau or Zoelly turbines, and both the rotating and stationary blades of Parsons turbines, fall into this class.

(b) *When the Pressure Drop is Greater than the Critical Drop.*

i.e., when $P_2 < 0{\cdot}577P_1$, for saturated steam; $P_2 < 0{\cdot}546P_1$, for superheated steam.

In this case let the suffix m denote the conditions in the minimum section or 'throat' of the nozzle.

Then whatever the total pressure difference over the nozzle, that from P_1 to the throat pressure is always equal to the critical value, and the nozzle must be convergent to the throat.

By combining (1) with (2) and (4), the velocity in the throat is obtained.

$$e_t = \sqrt{g\lambda P_2 v_2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7a$$

alternatively,

$$= \sqrt{2g \frac{\lambda}{\lambda + 1} P_1 v_1} \quad . \quad . \quad . \quad . \quad . \quad (7b)$$

if $\phi = 1{\cdot}0$.

(7) is identical with the expression for the velocity of sound in the conditions present in the throat, so that the velocity in the throat, or the critical velocity, is equal to sound velocity.

By substituting from (1) and (4) in (5)—

$$W = k S_m \sqrt{2g \frac{\lambda}{\lambda + 1}\left(\frac{P_1}{v_1}\right)\left(\frac{2}{\lambda + 1}\right)^{\frac{2}{\lambda - 1}}} \quad . \quad . \quad . \quad . \quad . \quad (8)$$

from which the discharge per second can be obtained, S_m being the area at the throat in square feet.

The nozzle from the throat to the mouth must be divergent, the area at the mouth being calculated from the relation

$$= S_m \cdot \frac{V_2}{V_m} \frac{c_m}{c_2} = S \left[\left(\frac{2}{\lambda+1}\right)^{\frac{1}{\lambda+1}} \left(\frac{P_1}{P_2}\right)^{\frac{1}{\lambda}} \sqrt{\frac{\frac{\lambda-1}{\lambda+1}}{1-\left(\frac{P_2}{P_1}\right)^{\frac{\lambda-1}{\lambda}}}} \right] \quad . \quad . \quad (9)$$

Expressions involving λ are strictly applicable only when the expansion takes place wholly in either the superheated or the saturated region, the corresponding value of λ being introduced.

The following expressions will be found to give approximately the same results as (9).

For Superheated Steam.

If $\quad P_1 = (1{\cdot}732 \text{ to } 20)\, P_2 \qquad S_2 = S_m\left(0{\cdot}7175 + 0{\cdot}163\, \frac{P_1}{P_2}\right)$

$\quad P_1 = (20 \text{ to } 100)\, P_2 \qquad S_2 = S_m\left(1{\cdot}5 + 0{\cdot}125\, \frac{P_1}{P_2}\right)$

For Saturated Steam.

If $\quad P_1 = (1{\cdot}832 \text{ to } 25)\, P_2 \qquad S_2 = S_m\left(0{\cdot}777 + 0{\cdot}1216\, \frac{P_1}{P_2}\right)$

$\quad P_1 = (25 \text{ to } 100)\, P_2 \qquad S_2 = S_m\left(1{\cdot}875 + 0{\cdot}0812\, \frac{P_1}{P_2}\right)$

Introducing the numerical value of λ (1·135 for saturated steam and 1·3 for superheated steam), and with $g = 32{\cdot}2$, formula (7) becomes—

For Saturated Steam.	*For Superheated Steam.*
$c_m = 70{\cdot}2\, \phi\, \sqrt{p_1 v_1}$	$c_m = 72{\cdot}38\, \phi\, \sqrt{p_1 v_1}$

In the same way formula (8) would produce two expressions for the discharge depending on the condition of the steam as regards superheat. Researches by Loschge* and Bendemann have however shown that the numerical coefficient of the formula for nozzles having a convergent entrance is the same both for saturated and superheated steam, and that this value is 2 per cent. higher than is obtained by inserting $\lambda = 1{\cdot}135$.

This is in accordance with the previously known fact that for saturated steam the discharge from such a nozzle exceeds the theoretical amount.

Just prior to the publication of these researches Mr. H. M. Martin* propounded the ingenious theory that with steam initially saturated an unstable condition exists in the throat, cooling taking place below the saturation temperature without condensation. The decrease in specific volume which results from this 'Under-Cooling' would account for the measured excess in discharge over that calculated on the assumption of adiabatic expansion.

Prof. Stodola has suggested that this under-cooled steam obeys the same law of expansion as superheated steam, so that the experimental fact that the discharge both for saturated and superheated steam is given by one formula is rational and in line with theory.

The formula for discharge deduced from Loschege's experiments is :—

$$W = 44{\cdot}11\, k\, S_m \sqrt{\frac{p_1}{v}}.$$

Fig. 1 shows the theoretical discharge of steam per second per square inch of throat area with critical pressure drop, and is calculated from Callendars' approximate formula :

$$W = 0{\cdot}3153 \sqrt{\frac{p^1}{v_1}}$$

* *Engineering*, October 17, 1913.

The following simple formulæ, the first due to Napier and the second to Rankine, are often useful when an error of a few per cent. is admissible.

For Dry Saturated Steam.

$$P_1 > \frac{5}{3}P_2,\ W = \frac{s \cdot p_1}{70}; \qquad P_1 < \frac{5}{3}P_2\ \ W = 0{\cdot}029\ s\ \sqrt{p_2(p_1 - p_2)}$$

where s = area of orifice in square inches;

Design of Nozzles.

The values of ϕ and k as determined by experiment are given in Table I. for orifices and nozzles of various kinds.

FLOW OF STEAM THROUGH NOZZLES.

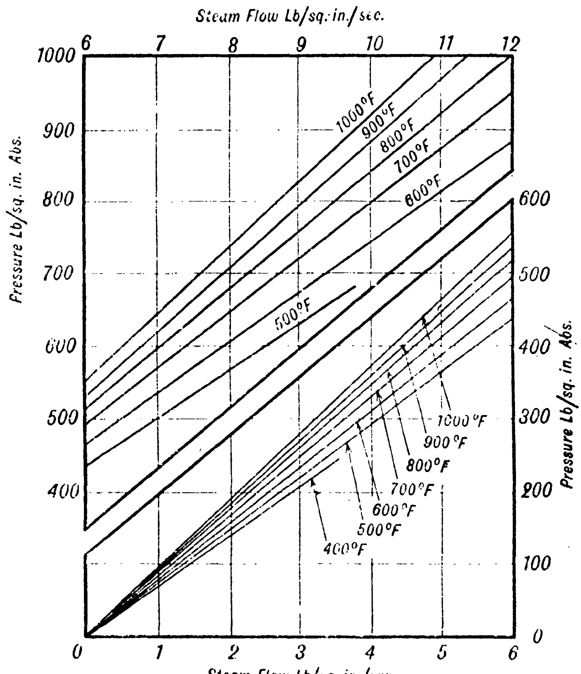

FIG. 1.

The coefficient of discharge k depends amongst other things upon the friction loss, the coefficient of contraction, and usually for a pressure drop below the critical, upon the ratio $\frac{P_2}{P_1}$.

Professor Rateau found that for nozzle C the value of k was slightly greater than unity when P_2 is less than $0{\cdot}5P_1$.

		$k = 1{\cdot}0$	Loschge	Z. Ver. Deutsch. Ing. January 1913.

In reference to nozzles G and H, which are of the types used in impulse turbines, it should be mentioned that although the value $k = 1 \cdot 0$ has been inserted in Table I., Dr. Ohristlein found that the actual discharge exceeds the theoretical by a few per cent. This effect had already been observed by Dr. Rosenhain for nozzles of form F having well-rounded entrances, and he concluded from his experiments that a loss in efficiency results, and was, therefore, led to recommend that the entrance should be only slightly rounded.

These facts are confirmed by Dr. A. Loschge's researches and explained by Mr. H. M. Martin's theory, which is referred to in the preceding paragraph.

The value of ϕ for nozzle G cannot be very satisfactorily determined from Dr. Ohristlein's experiments; for a given value of c_1, ϕ appears to increase with the pressure and to decrease with the superheat before the nozzle.

Unfortunately, the results of Dr. Rosenhain's experiments, like those of Messrs. Siberly and Kemble, are vitiated by the fact that the wetness of the steam during the experiments was not measured.

Nozzles of type B are useful for approximate measurements of the amount of steam flowing through a pipe line. It is only necessary to put a thick plate having a cylindrical hole in it between two of the pipe flanges. If the pressure is observed before the plate (P_1) and also in the cylindrical hole (P_2) by means of a hole drilled from the rim through the centre thickness of the plate, the flow can be calculated from formula (5).

Of course, the hole in the plate should be of such a diameter that the ratio $\frac{P_2}{P_1}$ is not less than $0 \cdot 6$.

Several steam meters operate on this principle.

The nozzles of turbines are usually of rectangular cross-section, and the steam in passing through them turns through an angle of about 70°, as indicated in figs. G and H, p. 109. It is important to bear this in mind when employing data relating to ϕ and k deduced from straight nozzles of circular cross-section—the type usually favoured by experimentalists.

For a given ratio of expansion the length of the nozzle depends on the angle of divergence. If this angle is too great the steam does not completely fill the cone, which results in considerable loss. If the angle is too small the length of the nozzles becomes very great, and many experiments indiczte that the friction loss depends on the length. An angle of divergence of 10° is very common.

The experiments of Dr. Rosenhain, and more recently of Messrs. Siberly and Kemble, show that there is no appreciable difference in efficiency for angles varying from 9° to 20°.

If the ratio $\frac{S_2}{S_m}$ is less than that theoretically required, expansion is completed beyond the nozzle. Rateau's experiments demonstrate that when this *under-expansion* is small, little loss results. On the other hand, if $\frac{S_2}{S_m}$ is greater than that theoretically required, the steam is expanded in the nozzle below the condition into which it discharges. Such *over-expansion* results in steam shock with great loss of efficiency.

When the divergent nozzles of a turbine are correctly designed for the normal load, over-expansion takes place at overloads, and under-expansion at partial loads, with nozzle cut-out governing.

The entrance of divergent nozzles should be smoothly rounded off, with a radius about equal to the throat diameter; larger radii are unnecessary and should be avoided.

Since the efficiency of a nozzle depends upon the smoothness of the surfaces with which the steam is in contact, the material of which it is constructed should be capable of withstanding erosion and oxidisation—nickel steel or a bronze highly polished is usually employed for the divergent nozzles of De Laval and Curtis turbines where high steam velocities are encountered, while cast in mild steel plates have given quite satisfactory results with the large nozzle areas and moderate velocities used in the convergent nozzles of Rateau and Zoelly turbines.

The state of knowledge on the efficiency of steam nozzles has been recently advanced by the researches carried out for the Nozzle Research Committee of the Institution of Mechanical Engineers by Dr. Stoney and Dr. Telford Petrie.

The apparatus used is of the impact plate type, largely designed by Mr. H. M. Martin. The first two reports dealt with tests taken on 1-in. wide reaction blading having a nominal outlet angle of 20°, and on impulse nozzles having an outlet angle of 20° with guide blades $0 \cdot 04$ in. thick.

FIG. 3.

The mean velocity coefficient (ϕ) values for the impulse nozzles obtained on those tests are shown on fig. 2, p. 111, for nozzles with throats of various proportions The corresponding curves for the reaction blading are shown by the dotted curve.

The notable feature of these tests is that they were carried out as large-scale experiments on commercial blades and nozzles.

The character of the curves, particularly for the impulse nozzles showing a rising value at low velocity, is particularly notable, as the region was not previously explored in published researches.

The third report of the Nozzle Research Committee of the Institution of Mechanical Engineers contains the results obtained with thick plate impulse nozzles summarised in diagram, fig. 3.

It will be observed that although the efficiency of the thick plate nozzles is materially lower than that of thin plate nozzles, the efficiency of the former can be improved to that of the latter by suitably chamfering the outlet.

In this report the experimental results on the efflux angle of the discharged steam suggest that its value is equal to $\sin^{-1}\frac{o}{p}$, and not to the geometrical angle (see fig. 4, and table II).

Experiments were also carried out on straight nozzles well radiused at the inlet and having ong parallel throats equal to about three diameters in length.

The efficiency of this nozzle was very high, giving a velocity coefficient θ of about 0·98 for 500 ft./sec., 0·97 for 300 ft./sec., and 0·98 for 1,700 ft./secs.

The experiments also lead to the conclusion that the efficiency of a nozzle is decreased as the superheat is increased.

GENERAL PRINCIPLES OF STEAM TURBINE DESIGN.

(1) *Preliminary Estimate of Efficiencies and Steam Consumption.*

This will be done very largely as a result of test results on similar machines and careful estimates of the effects of any new features in the turbine under consideration. A preliminary estimate may be made from the notes given on pp. 114 *et seq.*

(2) *Last Blade Dimensions.*

In estimating the steam consumption of the machine some allowance must be made for the throw away or leaving loss at the last row of blades and the exhaust loss. For a given permissible leaving loss, the area through the last row of blades will be fixed by the specific volume at the exhaust pressure specified and the total steam quantity passing to the condenser. As the relation between last blade height and mean diameter tends to a constant ratio (usually fixed by the difficulty of obtaining suitable steam passages through long blades at the root and the tip), the output of the machine will usually determine the length and mean diameter of the last blade. Similarly maximum output at any speed of rotation will be limited by the mechanical considerations involved in providing sufficient leaving area (depending on blade height and mean diameter), and the use of such devices as double flow or Baumann exhausts.

(3) *Number of Stages and Mean Diameters.*

Maximum efficiency for any type of blading can only be obtained by the employment of suitable ratios between steam speeds and peripheral speed of blades (see curves, p. 123). Small auxiliary turbines of moderate efficiency utilise the whole of the pressure drop available in a single stage running at a high speed of rotation and geared down to the speed required by the driven element. In larger machines where moderate speeds of rotation are employed, the heat drop is usually divided into several stages. Where efficiency is of the highest importance the heat drop available will usually be large, and the provision of a correspondingly large number of single row impulse or reaction stages is essential. The area through the early stages will be small, and as there are practical lower limits to the height of blading of accurate manufacture, the h.p. blade diameter will also be small, and the number of stages correspondingly increased (the heat drop capacity of any given stage depending on the product of speed rotation and mean diameter). With high stop-valve pressures, therefore, and low vacua, considerations of critical speed of shafts usually demand two or more cylinders, an arrangement which has many advantages with high inlet pressures and temperatures.*

Where efficiencies are of less importance, or questions of space or first cost demand it, a shorter, less expensive machine may be obtained by utilising a two-row impulse wheel, or a single-row impulse wheel of large diameter in the first stage, with partial admission. This arrangement has the advantage of reducing the pressure and temperature in the cylinder of the turbine, and with partial admission cut out governing may be employed.

(4) *Preliminary Layout.*

These particulars being decided, a preliminary layout of the turbine may now be made. Based on previous experience the general dimensions of the rotating elements may be estimated and the shaft critical speeds approximately determined, along with sizes of bearings, thrust blocks, couplings and pedestals, cylinder dimensions and materials, and so on. As this preliminary work will form the basis of, and be to some extent modified by, more detailed calculations, it is clear that a good deal of judgment is necessary in this stage of the design.

(5) *Determination of Blade Areas.*

From these preliminary designs a more detailed calculation may now be made of the areas, heights and angles of the blading, and of the steam conditions in the various stages of the machine.

For this purpose accurate steam charts or tables will be required, and the steam condition line can be approximated by provisional estimates of the internal efficiency of the various stages of the turbine. The final state point at the exhaust of the machine, depending on the internal efficiency of the whole turbine, may be estimated with some accuracy from a consideration of tests on existing machines, together with such data as are available as to the mechanical losses involved.

(6) *Mechanical Considerations.*

The stage pressures being determined, detailed calculations may now be made of the stresses and deflections of diaphragms. The bending stresses in moving blades, together with centrifugal stresses and angles required, will dictate dimensions of moving blades, from which the stresses in wheels may be calculated. The estimation of natural frequencies of vibration of moving blades and wheels can usually be made from previous tests, and the accuracy with which this may be done will depend on the degree of variation from blades and wheels already made and tested. Where this is necessary, the final tuning should be done by tests in the actual blades and wheels.

(7) *Efficiency Calculation.*

A closer approximation may now be made to the efficiency and steam consumption of the machine, by the detailed calculation of the various losses (see p. 1505 *et seq.*). Here, again, experience is required as the separate losses in a steam turbine are not readily measurable, and the closeness with which the calculated overall efficiency agrees with the actual efficiency eventually obtained in the turbine on test will depend on the judicious estimate of the many small individual losses involved.

ESTIMATION OF STEAM CONSUMPTION.

The 'Overall Efficiency' of a turbine is obtained by comparing the work actually done per lb. of steam, with that which would be performed by an ideal engine working on the Rankine cycle and having the same initial and final steam conditions as the turbine.

This latter amount of work is equal to the mechanical value of the change in total heat contents (h_a B.Th.U.) which takes place during adiabatic expansion from the steam conditions before the governor valve, to those obtaining in the turbine exhaust.

h_a is referred to as the 'adiabatic heat drop' or the 'available heat drop,' and its value for the steam conditions usual in practice is given in Table IV., p. 118.

TABLE III.—ADIABATIC HEAT DROP IN B.TH.U./LB. DRY SATURATED STEAM.

If

d = steam consumption in lbs. per S.H.P. hour; η_T = overall efficiency of the turbine,

then

$$\eta_T = \frac{2{,}544}{d.\,h_a} \times 100 \text{ in per cent.}$$

If

d_1 = steam consumption in lbs. per kWh.; η_G = generator efficiency in per cent.,

then

$$\eta_T = \frac{3{,}412}{\eta_G d_1.h_a} \times 100 \text{ in per cent.}$$

The total steam consumption of the turbine is given by

$$W = \frac{d\,(\text{S.H.P.})}{3{,}600} \text{ lbs. per sec., or, } W = \frac{d_1\,(\text{kW.})}{3{,}600} \text{ lbs. per sec.}$$

While the efficiency calculated with h_a as already defined is the true index of the performance of a turbine when running, it is sometimes the practice—and it is one which has a special value to turbine designers—to calculate the efficiency by taking the heat drop h'_a as that available between the conditions existing after the governor valve, that is, before the nozzles, and the exhaust of the turbine.

This is equivalent to eliminating the consideration of the pressure drop through the governor valve, which is rightly regarded as not being an inherent loss to any given turbine.

Suppose, for example, that two turbines are sold as 1,000 kW. units to operate with certain steam conditions, and that one is actually capable of developing a load of 1,100 kW., while the second can only pull a load of 1,000 kW.

If these two turbines are tested on a load of 1,000 kW.. the latter will show the better steam consumption, because with the former the steam will be throttled at the governor to the greater extent. Of course, the first machine is in every way the better from the customer's point of view, provided the excess of power is not too great to be carried by the generator.

For estimating purposes steam consumptions may be obtained by means of figs. 5, 6, and 7. Fig. 5 shows turbine efficiencies at economical load for various sizes of machines with steam at 200 lbs./sq. g. 200° F. superheat, and with a vacuum at the exhaust flange of 29 ins. For other

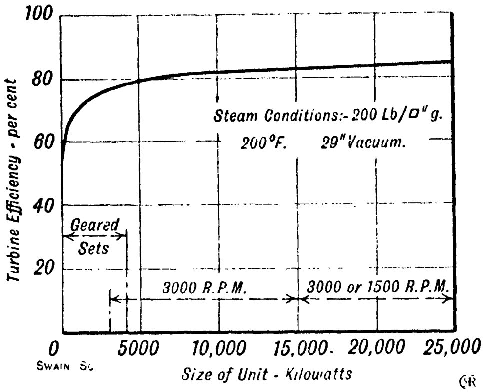

FIG. 5. TURBINE EFFICIENCY FOR H.P. TURBINES.

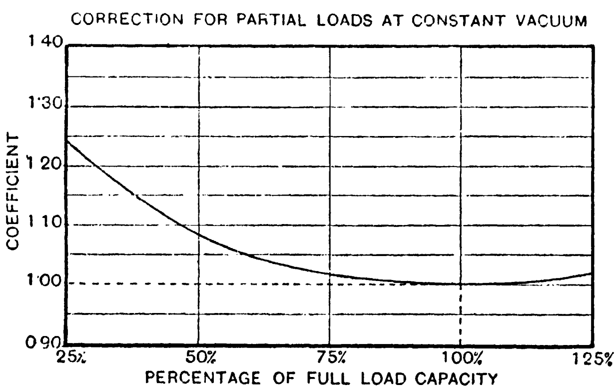

FIG. 6.

conditions the efficiency at economic load may be estimated by using the efficiency correction curves given in fig. 7.* When the economic load consumption is known, consumptions at other loads may be estimated from fig. 6.

* See Baumann, 'Some Recent Developments in Large Steam Turbine Practice,' *Proc. Inst. Elec. Eng.*, June 1921.

Efficiency Corrections for Turbines Designed for Various Conditions.

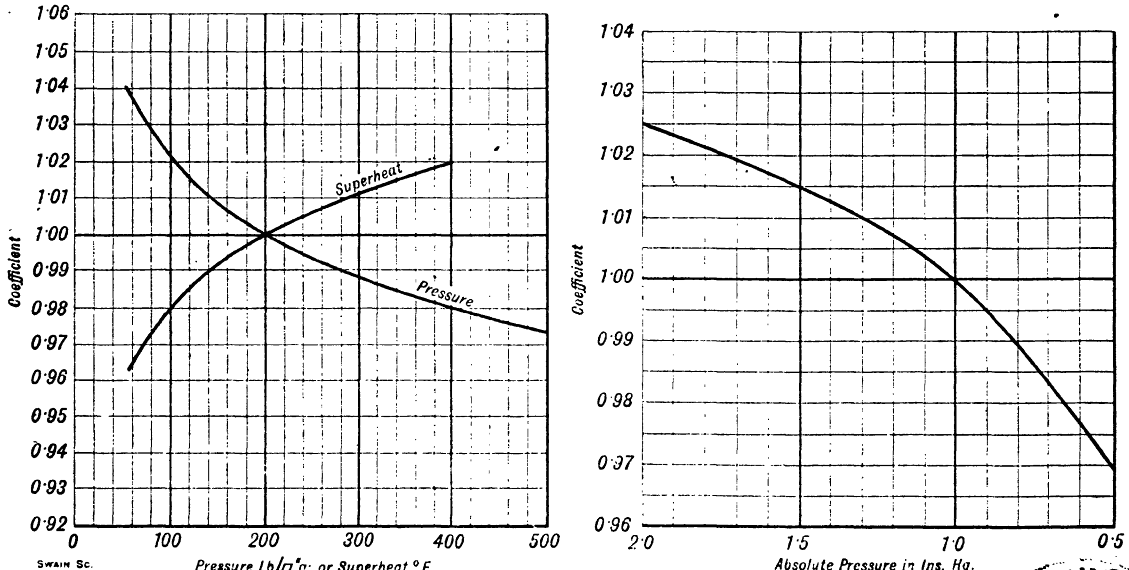

Fig. 7.

Standard Steam Conditions: 200 lbs. per sq. in. g. 200° F. 29 in. Vac.

For other steam conditions, multiply the efficiencies obtained from fig. 5 by the coefficients obtained from the curves.

The figures in the above tables have been abstracted from 'Heat Drop Tables' and 'Extended Heat Drop Tables' prepared by Prof. H. L. Callendar, F.R.S., and published by the British Electrical and Allied Industries Research Association.

IMPULSE TURBINES.

A pure impulse turbine is one in which the available heat energy of the steam is completely converted into kinetic energy in stationary nozzles.

The steam jet thus produced performs mechanical work by impinging on a rotating row of blades or successive rows of rotating and guide-blades placed immediately before the nozzles.

An impulse turbine in which the whole pressure drop available is utilised in a single set of nozzles is said to consist of one *pressure stage*. If the pressure drop is subdivided between two, three, or more successive sets of nozzles, it consists of two, three, or more pressure stages.

When the kinetic energy of the steam jet is utilised in one row of rotating blades, the turbine is said to have one *velocity stage* per pressure stage. If, after the first row of rotating blades, a guide blade is placed to reverse the direction of steam so as to impinge on a second row of rotating blades, the turbine is said to have two 'velocity stages,' and so on.

Since a minimum nozzle height will be fixed by practical considerations (not less than ¼ in. even in the smallest turbines), the arc over which the nozzles will extend depends upon the total nozzle mouth area required. In the high-pressure stages this may be less than the mean circumference of the blades. Such a turbine is said to be working with partial admission, and the arc over which the nozzles extend is termed the 'arc of admission.'

This arrangement lends itself especially well to conveniently and efficiently dealing with overloads, it being only necessary to increase the 'arc of admission' by admitting steam to additional sets of nozzles.

In the same way it is possible to divide the total number of nozzles into blocks controlled by separate cutout valves. Thus one block of nozzles can be designed to give all loads from 0 to ½ full load, while these together with a second block give ½ to ¾ and so on.

By this means the loss of pressure through throttling at the governor valve is reduced to a minimum, and substantial economies can be effected on partial loads. The nozzle cutout valves may be operated automatically or by hand. Nozzle cutout governing is not possible with reaction turbines.

(a) Single Pressure Stage Turbine with a Single Velocity Stage.

The nozzles of all impulse turbines can be designed by the methods already indicated, while the work done and the efficiency can be obtained by drawing the triangles of velocity a_1 and a'_1 (see fig. 8). All velocities are in feet per second.

Let

W = total weight of steam through nozzles in lbs. per sec.; c_1 = absolute velocity leaving nozzles; U = peripheral velocity at mean diameter of blades; w_1 = relative velocity at entry

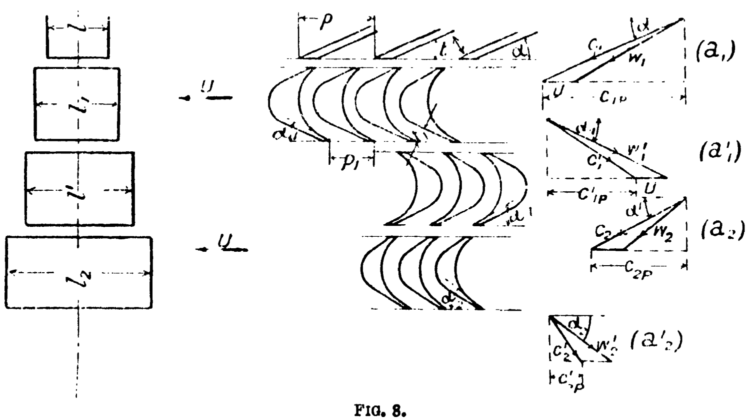

FIG. 8.

to moving blades; $w_1{}'$ = relative velocity at exit from moving blades; c_1 = absolute velocity leaving the moving blade; c_{1p}, $c_1{}'_p$ = the peripheral components of c_1 and $c_1{}'$, respectively.

Then

$$w_1{}' = \psi w_1,$$

where $(1 - \psi_1{}')$ is the loss of velocity due to friction in the blade (see fig. 12, page 124) ψ is called the *velocity coefficient* for the blades.

$$\left.\begin{array}{l}\text{The total work done, or}\\ \text{The indicated work}\end{array}\right\} = \frac{WU}{g}(c_{1p} + c_{1p}^{1}) \text{ ft.-lbs. per sec.}$$

$$\text{The blading efficiency } \eta_B = \frac{\text{(total work in ft.-lbs. per sec.)}}{W.\,J.\,g.\,h_a}$$

If

l = the required nozzle height; l_1 = the required blade height;

then

$$l_1 = l \cdot \frac{c_1}{w_1} \cdot \frac{t}{t_1} \cdot \frac{p_1}{p}$$

The de Laval turbine, which is of this type, is made in sizes from 5 to 500 h.p., running at 30,000 r.p.m. in the smallest size, and 10,000 r.p.m. in the largest outputs.

The peripheral speeds are as high as 1,300 ft. per second, and the steam velocity at exit from the nozzles as high as 4,000 ft. per second.

It can be shown that the efficiency varies with $\frac{U}{C_o}$, where Co is the velocity theoretically obtained if $\phi = 1{\cdot}0$.

For a maximum efficiency, $\frac{U}{C_o}$ should be about equal to 0·5 (see fig. 10, page 123).

(b) Single Pressure Stage. Two Velocity Stages.

In this case the work done in the first row of blades is obtained in exactly the same way as in case (a).

The guide-blade returns the steam jet towards the direction of U, the steam leaving it with an absolute velocity $c_2 = \psi_2 c_1^{1}$.

The relative velocity of exit from the second rotating blade is $w_2^{1} = \psi_2^{1} w_2$, knowing which, the velocity triangles a_2, a_2^{1} can be drawn. In a_2 and a_2^{1} the same symbols are employed as in a_1 and a_1^{1}, a suffix 2 denoting the guide-blade, while a dash denotes the second moving blade.

The total work per second is now

$$= \frac{WU}{g}\left\{(c_{1p} + c_{1p}^{1}) + (c_{2p} + c_{2p}^{1})\right\} \text{ ft.-lbs. per sec.}$$

WORK DONE IN 1ST AND 2ND ROWS OF VELOCITY WHEELS. 3,000 R.P.M.

Initial conditions :—200 lbs. per sq. in. g., 200° F. supf.; steam pressure in casing = per sq. in. g.; temperature in casing = 410° F.

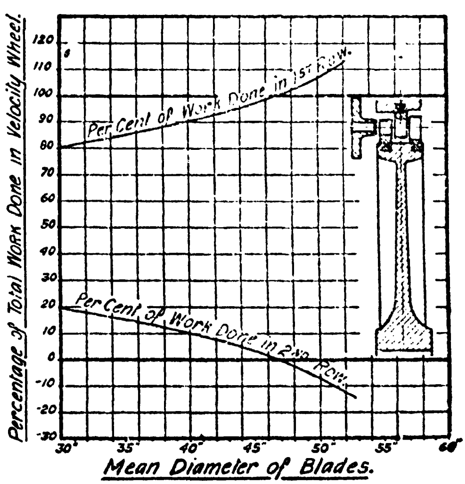

Fig. 9.

and

$$\eta_3 = \frac{\text{(Total work in ft.-lbs. per sec.)}}{W \cdot J \cdot g \cdot h_a}$$

$$\text{The height of the guide-blade } l' = l \cdot \frac{c_1}{c_2} \cdot \frac{t}{t^1} \cdot \frac{p^1}{p}$$

$$\text{The height of the second rotating blade } l_2 = l \cdot \frac{c_1}{w_2^1} \cdot \frac{t}{t_2} \cdot \frac{p_2}{p}$$

As the mean peripheral velocity of the blades increases the proportion of the work done in the first row increases. This effect is illustrated in fig. 9, from which it will be seen that for the condition stated the second row does no positive work if the mean diameter of the blades exceeds 47½ ins.; it can therefore be dropped with advantage. For this reason two-row wheels are rarely used in modern high-speed machines.

(c) Single Pressure Stage. More than two Velocity Stages.

The solution of this case can be obtained from (*b*) in exactly the same way as (*b*) was obtained from (*a*).

Single-wheel Curtis stages belong to classes (*b*) and (*c*) and are very much employed for small high-speed turbines, where efficiency is not the first consideration.

The peripheral speeds for Curtis wheels are as high as 600 ft. per second, and the steam velocity 2,500 ft. per second.

For a maximum efficiency $\frac{U}{C}$ should be about 0·23 for two rows of moving blades, and 0·15 for three rows (see fig. 10).

(d) Multi-Pressure Stage Turbine with Single Velocity Stages.

In order that reasonable efficiencies may be reached with practicable peripheral speeds, it becomes necessary to limit the heat drop utilised in each set of nozzles to some value considerably less than the total available between the conditions before the turbine stop valve and those present in the exhaust.

Up to a certain point, which is rarely reached in the conditions of actual design, the efficiency of each stage increases with the value of the ratio $\frac{U}{C_o}$ (see fig. 10).

When the value of $\frac{U}{C_o}$ is known, which corresponds to the desired turbine efficiency, the value of C_o and hence of h_a the heat drop to be utilised per stage can be calculated, since U will be fixed by mechanical considerations.

Then for an equal distribution of energy over the pressure stages,

if H_a = the total heat drop available for the whole turbine,

$$\text{The required number of stages } n = e \cdot \frac{H_a}{h_a}$$

where e is the '*reheat factor*' which depends on the amount of friction and eddy losses, the number of stages, the stage efficiency, etc., and varies between 1·03 and 1·07.

It is usually the practice to give the first stage a larger heat drop than the remainder, thus reducing the total number of wheels required, and having the considerable advantage of reducing the maximum temperature and pressure to which the turbine casing is subjected.

Having apportioned the heat drops, the steam conditions at each stage can be found—most conveniently by the Mollier diagram—and each stage can be designed as indicated under case (*a*).

The Rateau and Zoelly turbines are of this type.

In practice U varies from 350–600 ft. and the steam velocities from 800–1,600 ft. per second.

(e) Multi-Pressure Stage Turbines with Multiple Velocity Stages.

In precisely the same way as has been explained under (*d*), two- or three-row velocity wheels may be employed in the individual pressure stages.

The heat drop which can be advantageously used per pressure stage is then greater than in the case where a single row of blades is used, and thus the required number of pressure stages is reduced, but the efficiency is somewhat decreased, as may be deduced from fig. 10.

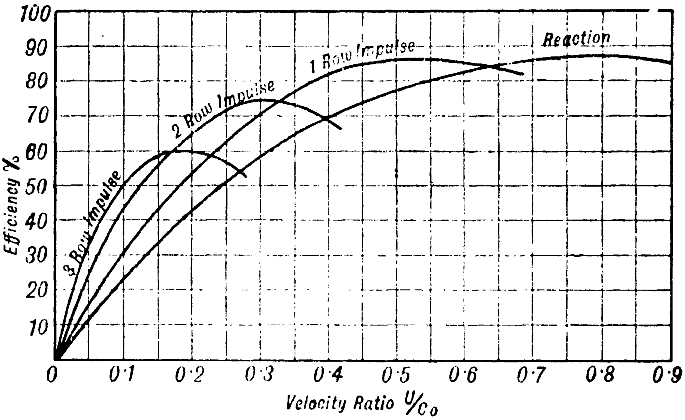

FIG. 10.

The general design of each stage is similar to that of case (*b*).

The Curtis turbine is of this type.

(f) Combination Impulse Turbines.

It has become a common practice to construct pressure-compounded impulse turbines of type (*d*) with a Curtis wheel having two rows of blades in the first stage. By this means a large heat drop can be employed in the first stage with reasonable efficiency and with the consequent advantages already mentioned.

The Curtis-Rateau and Curtis-Zoelly turbines are of this type.

CARRY-OVER ENERGY.

In pressure-compounded impulse turbines, the kinetic energy of the steam leaving the last blade of any pressure stage—except the last—is not entirely lost; part of it at least being recovered in the succeeding stage.

The total energy available in the succeeding stage is then greater than the adiabatic heat drop by an amount equal to $\frac{a\,c^2}{2g}$, where c is the absolute velocity of exit from the velocity blades and a is a constant.

For full admission, Prof. Rateau has suggested the value $a = \frac{2}{3}$, while for partial admission the value $a = \frac{1}{2}$ may be taken.

THE VALUE OF ψ, THE VELOCITY COEFFICIENT FOR BLADES.

The value of ψ has been the subject of researches by Prof. Rateau* and Dr. N. Briling.†

Prof. Rateau found that ψ was a characteristic of each type of blade depending on their size and spacing and slightly increasing with velocity.

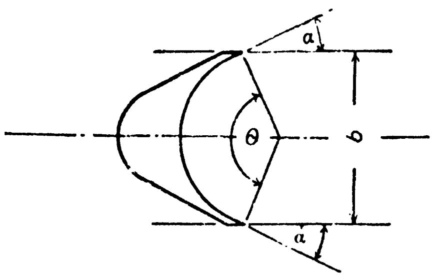

FIG. 11.

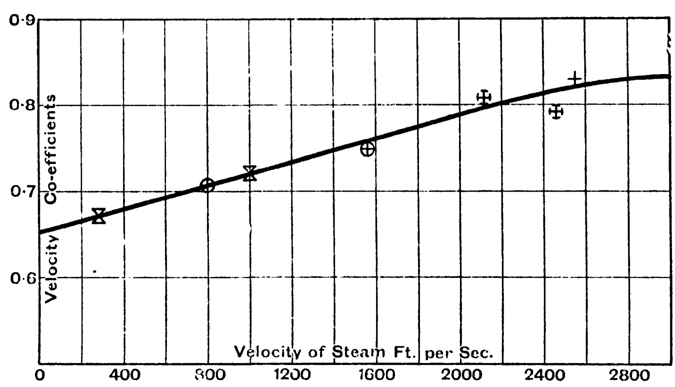
VELOCITY COEFFICIENT ψ.



⊕ *Rateau. (Engineering 10/12/09) Mean Values.*

⊕ *{Values deduced from Rateau's experiments on Bucket Reaction; Congrès International de Mécanique Appliquée 1900.*

X *Briling's Experiments with 20 m/m Buckets (Engineering 29/4/10).*

+ *{Stodola "Steam Turbines" deduced from Delaporte's Test of a de Laval Steam Turbine.*

FIG. 12.

Dr. Briling, whose experiments covered a wider field, found that ψ increased with velocity, decreased with the width of the bucket, and appeared to be principally dependent upon the angle through which the steam was diverted in the blade.

* *Engineering*, December 10, 1909. † *Z. V. d. I.*, January 1906.

Briling deduced the following formula from his experiments:

$$\psi = \psi_o - 0\cdot000432\,\theta^{\frac{1}{2}}$$

where θ = total angle in degrees through which steam is turned in the blade (see fig. 11).

ψ_o = 0·90–0·97 for blades with rounded inlet edges.
= 0·95–0·99 for blades with sharp edges.

Mr. H. M. Martin* has given a useful diagram combining Rateau and Briling's results with others deduced from various tests, which is reproduced in fig. 10; from this the following expression can be deduced:

$$\psi = 0\cdot65 + \frac{w}{15{,}000}$$

w being the velocity of the steam relatively to the blade in ft. per sec.

Pitch of Impulse Blades.

The best value of the pitch p has been determined experimentally by Dr. Briling † as being connected with the blade angle $\alpha°$—which he takes as being the same at the inlet and outlet—and the blade width by the following relation:

$$p = \frac{r}{2 \sin \alpha°}$$

$$r = \frac{b}{2 \cos \alpha°}$$

Briling is of the opinion that 30° is the most suitable angle for impulse blading.

In practice, the blade angle varies from 20° to 50°, the largest angles being used at the exhaust end of a turbine when it becomes difficult to provide sufficient area. The pitch varies from 0·5 to 0·75 of the blade width.

REACTION TURBINES.

In a reaction turbine the available heat energy of the steam is converted into kinetic energy both in the stationary and the moving blades.

In the most usual case—*considering a stage as consisting of a fixed blade and the following moving blade*—one-half of the available heat drop per stage is utilised in the fixed blade and the remainder in the moving blade. The turbine is then said to have a half degree of reaction.

Thus, both the fixed and moving blades perform the function of a nozzle in precisely the same way, and are identical in form and thermodynamic purpose.

Since there is a heat drop in the moving blades, there must also be a pressure drop across them. This is a characteristic of the reaction turbine as compared with the impulse turbine.

A second characteristic lies in the fact that the arc of admission to the first stage of a reaction turbine must extend around the complete circumference. For this reason nozzle cutout governing is not possible, and overloads can only be dealt with by admitting steam at some intermediate point in the expansion.

The steam enters the moving blades with a relative velocity approximately in an axial direction, and leaves them at a higher velocity in a direction inclined to the plane of rotation, the blades being impelled forward by the reaction of the leaving steam.

Reaction Blading with Half Degree of Reaction.

In this case since the outlet angles of the fixed and moving blades are the same, and the heat drop utilised in both is the same, the velocity triangles at inlet to and exit from the moving blade are identical (see fig. 13).

* *Steam Turbines—their Theory and Construction*, H. M. Martin.
† *Z. V. d. I.*, January 1906.

Hence

$$c_1 = w_1^1\ ;\ c_1^1 = w_1.$$

If h = heat drop in any stage (one fixed and one moving blade) and with the remaining symbols as were used when considering impulse turbines—

$$c_1 = \frac{1}{2\,U\cos\alpha}\,(25{,}050\,\zeta\,h + U^2);$$

where $(1 - \zeta)$ is the energy loss in the conversion of heat to velocity.

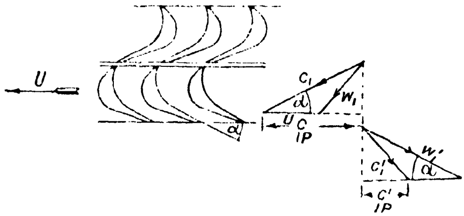


FIG. 13.

Capt. Riall Sankey gave 0·8 as the value of ζ, whereas the statement of Sir Chas. Parsons that the blading efficiency in the low-pressure end of the turbines of the 'Mauretania' reached the value of 85 per cent., shows that ζ may be as high as 0·86 under those conditions, while the efficiencies reported to have been obtained with the Ljungström turbine of quite small capacities could only be reached if ζ was as much as 0·35.

U and α being known, the velocity triangles can be drawn.

The work done per stage

$$= W\,\frac{(c_1^2 - c'^2_1)}{2\,g},\ \text{or,} = W\,\frac{(2k\cos\alpha - 1)}{g}\,v^2,\ \text{where } k = \frac{c_1}{U}.$$

The blading efficiency

$$\eta_B = \frac{c_1^2 - (c'^2_1)}{2g\,J\,.\,h},\ \text{or,} = U^2\,\frac{(2k\cos\alpha - 1)}{J\,.\,g\ h}.$$

The required blade length can be obtained from the relation

$$\pi\,.\,D_m\,.\,l\,.\,q = \frac{W\,.\,v_2}{W_1^1},$$

where D_m = mean diameter of annulus in feet; l = radial length of annulus in feet = (blade height) + (tip clearance); v_2 = the specific volume after the moving blade in cubic feet per lb.; q = annulus area factor.

At any stage the 'annulus area factor' is the ratio of the available area of the channels at exit from the blades in a direction at right angles to α, to the area of the annulus between the drum and the casing at that stage.

The properties of Parsons blading, with the exception of q and α, were published by M. Lelong,* and will be found in Table IV.

As in the case of impulse blading, the blading efficiency varies with $\frac{U}{c_1}$ and reaches a maximum when $\frac{U}{c_1} = 0{\cdot}945$ if $\alpha = 19°$, the normal angle for all but the last stages of reaction turbine. Under this condition U becomes equal to $c_1 \cos\alpha$. Such a high value is not practicable in ordinary working conditions, nor is it necessary for the realisation of high efficiency, because the curve connecting $\frac{U}{c_1}$ and η_B is very flat in the region of its maximum.

Fig. 14 (p. 128), which gives this relation for $\zeta = 0{\cdot}8$, is due to Stodola.†

The efficiency for changes of ζ within the limits actually to be met with can be obtained by increasing the efficiency as obtained from fig. 9 by the same percentage as ζ exceeds 0·8.

In electrical work $\frac{U}{c_1}$ varies from 0·5 to 0·8.

The peripheral velocity of forged steel drums may be as high as 400 ft. per second, and even higher speeds are possible with solid drums, or drums made from special steels of high ultimate strength.

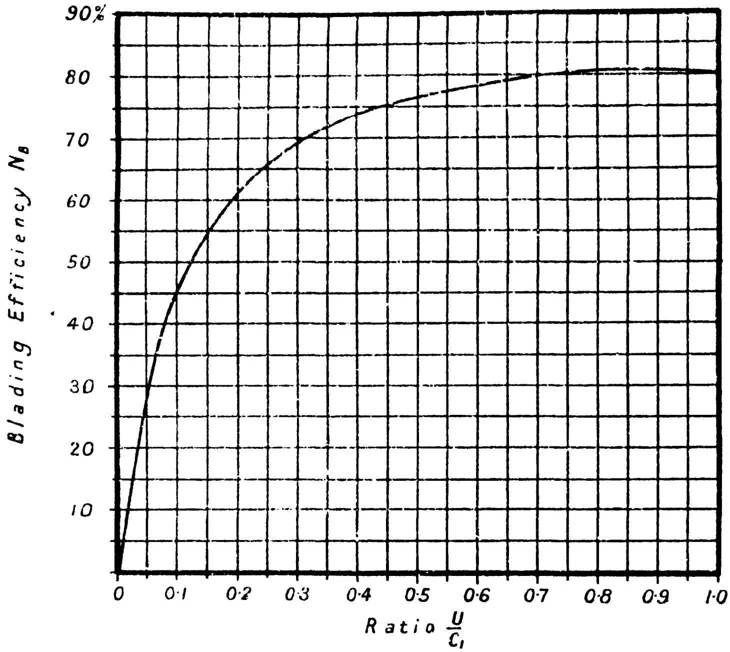
For Double Wing Blades $\alpha = 30°$; $q = 0·85$ in.



EFFICIENCY OF REACTION BLADING FOR $\zeta = 0·8$.

FIG. 14.

The velocity of the steam c varies from 300 ft. per second in the initial to 1,000 ft. per second in the final stages.

In marine work $\frac{U}{c_1}$ varies from 0·3 to 0·45, and for the high-pressure stages the peripheral velocity varies from 80 to 120 ft. per second.

REACTION TURBINE DESIGN.

The blades of Parsons turbines are not usually increased in height from row to row, but are arranged in groups having the same height and the same mean diameter. The angles of the blades of any one group are usually the same, but in some cases they are gradually increased so as to obtain the correct progression of areas for constant steam velocity relatively to the blade.

The blades of such turbines for land purposes are generally placed on three-drum diameters of increasing size, referred to as the H.P., I.P. and L.P. expansions.

The relative distribution of heat drop between the different expansions and their relative geometric properties are given in the following table :—

Expansion.	H.P.	I.P.	L.P.	H.P.	I.P.	L.P.
Adiabatic heat drop used . .	1	1	2	1	1	1
Number of groups of blades .	1	1	2	1	1	1
Mean diameter of annulus . .	1	$\sqrt{2}$	2	1	$\sqrt{2}$	2
No. of rows of blades per group .	1	½	¼	1	½	¼
No. of rows of blades per expansion	1	½	½	1	½	¼

The first of these arrangements is that most commonly adopted.

In electrical work there are from two to three groups of blades in the H.P. expansion.

In any given turbine and for groups of blades with the blade angle the same, the ratio $\frac{D^2 l}{v}$ should be constant, where D = mean diameter of the blades, l = their length, and v = the mean specific volume of the steam in the group.

The last three rings on the L.P. expansion were formerly made the same height, but with increasing discharge angle, the latter corresponding respectively to 'normal,' 'semi-wing' and 'wing.' By this means the final ring (*i.e.* wing blades) has double the discharge area of the ring of 'normal' blades of the same height, but without any increase in the centrifugal stresses. The practicable height ratio of $\frac{\text{blade height}}{\text{rotor diameter}}$ was $\frac{1}{4}$ with blades cut from rolled parallel strip. In modern practice a still larger height ratio ($\frac{1}{3}$) is obtained, with a view to obtaining still larger discharge area in the final ring, by the use of twisted blades which are also, if necessary (on account of centrifugal stresses), tapered from root to tip. In these blades the discharge opening ratio $\frac{e}{p}$ is kept constant from root to tip and equal to about 0·71 (*i.e.* wing), but the discharge angle is progressively varied by twisting. The guide ring is made complementary to the final rotating ring, being twisted, but not tapered.

In order to reduce the unsupported length between bearings, and to enable the tip clearance to be kept small, it is becoming the practice in turbines of 5,000 kw. and over to use two cylinders. The first cylinder contains the H.P. expansion only and can be made of cast steel, very fine clearances being possible by eliminating the danger due to the growth of cast iron.

c_1, for any particular stage, can be calculated from the formula already given when the heat drop h is known.

The blading efficiency throughout the turbine can be found from fig. 14 when the ratio $\frac{U}{c_1}$ is known.

For groups of blades having the same angles and height:

if

n = number of blades in the group considered ; R = ratio of expansion over the group;
H_a = adiabatic heat drop for the group,

then the heat drop used in the first stage

$$h_1 = \frac{(1+e)H}{\left[0{\cdot}07 + \left(\frac{R^{\frac{2}{N}} - 1}{R^{N} - 1}\right)\right]}$$

The heat drops for the other stages of the groups form with h_1 a geometric progression having $R^{\frac{2}{N}}$ as a common ratio.

In most cases it will be sufficient to calculate the first and last stages of any one group.

Disc and Drum Type.

Just as in the development of the pure impulse turbine combinations of the simple types have been evolved, so the disc and drum type has been introduced into the sphere of the reaction turbine.

In this case the high pressure and less efficient part of the reaction turbine is replaced by a Curtis wheel having as a rule two rows of blades. This design possesses the advantages already mentioned in connection with combination impulse turbines, and in addition it results in a considerably shorter and stiffer rotor than in the pure Parsons machine.

TURBINE LOSSES.

Diaphragm Gland Loss.

The diaphragms of a pressure-compounded impulse turbine must obviously be provided with a clearance between themselves and the shaft, thus providing a leakage area through which steam can pass.

The diaphragm gland is usually made either as a labyrinth packing or as a closely fitting white metal bush.

Although the clearances may originally be very small they are greatly increased by whipping of the shaft, or even by the static deflection.

The percentage leakage can be estimated as being equal to the ratio of the clearance area to the nozzle area in any diaphragm.

In order to reduce this loss, some designers employ carbon packings held together by garter springs in the diaphragms.

The diaphragm clearance is usually from $\frac{10}{1000}$ ins. to $\frac{30}{1000}$ ins. radially.

PACKINGS.

Labyrinth Packings.

The glands at the cylinder ends are usually of the labyrinth packing type.

In impulse turbines the labyrinth is invariably of the radial clearance type, while in Parsons turbines the packing at the thrust block end is of the axial clearance type, the other being of the radial clearance type.

Mr. H. M. Martin* has deduced the following formulæ:

$$\text{Weight of leakage steam} = 68 \,.\, A \,.\sqrt{\frac{p_o\left(1 - \frac{1}{r^2}\right)}{v_o\,(N + \log_e r)}}\ \text{lbs. per sec.,}$$

where

p_o = pressure before the gland in lbs. per sq. in.; v_o = specific volume of steam in cu. ft. per lb.; r = ratio of expansion through gland; N = number of labyrinths; A = sectional area of leakage path in sq. ft.

If the velocity with which the steam flows out of the last labyrinth is greater than sound velocity, this formula should be amended, but the correction is small, and as it is in the nature of a reduction in the weight of the leakage steam, it can safely be neglected where N is greater than 8, which is the usual case in practice.

N varies between wide limits and may be from 8 in the case of low-pressure glands of impulse turbines to 30 for the high-pressure glands of Parsons turbines.

The clearance usually allowed varies from $\frac{10}{1000}$ in. to $\frac{20}{1000}$ in., but this may increase in actual working in the same manner as the diaphragm clearances.

In order to reduce the loss of turbine efficiency due to gland loss, which might otherwise be considerable, the high-pressure packing is usually connected at one or two points in its length to some intermediate stage in the turbine.

The leakage over each of these sections can be calculated by the formulæ already given, r now being the ratio of expansion over any section, and p_o, v_o the conditions before that section.

Except in those cases where a water gland is used, the gland at the exhaust end is sealed by steam at a higher pressure than atmospheric, taken from a stage in the turbine, and in order to ensure that air is not leaking into the exhaust, the pressure is adjusted until a small quantity of steam is seen escaping into the engine-room.

The cylinder glands of the A.E.G., Zoelly, and Curtis turbines are of the carbon type, for which a considerable reduction in leakage is claimed.

The advantages of these are questionable since they cannot be renewed or adjusted without opening the turbine, and in some designs it is even necessary to strip the rotor.

The carbon rings which are in segments are kept together and caused to bear on the shaft by garter springs.

Dummy Loss.

In the majority of single-flow Parsons turbines the axial thrust on the blades and drum is balanced by dummy pistons. A labyrinth packing is formed on the periphery of the dummy pistons to reduce the leakage of steam which would otherwise take place across the dummy piston to the exhaust to which they are connected on one side.

The loss of steam through the dummy clearances can be calculated in precisely the same way as the loss through a labyrinth packing.

The double-flow type of turbine obviating the necessity of balance pistons eliminates this loss.

* *Steam Turbines—their Theory and Construction*, H. M. Martin.

Disc Friction.

A considerable amount of work may be absorbed in rotating the discs of impulse turbines in the dense steam present in the first stages of a pressure-compounded (disc) turbine.

Professor Stodola * has given the following formula for the disc friction loss:

$$\text{B.H.P.} = \frac{6.1}{10^{9}} D^{2} U^{3} \gamma,$$

where,

D = mean diameter of blades in feet; U = mean peripheral velocity feet per sec.; γ = density of steam in lbs. per cu. ft.

The experiments upon which this formula is based were performed either in air, superheated steam, or in steam whose exact condition as regards wetness was unknown.

Professor Lewicki has demonstrated that the combined work of disc friction and windage falls off with superheat, some of his experiments showing a reduction of 10 per cent. in the work done for an increase of superheat of 100° C. As the total loss due to disc friction is usually of the order of a few per cent. of the output of the turbine, the reduction with superheat is of little importance.

On the other hand, it seems probable that the disc friction would increase rapidly with the wetness of the steam, but there are at present no data for estimating this increase. For these reasons, the disc friction loss for any given turbine cannot be calculated with certainty.

Windage.

In addition to the disc friction, loss results from the fanning action of the blades as they rotate.

The laws governing this action cannot be regarded as established, the range of experiments has been limited, and results by the same experimenters are discordant. Professor Stodola* gives the following formula:

$$\text{B.H.P.} = \frac{4.6}{10^{7}} . D . l^{1.5} . U^{3} . \gamma,$$

where,

l = blade length in inches; D = mean diameter of blades in ft.; U = mean peripheral velocity in ft. per sec.; γ = density of steam in lbs. per cubic ft.

Mr. W Kerr carried out some careful tests on this subject, and by comparing his own results with those of Professor Stodola and Dr. Lasche, suggests that for wheels carrying two rows of blades the work calculated by the above formula must be multiplied by 1·23, for three rows by 1·8, and for four rows by 2·9.†

When mixed pressure turbines are working with low-pressure steam the high-pressure end is rotating idly in an atmosphere of steam, and with disc turbines the work done in disc friction and windage is not negligible. With reaction turbines a windage loss alone is present, and this is mainly due to the fanning action of reaction blading. Sir C. A. Parsons has stated that in the case of a reverse element of a marine turbine rotating in a vacuum the loss is of the order of 1 per cent., so that the loss due to the rotation of the high-pressure element of a mixed-pressure Parsons turbine rotating in steam twelve times as dense as a 28-in. vacuum may by considerable.

Water Glands.

An interesting feature in the development of turbine design consists in the introduction of the water gland.

In this type, an air-seal is produced by a paddle-wheel acting as a centrifugal pump. The pressure difference over the gland is balanced by the centrifugal head produced in the water as it is whirled around covering areas of different internal radii on the two faces of the paddle.

The ribs on the sides of the paddle should be ¼ in. deep.

If P_1 (fig. 15) = the pressure on the high-pressure side in lbs. per square ft.; P_2 = the pressure on the low-pressure side in lbs. per square ft.; R_1 = inner radius in ft. of the whirling water on the H.P. face; R_2 = inner radius in ft. of the whirling water on the L.P. face; ρ = density of water = 62·3; ω = angular velocity of paddle in radians per second.

Then

$$P_2 - P_1 = \frac{\omega^2 \rho}{240\,A}(R_1^2 - R_2^2) \text{ and } P_2 - P_1 = \frac{\omega^2 \rho}{240\,A}(R_2^2 - R_1^2)$$

The value of A varies from 0·9 to 1·10″.

Although the water gland when first introduced gave rise to troubles, it has proved successful when used in conjunction with a labyrinth packing, for the purpose of preventing air leaking into the turbine casing.

Since a sufficient centrifugal head to form a seal is not developed until the turbine is running at some speed near the normal, it is necessary to steam-seal the glands as the turbine is started up.

The gland must be supplied with a constant stream of water to make up the loss which takes

* *Die Dampfturbinen*, 4th Ed., Professor A. Stodola.

† *Engineering*, August 22, 1913.

place by evaporation on the vacuum side of the seal. The water is admitted at the periphery of the gland, and should be supplied from a head of about 15 ft. This will, of course, be equal to (P_2-P_1).

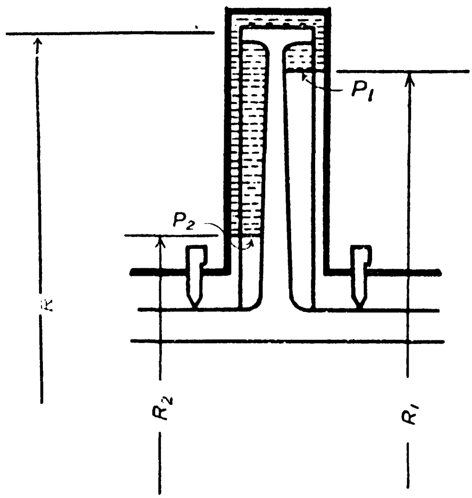


FIG. 15.

A water gland cannot be used to seal against steam at a pressure above atmospheric, because the water boils and the seal is destroyed.

Tip Clearance Loss.

As has already been pointed out, there is always a difference of pressure over both the fixed and rotating blades of a reaction turbine. In consequence of this there is always a leakage of steam

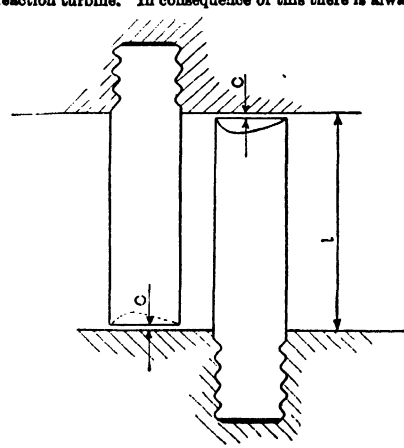

FIG. 16.

at the tips of the blades through the working clearances which have to be provided. In parallel flow reaction turbines there are two principal ways of providing these clearances:

(1) By means of radial clearance reaction blading (see fig. 16).

(2) By means of axial clearance or 'end tightened' reaction blading (see fig. 17).

The clearance C usually allowed in design varies approximately between the following limits for radial blading, all dimensions being in inches:

$$c = 0{\cdot}0008\,d \text{ to } c = 0{\cdot}0008\,d + 0{\cdot}004 \quad + 0{\cdot}015,$$

where,

d = mean diameter of blades.

l = blade height,

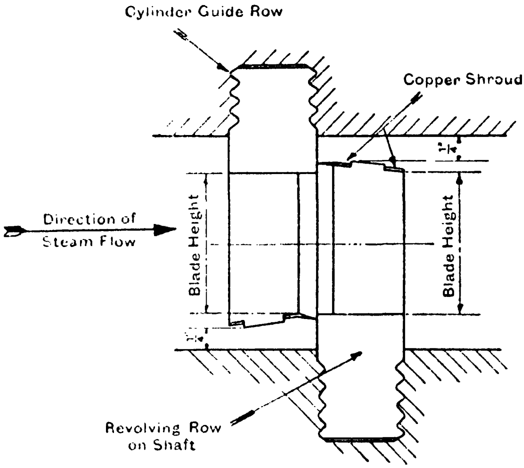

FIG. 17.—High-Pressure Turbine 'End Tightened' Reaction Blading.

If q is the annulus area factor—approximately one-third for normal reaction blading—the loss due to tip leakage can be expressed by $\frac{\lambda c}{q l}$; the value of λ deduced from the work of a number of experimenters varies from 1 to 2. In the case of end tightened reaction turbine blading illustrated in fig. 17 the fine clearances are arranged in an axial instead of a radial direction. This type of blading is usually confined to the high-pressure end of the turbine, and an adjustable thrust block is provided to enable this clearance to be adjusted.

Bearings.

l = the length of a bearing in inches; d = diameter of journal in inches; p = pressure on bearing per square inch projected area; N = speed of turbine in R.P.M.; μ = coefficient of friction; v = peripheral speed of journal in feet per second.

Then the work done in overcoming the bearing friction is

$$\text{Friction work} = \frac{\mu \pi l d^2 p N}{720} \text{ ft.-lbs. per sec.}$$

The heat equivalent of this work must be carried away from each bearing if they are to remain at a constant temperature.

According to Lasche's experiments, if $t°$ F. is the final steady temperature of the bearing, the coefficient of friction is given by the following relation:

$$\mu \, . \, p \, . \, (t° - 32°) = 51{\cdot}2.$$

For turbine bearings $t°$ should be from 120° F. to 150° F.

Assuming a temperature of 140° F., which is about an average value, these expressions can be reduced to:

$$\text{Work done in friction} = 3\cdot75\left(\frac{l}{10}\right)\left(\frac{d^2}{100}\right)\left(\frac{N}{1{,}000}\right)\text{ b.h.p.}$$

With average bearings bedded in the normal way, it is found that the work done exceeds the amount just given, being usually about twice as great.

One of the striking features of the recent developments in steam turbines has been the successive increases in the specific loadings and rubbing speeds on bearings.

This rating up of bearings has been accompanied by uniform success in all cases where the natural requirements of good lubrication have been safeguarded.

The oil supplied to the bearing has two functions to perform: it must sustain the oil film, and it must flush the bearing copiously to carry away the heat generated in shearing the oil film.

The quantity of oil required by the latter consideration is by far the greater of the two; the necessary amount of oil can readily be estimated from the relation that for ordinary turbine oils—

1·0 b.h.p. in oil friction raises 1·0 gallon of oil per minute by 10° F.

In the average case the temperature of the oil passing through the bearings is such that its temperature rise in passing through the bearing is from 20° to 40° F.; therefore, for 40° F. rise in temperature the oil quantity which should be supplied to a bearing is given by oil which should be supplied $= 2 \times \dfrac{3\cdot75ld^2N}{40 \times 10^6}$ gals. per min., or, approximately, $= \dfrac{2ld^2N}{10^6}$ gals. per min.

This represents the minimum quantity required, and may be increased up to double this amount with advantage.

The lengths of turbine bearings vary from $l = 2\cdot5d$ to $l = d$, the former value being usual for lightly loaded slow-speed bearings of older design, and the latter being approached with modern high-speed high-rated bearings.

At the present state of the art it is impossible to state the upper limits for permissible loading and rubbing velocity. Bearings are now quite common with loadings up to 110 lbs. per sq. in. and with rubbing velocities up to 130 ft. per sec.

According to modern ideas and practice, the old rules of the form pv = constant are quite unsound—in fact, when p is increased, v can and should be increased.

After leaving the bearings the oil is passed through an oil cooler, where it is cooled to some temperature usually below 110° F., although, of course, the actual temperature depends upon that of the cooling water available.

Turbine bearings give remarkably little trouble, provided the oil is kept clean and there is no tendency to emulsify.

In very small turbines the bearings are sometimes ring-lubricated, and in such cases the peripheral speed should not exceed 40 ft. per sec.; at higher speeds the oil tends to be thrown to the outside of the ring by centrifugal force.

Even in very small turbines there is now a tendency to fit a forced lubrication system provided with an oil cooler.

Recent Developments in Steam Conditions and Modification in Operating Cycle.

The component elements in a modern steam turbine and boiler plant are indicated in fig. 18.*

The various parts shown of steam turbine, regenerative feed heaters A, B, C, and D, economisers, boiler, superheater, resuperheater and air preheater, may be used all together, or one or other of the various elements may be omitted. For instance, the resuperheater appears desirable if steam pressures above 500 lbs./sq. in. are used, while air preheating will usually be employed if the feed

* The figures and data used in this section are taken from 'Economic Value of Increased Steam Pressures' of 1927, or from 'Tendencies in Steam Turbine Development' of 1929, both by H. L. Guy, before the Institution of Mechanical Engineers.

water is heated above 230° F. by the turbine feed heaters. In order to consider the influence of these elements on plant efficiency, the influence of steam pressure, steam temperature, regenerative feed heating and resuperheating will be considered separately.

Increased Steam Pressure.

The influence of steam pressure on heat consumption of the steam turbine itself is shown in fig. 19 by curve G; while curve M shows the corresponding gain when the effect of the turbine and boiler auxiliaries is taken into account. The meaning of the remaining curves in the figure will be evident.

Curve R shows the way in which the gain flowing from the use of increased steam pressure is increased by the use of four stages of regenerative feed heating, and therefore represents th relative gain which can be realised in a fairly elaborate modern installation of reasonable capac The last reservation arises from the fact that the gain which can be obtained by using incre pressure depends very much on the capacity and speed of the installation. The figures giv apply to an installation of about 20,000 kw. capacity if the speed is 3,000 r.p.m., or 40,000 kw capacity if the speed is 1,500 r.p.m. For much larger installations the returns will be ve slightly increased. For sensibly smaller capacities the gains will be materially reduced. Fr curve R the following table has been deduced, showing the pressure steps and pressures wh correspond to definite gains in coal consumption of 3 per cent. each time:

Table VI.—Increase in Steam Pressure for 3 per Cent. Steps in Thermal Efficiency.

Basis.—700° F. total temperature, 29-in. vacuum, four-stage feed heating. Including boiler and condenser auxiliaries. Capacity not less than 40,000 kw. M.C.R. at 1,500 r.p.m.; 20,000 kw. M.C.R. at 3,000 r.p.m.; 10,000 kw. M.C.R. at 6,000 r.p.m.

For 900° *F.*—Gain with pressure as above between 200 lbs. per sq. in. and 750 lbs. per sq. in. Gain with pressure increased by $\frac{1}{6}$ per cent. per 100 lbs. per sq. in. between 750 lbs. and 1,400 lbs. per sq. in.

For 28-*in. Vacuum.*—Gain with pressure increased by 0·3 per cent. per 100 lbs. per sq. in. between 200 lbs. and 750 lbs. per sq. in. Gain with pressure increased by 0·2 per cent. per 100 lbs. per sq. in. between 750 lbs. and 1,400 lbs. per sq. in.

The absolute values of the most important quantities entering into the calculation of the curves in fig. 19 are given in Table VIII. The figures given in lines 21 and 22 under 'Plant Efficiency' are based on a generator efficiency of 96 per cent. and a boiler efficiency of 84 per cent. It should be stated that all the preceding figures are based on an initial temperature of 700° F. and on a vacuum of 29". The relative position is not sensibly affected by increased steam temperature, but the net gains increase as the vacuum is decreased. For instance, the gain with 28" vacuum at 2,000 lbs./sq. in. is some 2 per cent. greater than that shown for 29" vacuum.

Increased Steam Temperature.

The most recent tendency in turbine development has been in the direction of increasing the initial temperature at which steam is supplied to the turbine. The increases in thermal efficiency resulting from increase in initial temperature are given in Table VII.

TABLE VII.—INCREASE IN TOTAL TEMPERATURE FOR 3 PER CENT. STEPS IN THERMAL EFFICIENCY.

Basis.—700° F. total temperature, 29-in. vacuum, four-stage feed heating. Including boiler and condenser auxiliaries. Capacity not less than 4,000 kw. M.C.R. at 1,500 r.p.m.; 2,000 kw. M.C.R. at 3,000 r.p.m.; 1,000 kw. M.C.R. at 6,000 r.p.m.

Comparison of Tables VI and VII reveals the following interesting characteristics of pressure and temperature increases.

If the total temperature is kept constant, the changes in pressure necessary to secure a given gain in efficiency increase very rapidly, both with the initial pressure and with the magnitude of the gain in efficiency considered. On the other hand, the increase in temperature necessary to secure a given gain in efficiency is sensibly constant at all initial steam pressures whether the step in efficiency be 3 per cent. or 12 per cent.

In contrast with increases in initial pressure, the thermal advantage of increased temperature does not sensibly depend upon the size of the prime mover. A further distinction arises from the fact that a much smaller proportion of the complete boiler and turbine plant is affected by raising the temperature, than by raising the pressure.

Note.—Recently acquired knowledge on the properties of materials at elevated temperature has resulted in recognition of the fact that other things being equal steam pressures must be decreased as the steam temperature is increased. It is probable that the most desirable condition in the immediate future will be obtained by the adoption of a moderate steam pressure coupled with a higher steam temperature than has been normally used in the past.

Regenerative feed heating.

In recent years the practice of heating the feed water progressively by feed heaters supplied with steam tapped from the main turbine at various points in the expansion has developed until it has become standard. From one to four feed heaters are used, depending on the size and elaboration of the plant. The gains in coal consumption which can be expected at various steam pressures with from one to seven feed heaters are shown on fig. 20 (p. 137) for installations including an economiser and air preheater. If no air preheating is done, these gains are reduced to about two-thirds of those shown in this figure.

Resuperheating.

If steam is taken out of the turbine after partial expansion and passed through a superheater, the thermal efficiency is improved and consequently the coal consumption reduced. This gain in efficiency varies with the points in expansion at which resuperheating takes place. The upper

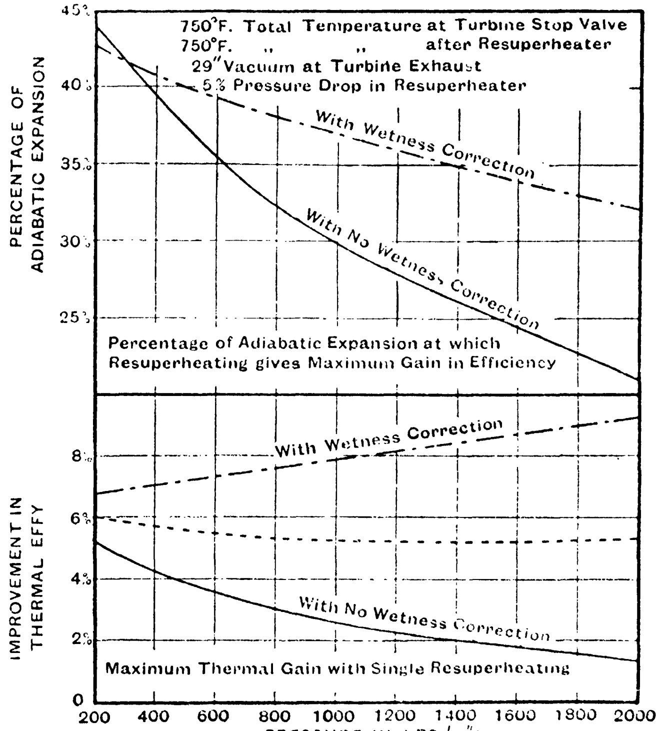

FIG. 21.

part of fig. 21 shows the percentages given of the total expansion which should precede resuperheating. The two curves shown should be treated as giving two limits. Again, in the lower portion, the two curves show the two limits for the reduction in coal consumption. The dotted curve shows the mean value and represents about the percentage which has so far been obtained by resuperheating.

TYPES OF TURBINES.

Turbines may be classified according to the steam conditions under which they operate. It should be noted that the energy available in adiabatic expansion of steam from 180 lbs. per sq. in. g. and 100° F. superheat to 28 ins. vacuum, is about twice that available if the expansion is carried down to atmospheric pressure only. Hence the addition of condensing plant approximately doubles the amount of work which can be done per lb. of coal, without necessitating any increase in boiler capacity.

HIGH-PRESSURE TURBINES.

High-pressure turbines take their steam directly from the boilers, and expansion takes place in the turbine down to the pressure in the condenser. This may be regarded as the fundamental class of turbine. The steam conditions are usually 350–150 lbs. per sq. in. g. pressure, 0°–300° F. superheat, and 27½ ins. to 29 ins. vacuum (30 ins. Barm.). Of course, the range of possible conditions is greater than these: for instance, in collieries and steelworks, steam pressures of 100–50 lbs. per sq. in. are to be met with, while steam temperatures of 800° F. will probably be adopted in the near future.

LOW-PRESSURE TURBINES.

Low-pressure turbines take their steam at about atmospheric pressure, the source almost invariably being the exhaust from non-condensing reciprocating engines. The initial steam pressure is usually from 20–15 lbs. per sq. in. abs., and should in all cases be above atmospheric pressure in order to eliminate the risk of air leakage into the steam pipe line. Low-pressure turbines require no governor gear if connected either mechanically or electrically to the recipro-

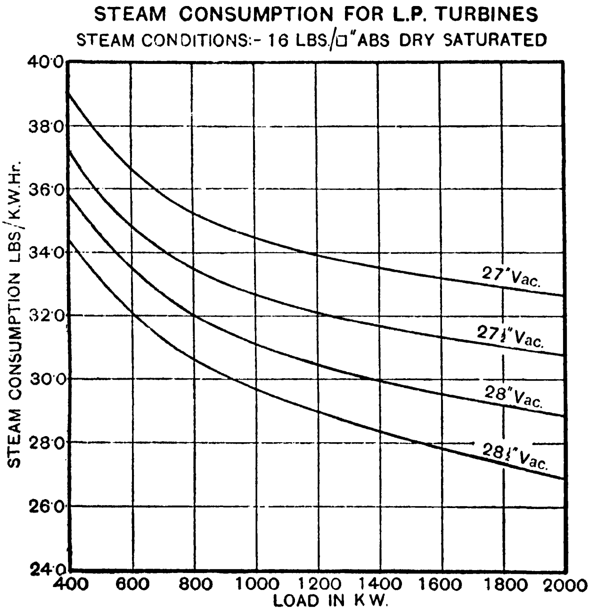

FIG. 22.

cating engine from which they obtain their steam. In the event of the engine being shut down the turbine is supplied with steam from the boilers through a reducing valve.

The efficiency with which low-pressure steam can be used naturally depends not only on the size and speed of the plant, but also on its capacity and costliness. As an average the steam consumption shown in fig. 22 can be used for estimating purposes when dry steam is supplied to a low-pressure turbine at a pressure of 16 lbs./sq. in. absolute.

Back-Pressure Turbines.

Back-pressure turbines take their steam directly from the boilers and exhaust at or above atmospheric pressure. Such turbines may be used in cases where the exhaust steam is required for heating purposes, and the back pressure usually ranges from 1 to 20 lbs. per sq. in. g.

In certain cases the back pressure may be as high as 40 lbs. per sq. in. g.

Back-pressure turbines are used to a considerable extent to drive the auxiliaries, their exhaust steam being utilised for feed heating; by this means the losses in the turbine are recovered in the feed heater, and an overall efficiency for back-pressure turbine and feed heater of over 90 per cent. is obtained.

Mixed-Pressure Turbines.

When L.P. steam is utilised in an L.P. turbine it is obviously desirable that the turbine set may be operated at will independently of the reciprocating engines from which it obtains its steam, so that in the event of the engine being shut down the turbine may operate with reasonable economy. This becomes possible by the addition of what is really a B.P. exhausting into the L.P. turbine, and having a common casing and spindle. This combination forms a mixed-pressure turbine, which can operate not only on either H.P. or L.P. steam, but if sufficient L.P. steam is not available to carry the load, the deficit is automatically supplied by admitting H.P. steam to the H.P. end of the turbine.

The governor gear is automatic and adjusts itself so that all the L.P. steam available is used in preference to H.P. steam.

In mixed-pressure turbines the governor gear is of special importance, as for successful working in parallel with other alternators the changes from L.P. steam to H.P. steam must be effected without any appreciable change in speed or load of turbo-alternator.

Reducing Turbines.

With a B.P. turbine the amount of steam available for heating purposes, and the work done by the turbine, are directly connected. In most installations it is desirable to be able to vary these quantities independently of each other, and to meet this demand 'Reducing' turbines were introduced.

Power Obtained from Heating Steam.

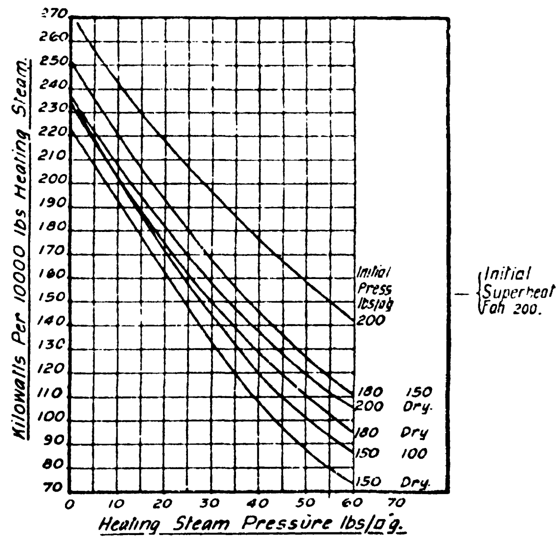

Fig. 23.

An R.P. turbine consists of a B.P. turbine to which an L.P. turbine is added. The B.P. turbine is designed for the maximum amount of steam required by the heaters it supplies.

As the demand for heating steam decreases, an automatic governor gear by-passes the supply to the L.P. end of the turbine, and at the same time the supply of steam to the H.P. end is decreased.

In this way the load the generator can carry is independent of the amount of heating steam required.

The governor gear should be operated in such a way that the pressure of the heating steam remains constant.

An increasing demand for this type of machine has arisen in recent years as a result of the extremely economical results which can be obtained in those manufacturing works requiring both electrical power and heating steam.

In order to obtain the best result the pressure at which steam is taken from the turbine for heating purposes should be as low as possible in view of the requirements of the heating process. The effect of back pressure on the consumption of heating steam can be seen from the following table, while the variation in the power which can be obtained from back pressure on reducing turbines is shown in fig. 23 for various steam conditions.

In recent years marked improvements have been made in the efficiency which can be obtained in H.P. ends of steam turbines. Whereas formerly the first step in expansion was accomplished with an efficiency of from 50 to 60 per cent., efficiencies of from 70 to 80 per cent. can now be realised in turbines of reasonable size and of other than the cheapest construction. It follows that in back pressure or reducing turbines of some considerable size, elaboration and costliness, the kw. obtainable per 10,000 lbs. of steam per hour can, in such cases, exceed those given in fig. 23 by some 25 per cent.

TABLE IX.

PERCENTAGE CHANGE IN STEAM CONSUMPTION OF WORK CAPACITY OF HEATING STEAM FOR A CHANGE IN HEATING STEAM PRESSURE OF 5 LBS. SQ. IN. G.

Initial Pressure. lbs. sq. in.	Initial Superheat. Degrees F.

150	9·25	8·65	8 1	7·5	6·95

TURBINE TEST CORRECTIONS FOR STEAM CONDITIONS.

While it is rarely possible to make tests upon a turbine under the exact steam conditions for which it has been designed, the performance which may be expected under the designed conditions can be estimated from the steam consumption actually obtained during the test.

The usual practice consists in correcting the test consumption for the difference between the steam superheat, pressure, and vacuum during the test, and that which is specified for the turbine

These 'corrections' are arranged as coefficients by which the observed consumptions must be multiplied, and are determined for any steam conditions from consideration of the changes in available heat-drop and turbine efficiency which take place with any change in that condition.

A very complete list of these corrections has been published by Mr. K. Baumann,* and the values he gives are incorporated in this section.

Superheat Correction.

Where the superheat is different from that specified, the following corrections should be made, both for high-pressure or low-pressure turbines.

Between :—

0–100° F. superheat 1 per cent. improvement of steam consumption for every 10° F. superheat.

100–200° F. superheat 1 per cent. improvement of steam consumption for every 12° F. superheat.

200–300° F. superheat 1 per cent. improvement of steam consumption for every 14° F. superheat.

Correction for Initial Wetness of Steam.

For each 1 per cent. wetness the steam consumption, if measured as condensed water, will be 2 per cent. too high.

* *Recent Developments in Steam Turbine Practice*, Inst.E.E., April 1912

Pressure Correction.

The correction which is to be made for the pressure depends upon whether the change in pressure is before the stop valve or before the nozzles.

Thus, if in the case of a high-pressure turbine working on a constant generator load the pressure before the stop valve is raised, say 10 lbs. per sq. in., the governor valve closes slightly, but the pressure before the nozzle will be very little altered, the only result being that the steam is throttled to a greater extent than formerly.

The effect of such an increase of pressure will be that the steam consumption will be improved by the small amount corresponding to the superheat due to the additional throttling.

In such cases the steam consumption will be improved by 0·5 per cent. for every 10 per cent. increase of pressure.

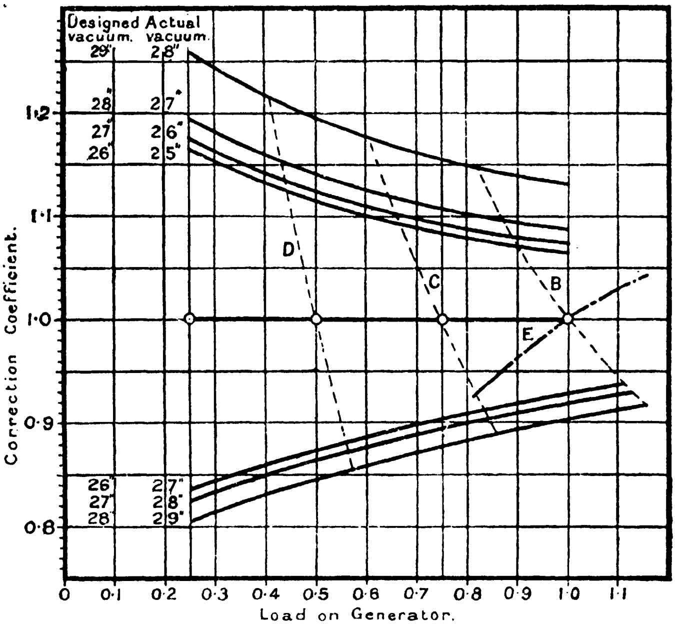

FIG. 24.—Vacuum Correction for Low-pressure Turbines.

When, on the other hand, the pressure before the nozzles is increased, the correction is of quite different magnitude and is:

For high-pressure turbines, an improvement of 1½ per cent. in steam consumption for 10 per cent. increase in pressure.

For low-pressure turbines, an improvement of 4 per cent. in steam consumption for 10 per cent. increase in pressure.

Vacuum Correction.

In any test, the correction for vacuum is usually of greater magnitude than that for pressure or superheat. Although every care has been exercised in estimating these corrections, it is obviously desirable that the total correction should be as small as possible, and if only for this reason every effort should be made to obtain during a test a vacuum as little different as practicable from that for which the turbine was designed.

Table X. gives the correction for vacuum which should be employed for various designed conditions with high-pressure turbines or mixed-pressure turbines, working with high-pressure steam.

TABLE X.—VACUUM CORRECTION FOR HIGH-PRESSURE AND MIXED-PRESSURE TURBINES.

Partial loads are expressed as fractions of the full load for which turbine is designed.

The correction is to be made when the turbine is run on a vacuum other than that for which it was designed.

The Theoretical Correction is given for 150° F. Superheat.

The actual correction given for various loads can be used for any superheat between saturation and 300° F.

It should be noted that at any load and for the same designed steam conditions and actual vacuum, the correction in the case of a mixed-pressure turbine (M.P.) is greater than for a high-pressure turbine (H.P.).

Thus, for example, the correction for a M.P. turbine at full load and working with high-pressure steam is the same as for a H.P. turbine on half load. The assumption underlying this is that the M.P. turbine is designed to give the same output on H.P. as on L.P. steam, and that, therefore, the conditions in the nozzles and blading of the L.P. end of the M.P. turbine are the same as that of a H.P. turbine designed for twice that output. Changes in vacuum only affect the conditions in the last few stages of a turbine, and these in a M.P. turbine on H.P. steam are operating under the same conditions as those of a H.P. turbine at half load.

Vacuum corrections for low-pressure turbines or for mixed-pressure turbines working with low pressure steam are still larger than those already considered.

In fig. 24 a coefficient will be found for various loads on the generator which is the ratio :—

(Steam consumptions for 1 in. above or below the designed vacuum.)

(Steam consumption for the designed vacuum.)

While the corrections as given above can be applied to the generality of cases, special conditions may arise where corrections must be separately considered.

Thus, it is possible to obtain little or no benefit by increasing the vacuum with a turbine designed for a certain load at a certain vacuum and modified to operate on a considerably higher load and a higher vacuum; in such a case the velocity in the exhaust would be exceedingly high, and may even approximate to sound velocity.

In back pressure turbines, or the high pressure end of reducing turbines, all corrections will be considerably larger than those given above, and these require separate consideration in each case.

It cannot be too strongly emphasised that every endeavour should be made to arrange the test conditions in such a way that all corrections are as small as possible.

Centrifugal Stresses in Drums and Discs.

Stresses in thin Ring or Drum.

Mean tangential stress $= 2\,(D)^2\left(\frac{N}{1000}\right)^2$ lbs./sq. ins.

Solid Parallel-sided Disc.

If U_2 = peripheral velocity at the outside diam. in ft./sec.,

then radial stress at any radius x is $\sigma_r = \frac{4{\cdot}36U_2^2}{100}\left[1 - \frac{x^2}{x_2^2}\right]$ lbs./sq. in.

and the tangential stress $\sigma_t = \frac{U_2^2}{100}\left[4{\cdot}36 - 2{\cdot}51\frac{x^2}{x_2^2}\right]$ lbs./sq. ins.

The maximum stress at the centre is given by

$$\sigma_{r\,max} = \sigma_{t\,max} = \frac{{\cdot}36\,U_2^2}{100}\ \text{lbs./sq. ins.}$$

If the diameter of the disc = D inches, this can be written

$$\sigma_{max} = 0{\cdot}835\,(D)^2\left(\frac{N}{1000}\right)^2\ \text{lbs./sq. ins.}$$

Parallel-sided Disc with Hole in Centre.

At any radius x

Radial stress $\sigma_r = \frac{4{\cdot}36}{100}U_2^2\left[1 + \frac{(x_1^2 - x^2)}{x_2^2} - \frac{x_1^2}{x^2}\right]$ lbs./sq. ins.

Tangential stress $\sigma_t = \frac{U_2^2}{100}\left[4{\cdot}36\left(1 + \frac{x_1^2}{x_2^2} + \frac{x_1^2}{x^2}\right) - 2{\cdot}51\frac{x^2}{x_2^2}\right]$ lbs./sq. ins.

Dimensional symbols as shown in fig. 25.

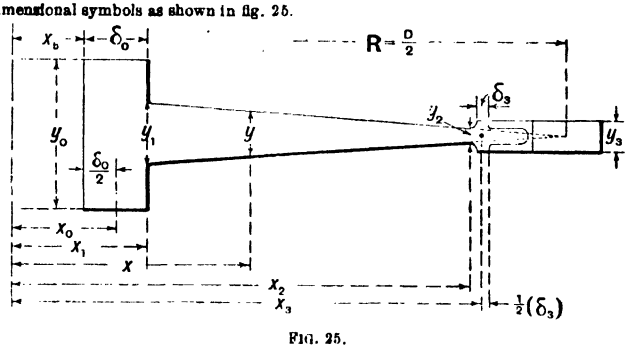

FIG. 25.

Disc with Hyperbolic Profile.

If the profile can be expressed as a hyperbolic function of the form $y = \frac{(\text{constant})}{x^a}$, the following analysis can be used ·

Let

ω = angular velocity in radians/sec. $= \frac{N \times 2\pi}{60}$;

E = Young's modulus of elasticity = 30×10^6 lbs./sq. in. for steel;

ν = Poisson's ratio = 0·3 for steel;

σ_3 = load on outer edge of disc due to blade loading in lbs./sq. in.;

σ_0 = stress at bore due to pinch fit;

μ = mass per unit volume;

then
$$a = \frac{\log\left(\frac{y_2}{y_1}\right)}{\log\left(\frac{x_1}{x_2}\right)}.$$

$$\psi_1 = \frac{a}{2} + \sqrt{\frac{a^2}{4} + a\nu + 1}, \quad \psi_2 = \frac{a}{2} - \sqrt{\frac{a^2}{4} + a\nu + 1}.$$

and
$$a = -\frac{(1-\nu^2)\mu\omega^2}{E[8-(3+\nu)a]}$$

then radial stress at any point

$$\sigma_r = \frac{E}{(1-\nu^2)}\left[(3+\nu)\,a\,x^2 + (\psi_1+\nu)b_1 x^{\psi_1-1} + (\psi_2+\nu)b_2 x^{\psi_2-1}\right] \quad \ldots.(1)$$

and tangential stress

$$\sigma_t = \frac{E}{(1-\nu^2)}\left[(1+3\nu)\,a x^2 + (1+\psi_1\nu)b_1 x^{\psi_1-1} + (1+\psi_2\nu)b_2 x^{\psi_2-1}\right] \ldots.(2)$$

In order to calculate constants b_1 and b_2, make use of the boundary conditions :—

Extension at outside, where $x = x_2$

$$\xi_2 = \frac{x_2^2}{E\,\delta_2 y_2}\left(\sigma_2 y_2 + \mu\omega^2\delta_2 y_2 x_2 - \sigma r_2 \frac{x_2 y_2}{x_2}\right) \quad \ldots.(3)$$

Extension at inside, where $x = x_1$

$$\xi_1 = \left(\frac{x_0^2}{E\,\delta_0 y_0}\sigma_0 y_0 + \mu\omega^2\delta_0 y_0 x_0 + \sigma r_1 \frac{x_1 y_1}{x_0}\right) \quad \ldots.(4)$$

But
$$\xi \text{ also} = a x_1^3 + b_1 x_1^{\psi_1} + b_2 x_1^{\psi_2} \ldots\ldots\ldots\ldots\ldots\ldots.(5)$$

and
$$\xi_2 = a x_2^3 + b_1 x_2^{\psi_1} + b_2 x_2^{\psi_2} \ldots\ldots\ldots\ldots\ldots\ldots.(6)$$

By equating (3) and (6), also (4) and (5), the two resulting equations can be solved for b_1 and b_2.

When these values are put in (1) and (2) the radial and tangential stresses at any point in the disc can be obtained.

Disc with Straight-sided Taper Profile.

Treating a disc as having a conical profile, Mr. H. M. Martin * has derived a means of arriving at the stresses, which, together with the amendment to incorporate the effect of the hub, as suggested by Mr. B. Hodkinson,† provides a useful method.

The stresses throughout a conical disc are:

Radial $= \sigma_r = Tp_0 + Ap_1 + Bp_2$ ....(1)

Tangential $= \sigma_t = Tq_0 + Aq_1 + Bq_2$..(2)

where T = stress in a thin ring

$= 2D^2\left(\frac{N}{1{,}000}\right)^2$ lbs./sq. in. for steel.

D = diameter of completed cone.

$p_0, p_1, p_2, q_0, q_1, q_2$, are given in the curves, fig. 26, co-ordinated with the ratio $\frac{x}{R}$.

The constants A and B have always to be found by writing 'boundary conditions.' Thus at the inner limit of the conical portion where it joins the hub :

$$\sigma t_1 = \left\{\sigma_4 \frac{2x^2}{x_1^2 - x^2} + 2\left(\frac{N}{500}\right)^2(0{\cdot}175x_1^2 + 0{\cdot}825x_b^2)\right\}$$
$$+ \sigma_{r_1}\left\{\frac{y_1}{y_0}\left[\frac{x_1^2+x^2}{x_1^2-x^2} - 0{\cdot}3\right] + 0{\cdot}3\right\} \ldots\ldots\ldots\ldots(3)$$

where σ_4 is the 'pinch' pressure inside the bore in lbs./sq. in. At the rim

$$\sigma_{t_2} = \left\{\frac{\text{Total centrifugal force of blades}}{2\pi\delta_2 y_2} + 2x_2^2\left(\frac{N}{500}\right)^2\right\} - \sigma_{r_2}\left\{\frac{x_2 y_2}{\delta_2 y_2} - 0{\cdot}3\right\} \ldots(4)$$

FIG. 26.

Putting in equations (1) and (2) the values of p_c, p_1, p_2, q_c, q_1, q_2, at the inner radius of the cone, and using the resulting expressions as σr_1 and σt_1 in equation (3), an equation involving only A and B is obtained. Writing similarly for the outer radius of the cone a second equation involving A and B, these constants can be calculated, whence the stresses anywhere in the disc are known.

The stresses throughout the hub then are:

$$\sigma r = \sigma_{r_1} \frac{y_1 (x^2 - x_b^2)}{y_0\, x_1^2 - x_b^2} \frac{x_1^2}{x^2} - \sigma_4 \frac{x_b^2}{x^2} \frac{(x_1^2 - x^2)}{(x_1^2 - x_b^2)} + 0\cdot825 \left(\frac{N}{500}\right)^2 \left(x_1^2 + x_b^2 - x^2 - \frac{x_b^2 x_1^2}{x^2}\right).$$

$$\sigma t = \sigma_{r_1} \frac{y_1 (x^2 + x_b^2)}{y_0 (x_1^2 - x_b^2)} \frac{x_1^2}{x^2} + \sigma_4 \frac{x^2}{x^2} \frac{(x_1^2 + x^2)}{(x_1^2 - x_b^2)} + 0\cdot825 \left(\frac{N}{500}\right)^2 \left(x_1^2 + x_b^2 - 0\cdot575\, x^2 + \frac{x_b^2 x_1^2}{x^2}\right).$$

Pinch fit for Discs and Drums.

In order to ensure that the wheels shall be tight on the shaft at normal speed, they must be pressed on the shafts with an interference fit at least equal to the elastic expansion of the bore due to centrifugal stresses.

This condition can be fulfilled without the maximum stresses in the wheel being greater when the shaft is at rest than the centrifugal stress at normal speed, because in wheels of normal proportions the wheel bore expands during pressing on by only about two-thirds of the pinch allowance, the shaft diameter compressing by the remaining one-third.

CRITICAL SPEEDS.

TURBINE SHAFTS.

At the critical speed of a loaded shaft, a small disturbance sets up vibrations which may reach a dangerous magnitude. For a uniform shaft, when the obliquity of the loading masses may be neglected, the critical speed coincides with the natural frequency of transverse vibration.

Although turbines have been run for considerable periods at their critical speeds without failure, this is a very dangerous proceeding and should be carefully avoided. It follows, therefore, that the critical speed should always be estimated, and should be at least 30 per cent. removed from the running speed.

This particularly applies to turbines of the disc type, and the calculation can be made with some degree of certainty. In drum turbines, the calculation is much more difficult, but in such cases as usually arise the critical speed is much above the running speed.

Table XI. (p. 150) gives the formula for calculating the critical speeds of shafts of uniform diameter in certain standard cases.

Dunkerley has evolved theoretically, and demonstrated experimentally, a law from which can be determined the critical speed of a loaded system which corresponds to any combination of the standard cases.

By means of Table XI. in conjunction with Dunkerley's formula, the first critical speeds of sensibly uniform shafts can be approximately calculated for any combination of loading, and any method of fixing the shaft at the bearings.

Thus if a rotor consists of a uniform shaft loaded with weights $W_2 W_3$ etc. as external loads

n_1 = the critical speed of the shaft without the external loads;

n_2, n_3, etc. = the critical speed of a massless shaft loaded with weights W_2, W_3 etc.;

then the critical speed N of the system is given by

$$\frac{1}{N^2} = \frac{1}{n_1^2} + \frac{1}{n_2^2} + \frac{1}{n_3^2} + \ldots$$

In those cases of rotors having shafts stepped in diameter, as is usually the case in practice, the method already given is only a rough approximation, owing to the difficulty of judging the diameter of the equivalent uniform shaft.

Such cases may be dealt with by obtaining the maximum static deflection y of the shaft under various loads, by the graphical methods due to Mohr.

Then if

N = critical speed in R.P.M.;

$N^2 y = C$, where C is constant.

For impulse turbine shafts supported in bearings which do not fix the direction of the shaft Mr. K. Baumann * has found that the value of C varies from 37,700 to 38,000 if y is in inches.

WHEEL VIBRATION.

Under the influence of such periodic disturbances as partial admission, or even irregularities in steam admission, turbine wheels may be set into synchronous vibration, about symmetrically placed nodal diameters or nodal circles, concentric with the wheel itself. Such vibration may be avoided by correct design.

* *Recent Developments in Steam Turbine Practice*, Inst.E.E., April 1912.

As whirling of shafts may be avoided by the use of rigid or of flexible shafts, so too wheel vibration may be avoided by the use of rigid wheels, every one of whose critical speeds lies well above each of the impulses in the turbine which may stimulate that vibration, and by flexible wheels, where the curve of possible impulses passes between two critical speeds of the wheels.

Of these two methods, that of the rigid wheel is the simpler as this method permits of any desired margin of safety, and, as the effect of rotation is always to increase the frequency for any mode, with the rigid-wheel information as to the magnitude of this increase need only be approximate, and it is only necessary to carry out tests on stationary wheels.

With flexible wheels the margin of safety is necessarily limited to half the range between the critical speeds lying above and below the impulse line. As this range is small it is necessary to know with accuracy the effect of rotation, and also of such factors as temperature.

The determination of the natural frequencies for the various modes of vibration is most readily accomplished by testing, the analytical method developed by Stodola involving very lengthy calculations on account of the number of variables.

For any mode of vibration the natural frequency of a rotating wheel depends on the rigidity of the wheel itself (as in the case of a stationary wheel) and the stiffening effect of centrifugal forces due to rotation. In the case of the usual turbine wheels, the former is by far the more important factor. The expression for a rotating wheel for any particular mode may be written :

$$f_r^2 = f_t^2 + Bn^2;$$

where f_r is the natural frequency of the rotating wheel,
f_t is the natural frequency of same wheel not rotating,
n is the speed of rotation.

For the coefficient 'B' Campbell suggests values from 2 to 3 as a result of extensive experimental work.*

As the periodic disturbing impulses likely to cause wheel vibration are mostly stationary in space it is not surprising that most cases of wheel vibration have been the result of wave forms travelling backward in the rotating wheel and stationary in space. For such vibrations it may readily be shown that the frequency of the periodic disturbances for 1, 2, 3, etc., nodal diameters is once, twice, three times, etc., the speed of rotation of the machine. Thus, for example, a speed of 3,000 r.p.m. would be unsuitable for a wheel whose natural frequency for four-diameter vibration was 200 per sec.

Blade Vibration.

Vibrations of moving blades are usually classified as tangential when the vibration occurs approximately in the plane of the wheel, or axial when the vibration is normal to the plane of the wheel.

Tangential vibration at the fundamental frequency has been mainly responsible for blade vibration troubles in steam turbines, the blades vibrating at a frequency which is a small, simple multiple of the speed of rotation of the machine. As a first approximation, the natural frequency of vibration may be calculated from the usual formula for a cantilever (Table XI.), but the vibration will be modified by a number of causes, such as the degree of rigidity of the attachment to the wheel or drum, the accuracy of manufacture of the blades themselves, and the stiffening effect of centrifugal forces due to rotation. Where blades are shrouded or laced in packets the blades in each packet will normally vibrate in phase, and the consequent bending of shrouding or lacing wire has the effect of increasing the frequency of vibration. The influence on blade frequency of the number of blades tied together has been investigated by Heckmann,† who states that the frequency is progressively increased up to four blades, but that beyond this point, up to twenty blades, the further increase is negligible.

Tangential vibrations at frequencies of the first or second harmonics have been known to cause trouble in some few cases, and here the rapidity of the stress reversals consequent on the high frequencies involved, usually causes failure by fatigue after very short periods of running. In such vibrations the stiffening effect of rotation is usually small, and in those cases where the disturbing impulses necessitate the vibration of blades out of phase with others in the same packet, vibration may be largely prevented by the introduction of a lacing wire at the point of maximum amplitude.

Axial blade vibration of the blades may be regarded as the limiting case of the vibration of a bladed wheel, such as would occur, for example, with blades attached to a wheel of infinite rigidity. In the normal case it is probable that the wheel itself takes some part in the vibration, and difficulties must be avoided by methods similar to those employed in dealing with wheel vibration.

In blade vibration, as in wheel vibration, the number of factors involved makes it difficult to determine the natural frequency with any accuracy by calculation alone : reliable figures can only be obtained by tests on the blades themselves.

TABLE XI.

Uniform Shaft with Distributed Load.		Concentrated Load Carried by a Weightless Shaft.	
Method of Support.	Critical Speed in R.P.M.	Method of Support.	Critical Speed in R.P.M.
	$N = \frac{1,853}{l^2}\sqrt{\frac{E\,.\,I}{w}}$		$N = 325\sqrt{\frac{E\,.\,I\,.\,l}{W\,.\,a^2\,.\,b^2}}$
	$N = \frac{662}{l^2}\sqrt{\frac{E\,.\,I}{w}}$		$N = 325\sqrt{\frac{E\,.\,I}{W\,.\,b^3}}$
	$N = \frac{2,960}{l^2}\sqrt{\frac{E\,.\,I}{w}}$		$N = 246\sqrt{\frac{E\,.\,I\,.\,l^3}{W\,.\,a^3\,.\,b^3}}$ Approximate; holds if load near centre.
	$N = \frac{4,200}{l^2}\sqrt{\frac{E\,.\,I}{w}}$		$N = 325\sqrt{\frac{E\,.\,I\,.\,l^3}{W\,.\,a^3\,.\,b^3}}$ Approximate; holds if load near centre.

N = Critical Speed in R.P.M.
w = Weight of Shaft or other Distributed Load in lbs. per inch run.
W = Weight of Concentrated Load in lbs.
a, b, or l = Length of Span in ins.

E = Young's Modulus of Elasticity in lbs. per sq. in.
I = Transverse Moment of Inertia in inch units = $\frac{\pi d^4}{64}$ for Round Shafts.
d = Diam. of Shaft in ins.

Note Units employed.

MATERIALS FOR TURBINE CONSTRUCTION.

The use of such high peripheral speeds as are common in turbine practice introduced a new consideration into machine design; because, unlike the conditions existing in reciprocating engine parts, the stresses in the various members are in the main due to centrifugal forces resulting from their own rotation. The stresses in a given turbine will, therefore, be proportional to the square of the numbers of revolutions per minute, and to the density of the material.

With an increase in the possible speed of rotation of a given turbine, the efficiency will in general be improved, since the average ratio $\frac{U}{C_0}$ in the various stages will be increased, or a greater heat drop can be utilised with the original efficiency.

On the other hand, the available heat drop per stage might be increased so that the required number of stages for a given efficiency can be correspondingly reduced, or with the same number of stages the mean diameter of the blades can be reduced inversely as the revolutions per minute, both of which alternatives would result in a cheaper turbine.

Hence, it will be seen that in turbine work it is eminently desirable to use the highest possible peripheral speeds, the limit of which will be determined by the ultimate strength of the material employed.

British Electrical and Allied Manufacturers Association's Specifications for Turbine Forgings, Etc.

The following particulars have been extracted from the Association's specifications for forgings for turbine discs, shafts, and general forgings for use on land turbines.

The following table gives the minimum physical properties acceptable for each of four grades of materials:

Grade	I.			II.			III.			IV.		
*	L.	T.	R.	L.	T.	R.	L.	T.	R.	L.	T.	R.
Minimum ult. tensile tons per sq. in.	30	30	30	35	35	35	40	40	40	48	48	48
Yield point .	15	15	15	17½	17½	17½	20	20	20	30	30	30
Minimum elongation per cent.	30	23	20	25	20	18	22	18	16	17	14	12
Minimum reduction in area, per cent.	45	40	38	40	35	32	35	32	30	40	35	30
Bending Angle .	180°	160°	150°	180°	150°	135°	180°	150°	120°	180°	130°	100°
Test radius .	⅜″	⅜″	⅜″	½″	½″	½″	¾″	¾″	¾″	¾″	¾″	¾″

* L.—Longitudinal. T.—Tangential. R.—Radial.

Grades Nos. I., II., and III. are for carbon steels, whereas grade IV. applies to an alloy steel. A margin of 3 per cent. below the reductions in area given in the above table is allowed to the steel maker providing this is compensated by a corresponding increase of 3 per cent. on the elongation.

Bend Tests.

A cold bend test is made upon test pieces having a rectangular section of ⅞ in. by ⅜ in. These test pieces shall be machined and the edges rounded to a radius of $\frac{1}{32}$nd. The test pieces shall be bent over the thinner section, and the bending shall be done by pressure or by blows. The test pieces must withstand being bent around the radii and through the angles given in the table without fracture.

Additional Test before Rejection.

If either tensile or bending test fail to fulfil the test requirements, and the inspector agrees that the test piece does not clearly represent the quality of the material, two duplicate specimens may, if the maker wishes, be tested, and if the results from both are satisfactory the quality of the material shall be judged therefrom, and not from the original test which failed. If, however, either of the duplicate tests fail the material represented will not be approved, and the manufacturer shall have the option of retreating and again presenting for test.

Table XII. gives the physical properties of steels used for steam turbine blading, the data for which have been supplied by the courtesy of Messrs. Thomas Firth & Sons, of Sheffield.

The blades of Parsons turbines are commonly of brass, the usual mixture being alloy of 63 per cent. copper to 37 per cent. zinc, having an ultimate strength of 20 tons per sq. in., an elastic limit of 12 tons per sq. in., and an elongation of 40–50 per cent.

The blades of impulse turbines are usually made of 5 per cent. nickel steel, although bronze blades are sometimes called for.

The physical properties of bronze are greatly dependent on the treatment to which it may have been subjected, cold working having the effect of raising the ultimate strength and reducing the ductility.

Such an increase in the ultimate strength is to a large extent artificial, the material returning to its virgin state under the influence of high temperature or vibration.

The importance of this effect will be emphasised by the figures published by M. Breuil * and reproduced in Table XIII., respecting the effect of temperature on some materials used for blading.

TABLE XII.—PHYSICAL PROPERTIES OF STEELS USED IN STEAM TURBINE CONSTRUCTION

Nature of Material.	Yield Point, Tons per sq. in.	Ultimate Strength, Tons per sq. in.	Elongation on 2-in. Gauge Points.	Purpose for which Material is Employed.	Remarks.
			Per Cent.		
5 per cent. nickel steel sheets	25	40	20	Turbine blades and shrouding strips supplied mild in sheets for stamping and bending	—
5 per cent. nickel steel sheets	—	35–42	20–24	Turbine blades and shrouding strips	Higher carbon content than above
5 per cent. nickel steel bars	30–35	40–45	25	To be drawn into blade sections	—

For some years so-called rustless irons and steels have been used for turbine blades. These materials can now be regarded as of proved usefulness for turbine blading, owing not only to their comparatively high resistance to erosion and corrosion, but to their attractive mechanical properties.

Rustless steels are a chromium alloy, usually for turbine blading of composition within the following limits : carbon, 0·10 to 0·40 per cent.; chromium, 12 to 15 per cent. Ultimate strength, 40 to 50 tons/sq. in.; yield point, 30 tons/sq. in; elongation, 25 per cent.; izod test, 25 ft./lbs.

Most non-ferrous alloys suffer under high temperatures in a loss of mechanical strength and other desirable physical properties.

The following table illustrates the effect of temperature on some typical materials :

TABLE XIII.—NON-FERROUS MATERIALS FOR TURBINE BLADING.

Nature of Material.	Elastic Limit, Tons per Sq. In.	Ultimate Strength. Tons per Sq. In.	Elongation.	Temperature.
			Per Cent	
70 per cent. copper, 28 per cent. pure zinc	34·9	36·2	11	Ordinary
	34·3	36·2	8·5	100° C.
	32·7	34·3	11	200°
	22·2	24·1	30	300°
	7·6	12·7	75	400°
85 per cent. copper, 15 per cent. manganese	38·7	41·3	10·2	Ordinary
	36·8	40·0	10·5	100° C.
	37·5	41·0	11·0	200°
	33·0	36·8	21·0	300°
	21·0	24·1	68·0	400°

* *Engineering*, July 5, 1912.

From this it follows that before figures relating to the strengths of alloys can be accepted as working data the effect of temperature and the previous history of the specimens fractured in the test should be known.

Phosphor bronze has been largely employed for impulse turbine blading when conditions were such that abnormal corrosion was expected, and gives satisfactory results with dry steam where the steam velocities are moderate and the stresses induced in the blades relatively small. The following represent the average properties of this material as given by Mr. W. B. Parker.*

Maximum tensile stress . .	Not under 24 tons per sq. in.
Elastic limit	" 12 "
Elongation on 2 ins. . .	13 per cent.
Modulus of elasticity . .	16,000,000 to 17,800,000 lbs. per sq. in. within a stress range of 0 to 10 tons per sq. in.

The average composition is as follows:

Tin	From 3 to 5 per cent.
Copper	From 94·9 to 96·9 per cent.
Phosphorus	Not less than ·1 per cent.

Nickel-copper alloys are now being used for the manufacture of turbine blading, the best known being Monel metal (*Henry Wiggin & Co., Ltd.*). This metal when drawn into the form of turbine blading has the following properties:

	At 60° F.	At 750° F.
Ultimate stress . . .	41·9 tons per sq. in.	36·4 tons per sq. in.
Yield point . . .	37·7 "	31·2 "
Elongation on 2 ins. .	24 per cent.	16·5 per cent.
Reduction of area . .	60 "	60 "

Modulus of elasticity: 22,500,000 lbs. per sq. in. over a stress range of 1 to 15 tons per sq. in.

The composition (tests by the National Physical Laboratory) is as follows:

Nickel	67%
Copper	28%
Iron	1–2%
Manganese	1–2%
Lead, tin, and antimony . . .	Nil.
Also silicon and carbon.	

Properties of Steel at High Temperatures.

The use of higher initial pressures and temperatures in steam turbines (and boilers) has been seriously hindered by lack of precise information on the behaviour of materials, particularly steels, at high temperatures. During recent years a good deal of work has been done on the subject, and though much still remains to be investigated, it is now possible to indicate, in general terms, the effect of high temperatures on the more important physical properties.

Ultimate and Yield Strengths.

The curves in figs. 27 and 28, due to Mr. K. Baumann,† show the ultimate tensile stress and yield point, or the limit of proportionality, for a 0·15 per cent. carbon steel and for an alloy steel, at various temperatures. It will be noted that the limit of proportionality of the carbon steel diminishes very rapidly at temperatures beyond 300° F., whilst the yield stress of the alloy steel falls off very little up to about 700° F., indicating that this steel is suitable for use at high temperatures. Mr. Baumann proposes a factor of safety of at least 2 on the proportional limit or 3 on the yield stress.

FIG. 27.

CREEP.

It has become recognised that materials sufficiently stressed at elevated temperatures extend continuously or 'creep.' The rate of creep depends on the stress and temperature to which the material is subjected and the character of the material itself. In order to ensure safety it is necessary to keep the rates of creep below certain defined amounts. It seems possible that creep occurs with stress at all temperatures, but increases very rapidly and at an increasing rate, with

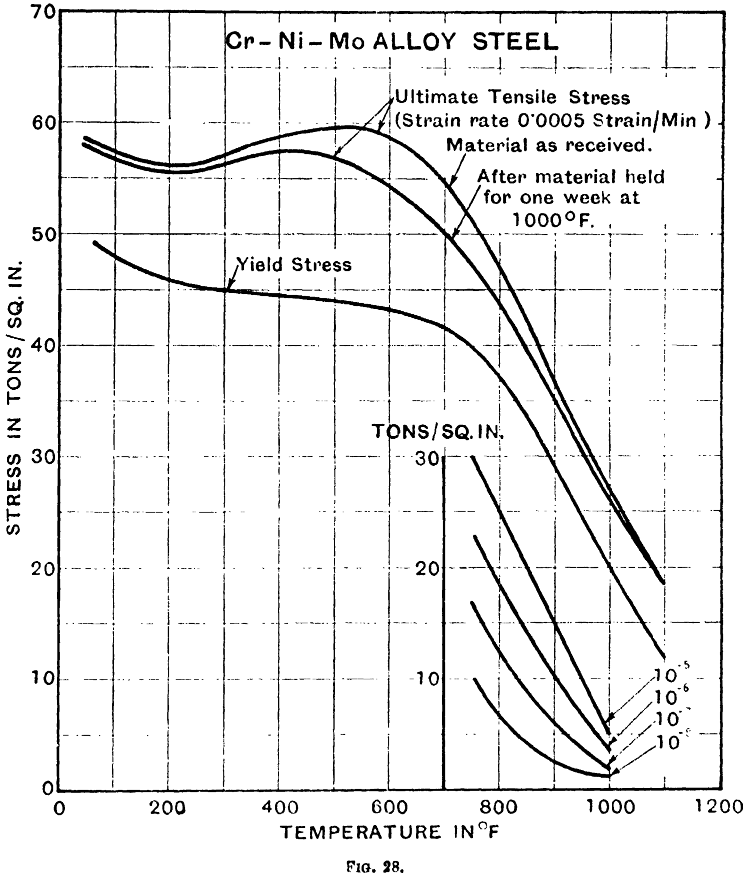

FIG. 28.

temperature and stress. It follows, therefore, that to maintain at higher temperatures the factors of safety on which design experience has been accumulated, it is necessary either to reduce the stresses to which the material is subjected, or to utilise materials known to possess high resistance to creep.

Fig. 29, produced by Mr. R. W. Bailey * from the results of his own tests and those of other investigators, shows the comparative creep resistance of medium carbon steels at temperatures from 750° F. to 1000° F., and indicates the reduction in stress necessary to maintain, for a given steel, the creep rates obtaining at 750° F.

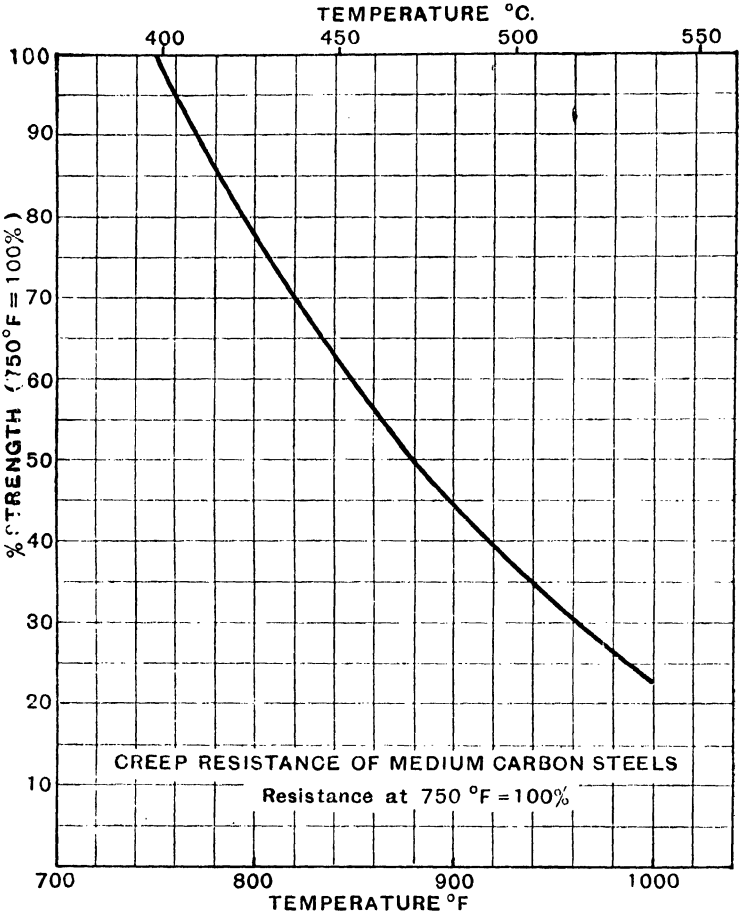

FIG. 29.

In figs. 29 and 30 are shown also the probable creep strengths of the materials cited, at the higher temperatures, for creep rates of 10^{-8} to 10^{-5}. It should be noted, however, that these curves cannot yet be regarded as established but represent an intelligent anticipation of the creep properties of the materials, from which the actual properties will probably not differ greatly.

* 'Creep of Steel under Simple and Compound Stresses.' World Power Conference, Tokyo, 1929.

The following permissible creep rates are suggested by Baumann * for various parts of steam plant.

Turbine discs pressed on shafts	10^{-9}
Bolted flanges, turbine cylinders	10^{-8}
Steam piping, welded joints, boiler tubes	10^{-7}
Superheater tubes	10^{-6}–10^{-5}

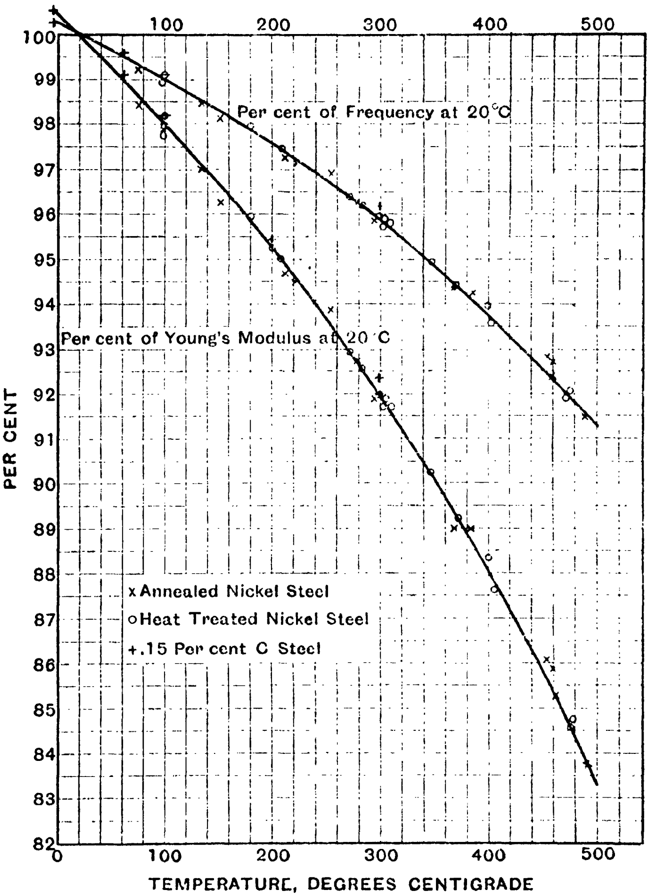

FIG. 30

It will be evident from figs. 27 and 28 that whilst in some cases permissible stresses will be limited by considerations of creep, in other cases the limit will be imposed by the necessary factors of safety on yield stress or proportional limit.

* *Loc. cit.*

Young's Modulus.

The variation with temperature of the Modulus of Elasticity, E, is shown for various steels in fig. 30,* which gives also the corresponding change in natural frequency of vibration. At 900° F. (480° C.), for example, the value of E is only 85 per cent. of its value at 60° F., so that deflection will be 18 per cent. greater and critical speeds 8 per cent. less than at 60° F.

Lubrication System.

In all cases except where ring lubrication is employed for small turbines, an oil pump is provided to maintain a pressure of about 10 lbs. per sq. in. in the lubricating system. It should be emphasised that the actual oil pressure is of secondary importance, the prime object being to flush the bearings with a copious flood of oil, and that for this purpose 2 lbs. per sq. in. may be sufficient in a properly designed system. The oil on leaving the pump passes through a cooler of sufficient capacity to maintain the temperature of the oil leaving the bearings at about 60–68° F. above that of the inlet cooling water, bearing temperatures of 150° F. being quite permissible. The main oil pump is usually driven by gearing from the turbine shaft, and the normal pressure is reached when the turbine motor is running at about one-third the normal speed. An auxiliary pump, hand-driven in the case of small turbines, but usually steam-driven, and controlled by an automatic regulator for larger machines, is usually provided to supply oil under pressure during starting up or shutting down, when the speed of the set is less than one-third the normal. An oil strainer should be placed on the suction side of the pumps to prevent grit being circulated. Two to three gallons of oil should be taken out of the tank daily and carefully filtered, the level of the tank being kept constant by making up with freshly filtered oil or, when necessary, new oil. Once in each twelve months the oil tank and all accessible portions of the lubricating system should be emptied and cleaned; the tank should then be filled sufficiently with paraffin oil to enable the whole system to be flushed by operating the hand pump. The paraffin oil dissolves any gummy matter which may have deposited from the lubricating oil and thoroughly flushes away all dirt to the oil tank; the paraffin can then be removed and new or freshly filtered oil put in. These simple precautions will result in a real economy in oil consumption and a freedom from troubles and maintenance charges which will amply repay the trouble involved.

There is a large number of lubricating oils supplied by makers of standing, all of which will give satisfactory results in operation. For turbines driving geared installations an oil to the following specification has been found to give satisfactory results:

Heavy Turbine Oil.

The specific gravity at 60° F. should be from 0·89 minimum to 0·91 maximum.

The flash point taken by a closed test should not be less than 390° F.

The viscosity measured with a Redwood viscometer should be within the following limits:

At 68° F.	Minimum 650 seconds.	Maximum 800 seconds.
At 140° F.	„ 90 „	„ 100 „

The acidity expressed as SO_3 should not exceed 0·005 per cent.

One of the most important properties lies in the freedom of a suitable oil from a tendency to form an emulsion. Suitable oils should satisfactorily pass the following test:

When steam is passed into 100 c.c. of oil until the total volume of the condensate and oil measures 200 c.c., the whole of the oil shall separate out within ten minutes, leaving the water clear.

The sludge value of the oil carried out, according to Dr. Michie's test should not exceed 1·2 per cent.

The following specification would apply to oils suitable for steam turbines driving generators, etc., direct:

Light Turbine Oil.

The specific gravity at 60° F. shall be 0·87 minimum to 0·89 maximum.

The flash point of the oil measured by a closed test shall not be less than 365° F.

The viscosity measured with a Redwood viscometer shall conform to the following:

At 69° F.	Minimum 300 seconds.	Maximum 400 seconds.
At 140° F.	„ 60 „	„ 75 „

The acidity expressed as SO_3 shall not exceed 0·005 per cent.

When steam is passed into 100 c.c. of oil until the total volume of condensate and oil measures 200 c.c., the whole of the oil shall separate out within five minutes, leaving the water clear.

The sludge value, measured by Dr. Michie's test, shall not exceed 1·2 per cent.

* Kimball & Lovell. American Physical Society, *Physical Review*, vol. 26, No. 1, July 1925.

PROCEDURE IN STARTING UP LARGE TURBINES.

While the general guidance given in the following remarks is, in the main, intended to apply to relatively large units (say turbines of 10,000 kw. capacity and larger), the procedure is an excellent one to follow on smaller sets.

The time intervals indicated can be reduced as the size of the set is reduced.

First operation.—Start up condensing plant and obtain 20 ins. to 24 ins. vacuum.

Second operation.—To warm up turbine, open stop valve sufficiently to start it rotating, then close it down until a steady speed of not more than 10 per cent. of the normal speed is obtained. Maintain this condition for ten to fifteen minutes during which vacuum is increased.

Third operation.—Increase the speed by gradual and steady increments at a rate of from 5 per cent. to 10 per cent. of normal speed per minute.

Fourth operation.—Synchronise set and switch on to bus bars.

Fifth operation.—Build up load on set at a steady rate of from 5 to 10 per cent. of normal load per minute.

The procedure here outlined is a safe one to be recommended in normal practice; in an emergency the time intervals can, of course, be reduced.

BRITISH STANDARD SPECIFICATION FOR STEAM TURBINES.*

No. 132 (Abstract).

RATING.

A steam turbine shall be capable of giving continuously a specified output when running under specified conditions as regards speed, steam pressure, temperature and exhaust pressure.

OUTPUT OF THE TURBINE WHEN WORKING NON-CONDENSING.

If the specified steam pressure is not less than 165 lbs. per sq. in. absolute, and the rated output of the turbine is not more than 3,000 kw., the turbine shall be capable of developing 30 per cent. of its rated output when exhausting to the atmosphere. For turbines of larger capacity the output must be settled between the purchaser and the manufacturer.

Note.—It is undesirable to work high-pressure steam turbines exhausting to the atmosphere, and this should only be done in cases of emergency. Even under this condition, the turbine should not operate in this way for a longer time than is absolutely necessary.

MAXIMUM SPEED.

The turbine shall be capable of withstanding for five minutes, without injury, a speed 15 per cent. in excess of the rated speed.

GOVERNING CHARACTERISTICS.

When the rated load is taken off or on the permanent speed variation shall not exceed 4 per cent.

SPEED ADJUSTMENT.

Means shall be provided to enable the speed to be adjusted by plus or minus 5 per cent. when working under synchronising conditions.

EMERGENCY CUT-OFF SPEED.

The emergency governor shall be set to shut off steam if the speed exceeds 9 to 11 per cent of the rated speed. When operating at rated speed and the rated load is thrown off the maximum variation in speed shall not be sufficient to bring the emergency governor into operation.

ECONOMIC RATING OF THE TURBINE.

The turbine shall be designed to give a minimum steam consumption at 80 per cent. of its rated output.

STEAM (OR HEAT) CONSUMPTIONS.

If steam (or heat) consumptions are guaranteed for various outputs, the average steam consumption shall be obtained by

Multiplying the consumption at the rated output by b_1.
" " 80 per cent. of the rated output by b_2.
" " 60 " " " b_3.
" " 40 " " " b_4.

* By permission of the British Standards Institution.

and dividing the sum by $b_1 + b_2 + b_3 + b_4$, the multiplying factors to be specified by the purchaser or mutually agreed.

The steam (or heat) consumption may be requested and furnished either for some specified load or for a series of loads, but the guarantee shall be confined to the one specified load or to the weighted consumption as above.

Tolerance.

For the purpose of comparing test consumption with the guarantee performance a tolerance calculated as follows shall be allowed :—

Percentage tolerance (+ or −) =

$$\frac{\text{Arithmetical sum of percentage corrections} - 5}{4} + 2\tfrac{1}{2} \text{ per cent.}$$

Hydraulic Test for Parts Exposed to Full Boiler Pressure.

All parts exposed to the rated steam pressure shall be tested with a hydraulic pressure 50 per cent. in excess of the rated pressure. The machine as a whole shall be tested with a hydraulic pressure of 15 lbs. per sq. in. gauge.

Critical Speed of Rotating Element.

The critical speed of the turbine shaft shall not be within 20 per cent. above or 20 per cent. below the rated speed.

TURBINE SPEED-REDUCTION GEAR.

The speed at which it is most desirable to run a turbine is limited only by the strengths of the materials used in its construction. Unfortunately this limit of speed cannot be approached when the turbine is employed for direct driving of propellers, D.C. generators of large output, rolling mills, line shafting, etc., and in such cases where comparatively low speeds are essential not only does the turbine become heavy, costly and inefficient, but direct turbine drive is often quite out of the question.

For this reason several systems of speed reduction have been introduced, and are being successfully applied.

Double Helical Gears.

Speed reduction by means of double helical gears was employed in the earliest days of turbine engineering by Dr. Delaval, whose turbines, running at speeds of the order of 10,000 r.p.m., could not be directly coupled to electric generators. The gearing of these turbines gave remarkably little trouble, and although the outputs were low it is notable that even to-day this is the most successful system of speed reduction.

Double helical gearing for large turbines was introduced by Sir C. A. Parsons, who with characteristic courage first introduced the system in the famous case of the propelling machinery of the s.s. 'Vespasian,' and the drive of a rolling mill at Calderbank Steel Works.

In the earlier installations difficulties were experienced through minute inaccuracies of the gear teeth, which gave rise to very noisy working. This was traced to errors in the gearing of the table of the gear-cutting machine by Sir C. A. Parsons, who has very materially reduced the trouble by arranging a 'Creeping' table giving the gear blank an advance of 1 per cent. relatively to the main table of the machine. The improvements in modern gear-cutting machines have eliminated the inaccuracies referred to, so that the creeping device is no longer essential.

The helix angle adopted varies from 20° to 45°, the usual angle in modern practice being 30°.

The teeth of modern double helical gears are of the standard involute type, the pressure angle adopted by different makers varying from $14\frac{1}{2}$° to 20°.

If p = average pressure in lbs./inch tooth face.
 L = total length of tooth face in inches.
 D = diam. of pitch circle of pinion in inches.
 R = revs. per minute of pinion.

$$V = \text{pitch speed in feet per second} = \frac{\pi D}{12} \times \frac{R}{60} = \frac{\pi D}{720} \times R.$$

Then

$$\text{Horse-power transmitted} = P = \frac{pLV \times 60}{33{,}000} = \frac{pLV}{550}$$

Dr. Stoney states that V should be kept between the limits 100 and 130 ft./sec. He also gives the maximum permissible pressure $p = 120d$ for pinions smaller than 5 inches diameter, and $p = 175\sqrt{d}$ for larger pinions.

Fig. 31 shows curves co-ordinating p and d, published by Mr. F. H. Hodgkinson *Engineering*, Jan. 10, 1919).

With pinions having two bearings where E = Young's modulus of elasticity = 30×10 lbs./sq. inch

$$I = \text{the moment of inertia of the pinion} = \frac{\pi D^4}{64}$$

$$\text{Transverse deflection at the centre} = \delta_1 = \frac{5}{384} \cdot \frac{pL^4}{EI}.$$

This is one of the determining factors in design, and, according to Stoney, should not exceed 0·0002 inch.

For pinions having three bearings, the maximum deflection on each portion of the pinion between two bearings should not exceed 0·0002 inch, and in most cases this is not the condition determining the diameter.

Another condition fixing the design of the pinion arises from the fact that the torsional deflection opens the teeth, thus preventing uniform distribution of pressure on them. This torsional opening, δ_2, according to Stoney, must be limited to less than 0·0001 inch, and is given by the following expressions:

$$\text{For two or three bearing pinions } \delta_2 = \frac{CL}{10 \times 10^4} \text{ inches over one helix.}$$

In the Melville-McAlpine gear, manufactured and developed by the Westinghouse Machine Co., the pinion is supported in a floating frame which permits its axis to take up a slight inclina-

DOUBLE HELICAL GEAR CURVES.

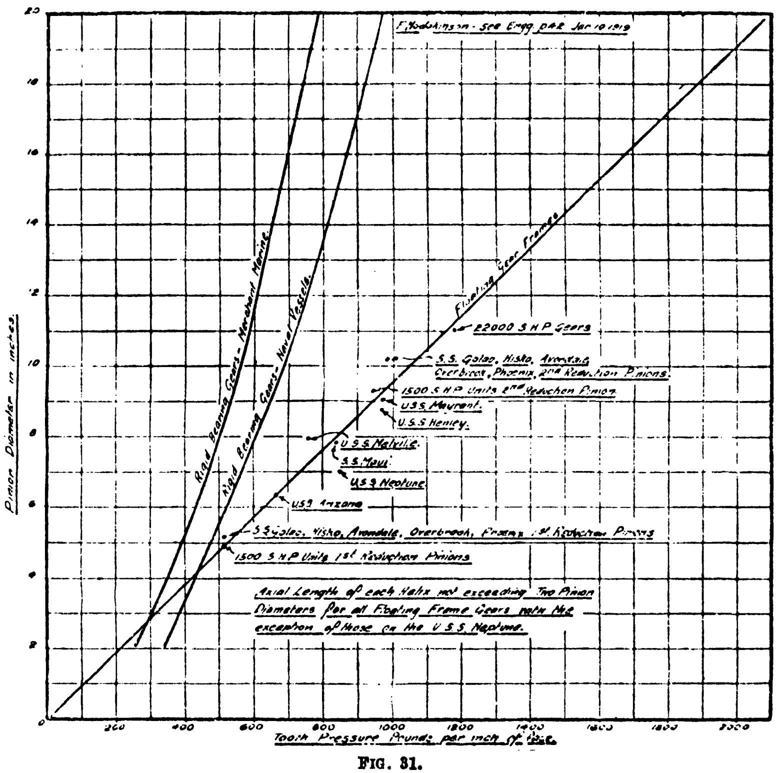

FIG. 31.

tion in the vertical plane relatively to the slow speed shaft. The torque on the pinion tends to increase the helix angle of one half of the pinion and decrease that of the other half, so that if the helix angle of the pinion is the same as that of the wheel, as load comes on, the helix angles become different. If the axis of the pinion is inclined in a vertical plane relatively to the wheel, the change in the helix angle with load can, it is claimed, be very largely compensated, so that with the floating pinion larger torques can be transmitted through a given size pinion than through a pinion supported in rigid bearings. According to the inventors, the floating frame also corrects to a certain extent errors in the teeth and in alignment of the gears.

The action of this gear is well explained, together with some authoritative notes on double helical gearing, in a series of articles by Mr. J. H. McAlpine, which appeared in *Engineering*, commencing May 5, 1916.

In these articles Mr. McAlpine suggests the use of the 'Power Constant' for comparing different gears; these he defines as follows:

If

D = pitch diameter of pinion in ins.; L = length of tooth face in ins.; p = average pressure in lbs. per in. of tooth face; R = r.p.m.; O = power constant; P = horse-power transmitted:

Then

$$P = \frac{\pi D R p L}{33000 \times 12}.$$

For correctly designed gears, p and L vary as D, therefore

$$P = O (D^3 R),$$

and

$$O = \frac{P \times 1000}{D^3 R}.$$

For gears having the pinion supported in two rigid bearings, the power constant 'O' should not exceed 1·5.

'O' is usually from 1·2 to 3·0, for gears having three bearings on the pinion.

Gears having the pinion supported in a floating frame have worked very successfully with a power constant of 4.

The ratio $\frac{L}{D}$ should preferably be equal to 4 in gears having the floating frame.

For best results the pinions for all sizes should have from 26 to 30 teeth; if the number is appreciably reduced interference takes place.

The efficiency in double helical gearing varies from 98·5 per cent. in large gears to 97·5 per cent. in small sets, so that from 1·5 per cent. to 2·5 per cent. of the heat equivalent of the power transmitted has to be dissipated in the lubricating oil cooling system.

The gears are usually lubricated by spraying the oil on the teeth at the point of contact.

The success of a gear depends to a larger extent than is generally supposed on the rigidity and correct design of the gear-box and lubricating system, and where experienced engineers are responsible for these details every confidence can be placed in a turbo-geared proposition.

Rapid advances have been made in the application of steam turbines to the mercantile marine, by the introduction of double reduction gearing. Single reduction gears having ratios larger than 15 to 1 are scarcely practical for ship propulsion, but a reduction of, say, 42 to 1 can be commercially obtained by a double reduction gear having two trains of wheels, the first having a reduction of, say, 6 to 1 and the second 7 to 1.

Such double reduction gears are now being used having efficiencies at full load of about 97 per cent.

Now that such large ratios of reduction are commercially practicable, both the turbine and the propeller can be run at the speed most suitable for each respectively.

See also p. 996 (Vol. I), and 'Reduction Gear for Propulsion,' p. 290.

The possibilities and limitations of this type of transmission are illustrated by the following figures given by Prof. Fottinger.*

No. of Stages.	Gear Ratio.	Estimated Efficiency.
1	5 to 1	90 per cent.
2	7½ to 1	90 ,,
3	10 or 12 to 1	88

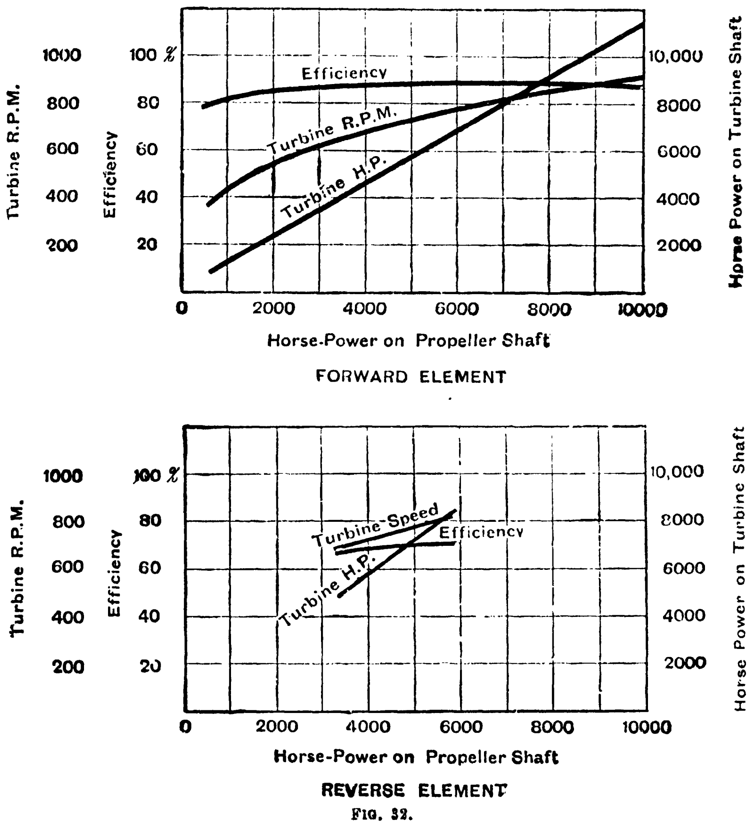

FIG. 32.

Unfortunately the ratios usually required for marine purposes are from 10 to 1 up to 20 to 1 and as it is doubtful if more than single stage transmitters could be commercially adopted, it will be seen the field open to this type is limited. A distinct advantage lies in the fact that the discharge from the turbine pump element can be diverted to a reverse water turbine, by which means reversal can be easily and economically effected. The water used in the transmitter is usually the boiler feed, and in this way some of the losses can be recovered in feed water heating, but it is difficult to see how the gain can possibly exceed 1 per cent. measured at the driven shaft.

Fig. 32 shows the results of tests on a 10,000 B.H.P. transmitter.†

* *Engineering*, March 14, 1913.

† *Z. V. d. I.*, May 16, 1913.

In Table XIV. are given some particulars of machines typical of modern large turbine practice. The table is based largely on that given by Gibb in 'Post-War Land Turbine Development,'* and it is pointed out by the author that in most cases the heat consumption must be regarded as approximate only, since in a large number of cases insufficient information is available and certain assumptions have had to be made.

A comprehensive analysis of particulars of large turbines by the leading manufacturers is given by Baumann in 'Neuere grosse Dampfturbinen.' (*V.D.I.*, June 14, 1930.)

SECTION XXVII

PART V

STEAM CONDENSERS — HEAT TRANSMISSION IN SURFACE CONDENSERS—AIR PUMPS—ROTARY AIR PUMPS—STEAM JET EJECTOR AIR PUMPS—FEED PUMPS—COOLING TOWERS—STEAM ACCUMULATORS.

(Revised by R. H. Parsons, M.I Mech E)

STEAM CONDENSERS.

The principal types of condenser are:—

(1) Jet condensers, in which the condensing water mixes with the steam.

(2) Surface condensers, in which the cooling water and the steam are kept separate.

The jet type involves much less initial cost than surface condensing plant, and requires less attention and cleaning, but requires more power to operate it. The choice of type depends to a very large extent on the nature and cost of the water available for cooling and for boiler feed.

Jet condensers are preferred to surface if the cooling water is fit for boiler feed or if a suitable boiler feed, other than the condensed steam, is available.

If ample water is available, but not suitable for boiler feed, the surface condenser is advisable. In some cases the water may be too bad even for use in surface condensers, causing choking of tubes or serious corrosion; jet condensers may then be used and boiler feed obtained from a limited supply of good water, even though the price of the good water is high.

Jet Condensers.

With low-level jet plants it is necessary that the cooling water should be drawn in by virtue of the vacuum, and an efficient vacuum breaker be fitted whereby, in the event of the pumps connected to the condenser suddenly shutting down, the vacuum will be broken, thus stopping the flow of the injection water, and preventing it from entering the L.P. cylinder.

The mixture of cooling water and condensed steam is preferably withdrawn at the bottom of the condenser, and the air is taken off near the top. This involves separate air and water pumps, but in the case of engines of moderate power having their own jet condenser one pump for both air and water is commonly used. In the barometric or elevated type of jet condenser no water extraction pump is required, as the condenser being fixed at the barometric height is self-draining. Usually, however, an injection pump is required to lift the water partly up to the condenser, as the vacuum can be utilised to a certain extent for drawing the water into the condenser the same as in the low-level plant. These condensers are more expensive than the low-level type, and, due to a long exhaust pipe being necessary, require to maintain a slightly higher vacuum for an equivalent exhaust pressure at the turbine or engine exhaust flange.

The capacity of a contra-flow jet condenser should not, according to *Sim*, be less than one-quarter of the volume of the cylinder or cylinders exhausting to it, and need not be more than one-half. For quick-running engines one-third is generally sufficient. For turbine work or continuous steam flow, 0·008 to 0·011 cub. ft. per lb. of steam per hour is reasonable.

Surface Condensers.

Cooling water should be arranged to pass through the tubes and steam to flow over the tubes. It is usual to divide the tube element in two, three, or four passes according to the design of the plant, the passes being arranged so that the hottest water meets the hottest steam.

Large spaces should be allowed between the tubes at the condenser inlet to obtain a good flow of steam into the heart of the condenser. The steam flow should always be as direct as possible, changing the direction of flow should be avoided, and to ensure an evenly distributed flow over the top of the tubes a dome should be formed on the top of the condenser body.

Internal guide plates are used by some makers, in order to distribute the entering steam uniformly over the tubes.

It is important that the drop of pressure across the groups of tubes should be reduced to a minimum. Baffles in the tube space are not recommended, as their total effect is harmful.

The pitch of the tubes should be such that they will allow sufficient area for the flow of steam without an excessive pressure drop through the condenser.

The number of tubes which can be fixed in a square foot of plate is,

$$N = \frac{166}{p^2};$$

where,

N = number of tubes per sq. ft. of plate; p = pitch of tubes in ins.

Air in the condenser must not be allowed to remain stagnant round the tubes.

Frequently a section of the condenser next the air pump suction branches is partitioned off to act as a cooler for the air passing to the air pump. The first water pass takes place through the tubes in this section. The cooling of the air reduces the volume to be dealt with by the air pump.

The condensate should be as hot as possible, and in good normal condensers, it is delivered at a temperature almost equal to that corresponding to the vacuum.

The drop of vacuum through the condenser should not exceed 0·2 in mercury.

The practice in power stations of extracting steam from the turbine for feed-heating reduces the steam passing to the condenser, and for turbines of a given output, the size of the condenser may be reduced.

A good rule for power station condensers is to allow a cooling surface in sq. ft. equal to the maximum rated capacity of the generator in K.W. This is equivalent to a heat transmission of about 5,600 B.Th.U. per sq. ft. per hour through the tubes at the economical rating of the machine.

The factors underlying the design of condensing plant were fully examined by Mr. W. T. Bottomley in a paper read before the N.E. Coast Institute of Engineers and Shipbuilders in 1941. He concluded that it was uneconomical to employ a higher velocity than 5 ft. per sec. for the water through the tubes on account of the increased pumping costs, and he maintained that, contrary to a prevalent opinion, experience showed that trouble from deposits in the tubes was not mitigated by increasing the quantity of circulating water. The only way of counteracting the formation of such deposits was by increasing the cooling surface and reducing the water velocity. The economical load on a condenser for dirty conditions should be about 5,300 B.Th.U. per sq. ft. per hour, instead of the 7,000 B.Th.U. generally recommended. When the size of the power house building was fixed, it paid to provide the largest possible cooling surface in the space available, not by reducing the pitch of the tubes but by increasing the overall dimensions of the condenser shells. Condensers working with tidal water or with cooling towers, and fitted with 1 in. tubes should have at least three passes, with four passes for the smaller machines. Only in cases where the circulating water pipes were very short, and the machines very large, could a single pass condenser be economically justified. Considerations of overall economy also indicated that the greater the length of the circulating water pipes, the less should be the quantity of cooling water, and the lower should be the designed vacuum.

The most practical operating check on the efficiency of a surface condenser is to note the difference between the temperature corresponding to the vacuum, and the outlet temperature of the circulating water. This difference is not affected by the temperature of the water at inlet and will not be affected by more than a fraction of a degree by large variations in the quantity of circulating water. Hence if the temperature differences are recorded at various loads when the condenser is known to be in perfect condition, the same differences should always be obtained at the stated loads. Any increase of the temperature difference at a given load is a sign that the condenser is getting dirty.

In order to prevent the formation of slime and growth of organisms in the tubes, chlorination of the circulating water has been introduced. It results in saving of cleaning and increasing the 'availability factor' of the plant.

Condensing Plant in Power Stations.

According to a 'Progress Review of Power Station Equipment,' by I. V. Robinson, (*Jour. Inst. Elect. Eng.*, March 1935), there is a tendency to specify a vacuum of which the corresponding temperature is only 21° F. above the inlet temperature of the circulating water.

While cast iron is still used for condenser shells, welded steel shells are very popular, with, as a rule, cast-iron water heads.

Single pass condensers remain the favourite in America but not in Europe.

Tube vibration has been largely overcome. Fine clearance in the holes of the supporting plates and uneven pitching of these plates are beneficial in preventing vibration.

Air ejectors are always of steam jet type, and except in few cases have surface inter- and after-condensers. Except for vacua below 29 in., 3-stage ejectors are generally used.

De-aerators are not much used as condensate is so well freed from air at the base of the condenser with the latest form of hotwell. Plants are now very airtight, 'a pot of paint is worth as much as a de-aerator.' In Great Britain it is established practice to instal air extractors having a dry air capacity of 1 lb. per 2,000 lb. steam, though this basis is admittedly unduly ample.

Surface Condenser Practice.—For a critical survey of practice in surface condensers and auxiliaries, see *The Engineer*, August 24 to November 23, 1934.*

Tube Plates.

These are usually of rolled brass alloy of copper 62 per cent., zinc 37 per cent., and tin 1 per cent., and are generally made of a thickness equal to tube diameter + 0·25 in.

Tubes.

These are of solid drawn brass alloy, of copper 67 per cent., zinc 32 per cent., tin 1 per cent., or where salt or corrosive water is used, of Admiralty mixture alloy, of copper 70 per cent., zinc 29 per cent., tin 1 per cent. A still better tube to use where corrosion is liable to occur is copper of 99 5 per cent. purity, but the initial cost of these is often found prohibitive. Tinned tubes should be avoided, since unless the tinning is absolutely perfect, serious pitting is liable to occur. The Admiralty practice is to adopt untinned tubes of the alloy referred to.

The unsupported length of tubes should not exceed 100 times the diameter, and where the length of the condenser exceeds this dimension, tube-supporting plates should be fixed. The tubes should be secured in the tube plates by tape packing and ferrules, the latter having an internal lip to prevent 'creeping' of the tubes.

Ferrules should allow a space for free movement of the tube ends, and should be rounded, so as to reduce to a minimum the loss of head of the water at its entry into the tubes.

According to Stanton, in a condenser of a given surface for maximum efficiency, the tube length should be as great as possible. As regards tube diameter he says that condensers will be equally efficient in which the ratio $\frac{l n^{-1}}{d}$ = constant, where l = length in feet, n = number of tubes, d = external diameter of tube in feet. Tube diameters should be chosen which offer the least aggregate resistance to flow. Resistance is, he finds, proportional to l^{4-2n}, and is therefore least when the tubes are the smallest practical diameter. He considers the best position for tubes is vertical and the water movement downward.

Tube diameters may vary from ½ in. to 1 in., but are usually ⅝ in. or ¾ in., in fact ¾ in. diameter and 18 S.W.G. (0·48 in.) thickness are practically standard.

Unannealed hard-drawn condenser tubes tend to become corroded more readily than tubes that have been annealed.

Cleaning Condenser Tubes.

A method of cleaning condenser tubes which has given good results is to shoot 'bullets' through the tubes by means of a compressed air pistol.

At Barton power station (see Guy and Lamb, Inst. Mech. Engineers, 1930) the bullets used for condenser tubes ·904 in. bore consist each of seven leather washers, giving a total thickness of 1¼ in., held together by a central pin. The washers are [illegible] in. diameter and are slightly staggered, the central holes having clearance for that purpose. Four rows of copper gauze are inserted between the washers and bent over their edges. The air pressure used is 70 to 80 lbs. per sq. in.

The condensers are cleaned, as a rule, when the vacuum has fallen 0·2 in. below the datum value.

The wages cost for cleaning by shooting as compared with brushing was reduced from £42 to £8.

The extra fuel cost of operating a 26,000 K.W. turbo generator at 0·2 in. loss of vacuum, with coal at 14s. 3d. per ton, was £2·96 per day.

* Reprinted as *The Surface Condenser*, by B. W. Pendred (Sir Isaac Pitman & Sons, Ltd.)

British Standard Specification for Condenser Tubes and Screwed Glands for Condensers for Marine Purposes.

(No. 3000—1931.)*

(*Abstract.*)

1. The material of the shells from which the tubes for condensers and for screwed glands are drawn shall be an alloy of copper and zinc as follows :—

***For Condenser Tubes :* 70/30 Alloy.—Containing not less than 70 per cent. of metallic copper**

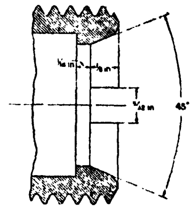

FIG. 1.—View of Outer End of Screwed Glands for ⅝ in. and ¾ in External Diameter Condenser Tubes.

and not more than a total of 0·75 per cent. of materials other than copper and zinc (except that, if so specified, it may contain 1 per cent. of tin or 1½ to 2 per cent. of lead).

***For Screwed Glands :* 60/40 Alloy.—Containing not less than 60 per cent. of metallic copper and not more than a total of 0·75 per cent. of materials other than copper and zinc (except that, if so specified, it may contain 1 per cent. of tin or 1½ to 2 per cent. of lead).**

3. The condenser tubes shall be of ⅝ in. or ¾ in. external diameter as may be specified—and they shall not be larger than, nor more than 1½ per cent. smaller than, the specified external diameter. The tubes shall be of uniform diameter throughout and the thickness shall be 18 S.W.G. within the usual manufacturing margins.

5. For ⅝ in. external diameter condenser tubes the average weight per 100 ft. run shall be not more than 32¾ lbs. and not less than 31¼ lbs., and for ¾ in. external diameter condenser tubes the average weight per 100 ft. run shall be not more than 40 lbs. and not less than 38 lbs., *i.e.* 2½ per cent. above or below the theoretical weight.

6. Each condenser tube shall be tested internally by water pressure to 600 lbs. per square inch.

Condenser Tube Corrosion.

See 'Eighth Report to the Corrosion Research Committee of the Institute of Metals.' Abridged Report, '*Engineering*,' Sept. 7, 1928.

Heat Transmission in Surface Condensers.

Let K = coefficient of heat transmission from steam to cooling water, *i.e.* the number of B.Th.U. transmitted per hour per sq. ft. of cooling surface per degree F. of mean temperature difference.

$\frac{1}{K}$ represents the resistance to the flow of heat. This resistance is made up of :—

(1) The resistance to the flow of heat from the steam to the external surface of the condenser tube, $\frac{1}{k_1}$ say ;

* See also B.S.S. 378—1941.

(2) resistance to conduction through the tube $= \frac{t}{k_2}$, where t = thickness of tube in inches and k_2 = conductivity of metal in B.Th.U. per hour per sq. ft. per temperature gradient of 1° F. per inch ; and

(3) the resistance to flow of heat from the tube to the water $= \frac{1}{k_3}$ say.

The total resistance $\frac{1}{K} = \frac{1}{k_1} + \frac{t}{k_2} + \frac{1}{k_3}$.

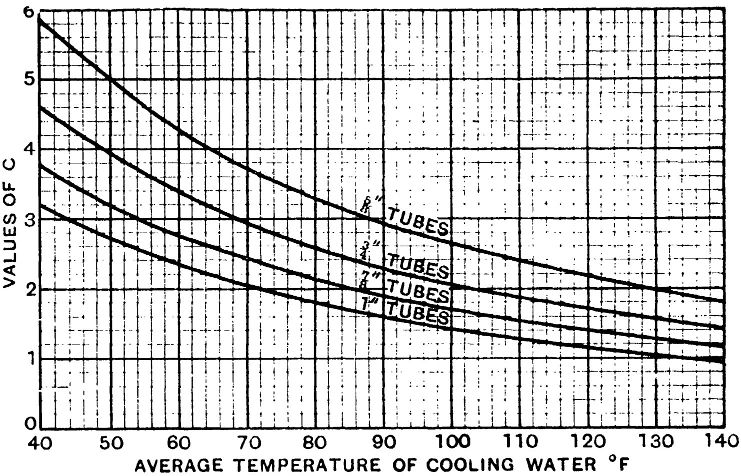

FIG. 2.

For brass tubes, 18 S.W.G. thick, the middle term $\frac{t}{k_2}$ is negligible in comparison with the others.

k_1, the coefficient for flow from steam to metal, depends on the velocity with which the steam flows over the tubes, the presence of air in the condenser, and the cleanliness of the tubes.

k_3, the coefficient for transmission from tube to water, is the most important term. It depends upon the water velocity, the diameter of the tube, cleanliness of tube surface, and also on the mean temperature, there being evidence that the heat transmitted is greater at higher temperatures even though the temperature *difference* is the same.

For the usual tube sizes and usual temperatures, it will be seen that the chief variable factor influencing the overall transmission rate is the water velocity.

Data for k_1 and k_3 are not yet thoroughly established, and the data given by various experimenters for the coefficient K also vary widely. This is due not only to experimental error but to the fact that frequently some of the factors influencing the transmission rate are not taken into account at all.

The resistance to heat flow may be expressed as—

$$R = R_a + R + R_t + R_w,$$

where

R_a is due to the effect of air blanketing the surface of the condenser tubes ;

R depends on the viscosity and density of the film of condensate clinging to the tubes;

R_t is the resistance to conduction through the metal ;

R_w depends on the velocity of the condensing water in the tubes, its density and viscosity, and the tube diameter.

Sim uses units such that $R = \frac{1{,}000}{K}$, where K is defined above.

In these units $B_a + B_f$ together may be taken as 0·6 to 1·2 for turbine plants, and 1·2 to 1·5 for reciprocating engines.

B_t for clean tubes 18 S.W.G. thick may be taken as 0·08. It increases considerably with dirty tubes.

B_w for a particular tube diameter $= \dfrac{C}{v^{0\cdot 82}}$, where v is the water velocity in feet per sec.

Values of C are shown by fig. 2.*

K is usually about 400 to 600 B.Th.U. per hour per sq. ft. per ° Fah. in typical designs, though in very high class condensers with clean tubes and small air leakage higher values are realised.

With certain recent regenerative condensers K = 600 to 800, or even up to 1,000.

An approximate formula (due to *Orrok*) is

$$K = \cfrac{1{,}000}{\cfrac{1{,}000}{140V + 250} + a}$$

where V is the velocity of the cooling water through the tubes, in ft. per second
and a = 1·1 for reciprocating engines
0·8 for turbines
0·6 for high class power station turbines.

The increased transmission rate—and consequently reduced cooling surface necessary—due to high water velocities is not all gain, however, for high velocity means increased power to circulate the water. The final design must be decided with reference to cost of pumping as well as initial cost of plant.

Fig. 3 shows the head lost in friction per 10 foot of tube element for ⅝ in., ¾ in., and 1 in. external diam. by 18 S.W.G. smooth brass tubes. For application it is necessary to take the total length of the tube element (the length of the tubes multiplied by the number of water passes and add the 'loss at entry (including loss at exit also) per pass,' values for which are given in the bottom curve.

The heat transmission, coefficient K_w, for heat flow *from condenser tube to water only*, may be taken from fig. 4 which is due to Guy and Winstanley (*Inst. Mech. Eng.*, 1934) and is based upon researches of Eagle and Ferguson (*Inst. Mech. Eng.*, 1930). The graph applies to tubes ¾ in. outside diameter, 18 I.W.G. thick, and to a heat transmission rate of 8,000 B.Th.U. per hour per sq. foot. Corrections for other rates are negligible, and corrections for other sizes of tube are not of great significance.

According to Guy and Winstanley (reference as above) the *overall* rates of heat transmission applicable to good condensers with clean tubes, may be based upon the above for the transmission from tube to water, and on 1,350 B.Th.U. per hour per sq. ft. per deg. F. for K_s, the coefficient for heat flow from steam to tube, and these values lead to an overall coefficient K expressed fairly closely by the expression

$$K = 650 \sqrt[3]{\frac{V_t}{5}} \times \sqrt[4]{\frac{t}{100}}$$

where V_t is the water velocity in the tubes in feet per sec.
and t is the arithmetic mean water temperature between inlet and outlet in deg. F.

Mean Temperature Difference.

The true mean temperature difference for condensers, heaters, coolers, etc., in which heat is transmitted between two fluids separated by a metallic wall is not the difference of the arithmetic mean temperatures.

If one of the fluids is cooled from T_1 to T_2 and the other heated from t_1 to t_2, then,

$$\text{mean temperature } t_m = \frac{(T_1 - t_1) - (T_2 - t_2)}{\log_e \dfrac{T_1 - t_1}{T_2 - t_2}}$$

Fig. 5 enables t_m to be readily determined from the maximum and minimum temperature differences $T_1 - t_1$ and $T_2 - t_2$.

Cooling Surface.

If

t_m = mean temperature difference between steam and water; K = heat transmission B.Th.U. per hour per sq. ft. per F.°; then,

$$\text{Sq. ft. of Cooling surface per lb. steam per hour} = \frac{1{,}050}{K \times t_m}$$

(1,050 is the number of B.Th.U. given by 1 lb. steam in the condenser, under usual conditions).

FIG. 5.

QUANTITY OF COOLING WATER.

If T_1 = temperature of cooling water at inlet to condenser; T_2 = temperature of cooling water at outlet of condenser; T_3 = temperature of steam at inlet, corresponding to the vacuum; T_4 = temperature of the condensed water at outlet; h_3 = sensible heat at inlet; h_4 = sensible heat of the condensed water at outlet; L = latent heat in B.Th.U. per lb. of steam; W = steam weight; Q = water weight; R = ratio of water and steam quantity; x = dryness fraction; then,

Heat (in B.Th.U.) given up by exhaust steam $= W\left\{xL + (h_3 - h_4)\right\}$

Heat (in B.Th.U.) gained by cooling water $= Q(T_2 - T_1)$.

In practice $h_3 - h_4$ may be neglected, therefore

$$WxL = Q(T_2 - T_1), \quad \text{and,} \quad \frac{Q}{W} = R = \frac{xL}{T_2 - T_1}.$$

To allow a small margin, x—which generally varies between 0·8 and 1·0—can be neglected, and as L only varies slightly with the vacuum, it is generally assumed to be a constant for all vacua at 1,050 B.Th.U. per lb. of steam. Therefore the general equation for all vacua can be taken as

$$R = \frac{Q}{W} = \frac{1050}{T_2 - T_1}.$$

For surface plants, T_3—T_2 ranges from 8° to 20° F., and for jet plants, 4° to 8° F.

The ratio of the amount of cooling water to that of the steam to be condensed usually varies from 35 to 40 for jet, and from 60 to 70 for surface condensers.

It is important that the condensed steam should be at as high a temperature as possible, since this water is usually returned to the boilers, therefore it is essential that all the heat possible should be recovered.

Every 8°-10° F. difference in the hot-well temperature means approximately 1 per cent. difference in fuel consumption. The gain obtained with an increase in hot-well temperature can be calculated as follows :—

$$\text{Percentage gain in B.Th.U.} = \left(\frac{100\,T}{H_T + T - T_4 + 32}\right) \times \frac{100}{B_p}$$

where,

T = difference in hot-well temperature (F.°); T_4 = final hot-well temperature (F.°) H_T = total heat of steam at boiler pressure (B.Th.U. per lb.), reckoned from 32° F.; B_p = percentage boiler efficiency.

In surface condensers for turbines, $(T_3 - T_4)$ is about 5° to 8°, and for reciprocating engines about 10° to 15°.

Vacuum Efficiency may be expressed as the ratio of the vacuum at the condenser inlet to vacuum corresponding to the temperature of the condensed steam; it is dependent both upon the design of the condenser and the air pump.

The *Efficiency of a Condenser* is best stated as a 'Coefficient of Performance,' which measures the extent to which the two conditions are fulfilled that (1) the condensate should be cooled as little as possible below the steam temperature, and (2) the quantity of cooling water should be a minimum, and hence its rise of temperature a maximum.

Sim takes as 'Coefficient of Performance' the ratio $(T_2 - T_1) \div (T_3 - T_4 + 10)$, and states that it should be 1·0 to 1·2 for good surface condensers.

Degree of Vacuum.—The maximum vacuum obtainable is dependent upon the inlet circulating water temperature. For engine work 26 ins. to 27 ins. is the maximum vacuum desirable, owing to the limitations in size of the low-pressure cylinder and ports, etc. For turbine work high vacua are necessary. The most economical vacuum depends upon individual installations, and is generally decided by the power required to be expended by pumping the cooling water, price of coal, available water supply, etc.

The following may be taken under average conditions to be the maximum commercial vacua.

Resistance to Water Flow in Condensers.

Guy and Winstanley (*Inst. Mech. Eng.*, 1934) propose the following formula for the total friction loss of head in the water passes of a condenser, including the losses due to changes of direction in the water heads :—

$$H = n\left(C_1 \frac{L}{D}\frac{V_t^2}{2g} + C_2 \frac{V_t^2}{2g}\right) + C_b \frac{V_b^2}{2g}$$

where n is the number of flows;
- L length of tube in feet;
- D diameter of tube in *feet*;
- V_t mean velocity of water through tubes in ft. per sec.;
- V_b velocity in outlet branches of water box.

C_2 depends upon the type of tube fixing and has following values :—

Tubes ferruled at both ends	1·5
Tubes bellmouthed and expanded at inlet, and ferruled at outlet . .	1·25
Tubes bellmouthed at inlet and expanded at outlet	1·00

It is suggested that C_b be taken as unity in view of the great difficulty of determining the water box loss.

For C_1 the value 0·30 is suggested for tubes cleaned by wire brushing, and for cooling water at 70° F. at velocity 5 ft. per sec. in ¾ in. external diameter tubes 18 I.W.G.

For other thicknesses and tube diameters, correction factors by which O_1 is to be multiplied are given (see original paper) which vary from 1·067 for ⅝ in. diam., 16 I.W.G., to 0·918 for 1 in. diam., 19 I.W.G. The paper gives a graph for correction factors for temperature and velocity varying from 1·3 at 40° and 3 ft. per sec., to 0·67 at 240° and 8 ft. per sec.

Air in Condensers.

Air enters the condenser in the following manner :—

1. With the steam entering from the boiler, having been dissolved in the feed water; this is usually a small amount in the nature of 1 to 3 per cent. of the total volume of feed water.

2. Air leakage from the atmosphere through the glands of the prime mover or other sources; this cannot easily be measured, and an allowance has to be made accordingly to cover contingencies.

3. In jet condensers air in solution with the cooling water which is released when in the vacuum space; this varies from 1 to 5 per cent. of the total volume of water.

Due to air contained in the cooling water in the case of a jet condenser, a much larger air pump is required than for a surface plant of similar duty.

For turbine work to cover cases (1) and (2) it is usual to allow for 6 to 8, and, in the case of low-pressure turbines, up to 11 lbs. of air per 10,000 lbs. of steam.

For engines, about two or three times this amount is required according to the type of engine.

These figures are for one unit only; if two or more turbines or engines exhaust to the one condenser an extra margin of 10 or 15 per cent. per extra turbine or engine, respectively, should be allowed.

The B.E.A.M.A. specifies a fixed allowance to cover air in steam due to leakage and entrainment. For land plants

$$W_a = \left(\frac{0\cdot 5W_s}{1{,}000} + 3\right) \text{ lbs. per hour}$$

where W_s = lbs. steam condensed per hour. It is probable that the actual air may be about half this allowance.

The Ejector Condenser.

This condenser is at once an air-pump and a condenser. It acts on the principle that steam will flow into a vacuum at a velocity of many hundred feet per second. The water supply to the ejector should flow to it under a head of several feet. The steam condenses in the jet of water, and the combined jet has a velocity which is a mean of the velocity of the steam and of the water. Thus let the water approach at a velocity 30 feet per second and the steam at 1,200 feet per second. Let the combined jet be assumed to have a temperature of 100° F. and the water to

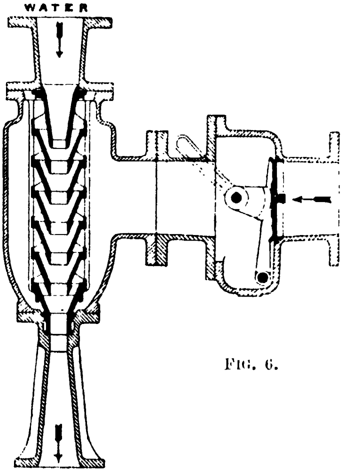

FIG. 6.

be supplied at 60° F. The water gains 40° F. The steam losses, say 1,100 B.Th.U. Then 1,100 ÷ 40 = 27 = ratio of water weight to weight of steam. The total weight of combined jet is 28. The velocity difference is 1,200 − 30 = 1,170, to be divided over a mass of 28, or $\frac{1{,}170}{28}$ = 42 feet per second nearly. Add the initial velocity of the water 30, and the final velocity is 72 feet per second

This corresponds with a head of $H = (72 + 8)^2 = 81$ feet; and since 1 foot of water column equals 0·43 pounds, 83 feet will represent 36 pounds nearly. Since a perfect vacuum is only 14·7 pounds, it follows that with ordinary ratios of water and steam an efficiency of less than 50 per cent. should give an excellent vacuum.

The apparatus (fig. 6) consists of a converging water nozzle into which water is directed from a centrifugal pump or other pressure source, or from an overhead source of 15 to 20 feet head. This jet flows downwards through a series of steam cones to which the exhaust steam has admission at their upper wide portion. The steam flows down each of these short cones and imparts further velocity to the jet as it condenses, and finally the jet flows into a divergent discharge cone at a velocity as above indicated, carrying with it any air that has come in with the steam, and discharging it. The degree of vacuum is of course that proper to the jet temperature, and the proportion of water can, as seen, be sufficiently great to admit of a moderate final jet temperature and therefore a good vacuum. The ejector condenser occupies very little space and for jet condensing is very simple. The centrifugal water supply pump is conveniently direct driven by an electric motor. While the jet final temperature is amply low for good vacua, the velocity of the combined jet is still more than sufficient to run freely against atmospheric external pressure; but it is always desirable to give the water a fair initial velocity, and there is nothing lost by giving the discharged jet a good fall in a long tail pipe.

The Barometric Condenser is a simpler form of ejector condenser, in which the water enters the head of the apparatus as a spray about the steam entrance, and the vacuum is produced by the fall of the water down a tail pipe of at least 30 feet in vertical drop. By suitable formation of the head the air which enters with the steam is entrained with the water, or, by means of a special surface condenser at the side of the head the air is drawn over cold tubes and carried down to a lower point in the draught tube, whereby it is withdrawn from the head at a minimum temperature, with the object of securing a maximum degree of vacuum.

Air-Pumps.

The essential feature of a plant having a high vacuum efficiency is an air-pump capable of operating without cooling the condensed steam. Excepting in small plants where the heat loss is not so appreciable, all surface condensers should be arranged with two pumps working on the vacuum side, *i.e.* an air-pump capable of dealing with all the air entering the condenser and a water-pump or extraction pump capable of dealing with all the condensed steam. This is what is known as a 'dry' system. Cases where only one pump is employed for the combined duty are known as 'wet' systems. In order to cut down the size of the air-pump in the latter system to reasonable proportions, the condensed steam is usually cooled by means of the last few rows of tubes in the condenser being arranged so that they are always flooded, or by an intercooler.

CAPACITY OF AIR-PUMP IN ORDER TO REMOVE GIVEN AMOUNT OF AIR.

The diagram (fig. 7, p. 179) shows the properties of mixtures of air and steam such as exist at the air-pump suction. Thus, if the temperature is 100° F., and the vacuum 26 ins., the volume of 1 lb. of air (together with the associated vapour) is 204 cu. ft. and the weight of air per lb. of steam is 1·75, *i.e.* 204 cu. ft. of the mixture contains 1 lb. of air and 0·57 lb. vapour.

The scale on the right provides a basis for calculating the air-pump capacity if the air leakage and the temperature and vacuum are known. For example, assume a surface condenser installation for a reciprocating engine in which allowance is to be made for 16 lbs. air per 10,000 lbs. steam, vacuum 27 ins., temperature at air-pump suction 100° F. From the right-hand scale the volume of air per lb. of condensate, measured at the conditions of the air-pump suction, is 0·395 cu. ft. for an air proportion of 10 lbs. per 10,000 lbs. steam. Thus in the present case the volume is

$$0 \cdot 395 \times \frac{16}{10} = 0 \cdot 63 \text{ cu. ft. per lb. steam.}$$

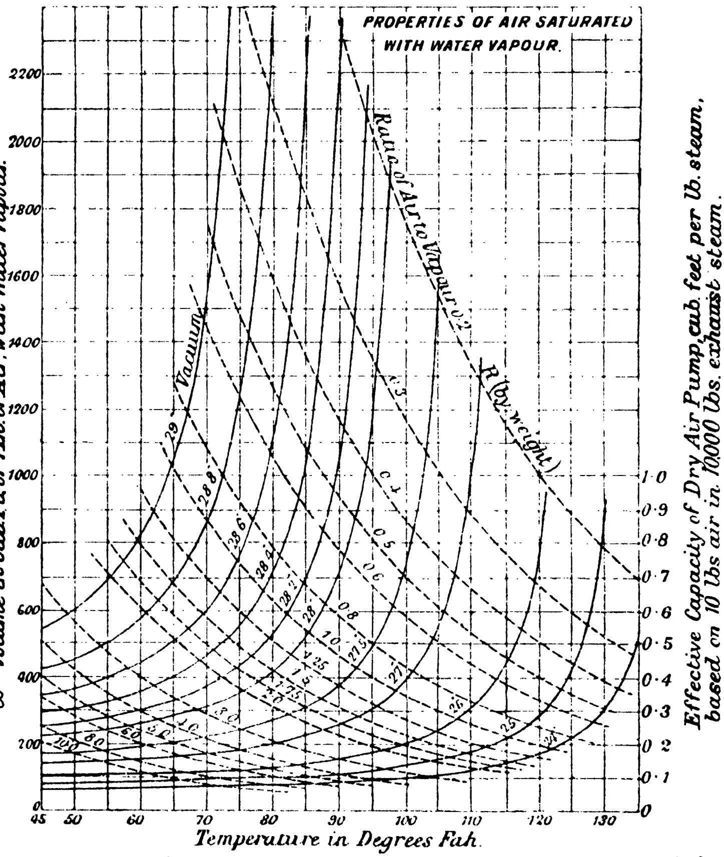
If the steam condensed is 15,000 lbs. per hour, the *effective* capacity of the 'dry' air-pump will then be

$$\frac{15{,}000}{60} \times 0 \cdot 63 = 157 \text{ cu. ft. per minute.}$$

For a 'wet' air-pump the volume of the condensate must be added. The actual capacity of the pump must be greater than the capacity thus found, on account of losses of volumetric efficiency due to clearance, slip, leakage, and valve or port resistance.

The diagram shows the reduction in volume due to cooling of the air-steam mixture before it passes to the air-pump.

DIAGRAM SHOWING THE PROPERTIES OF MIXTURES OF AIR AND STEAM, SUCH AS EXIST AT THE AIR PUMP SUCTION.



(Morley.)

FIG. 7.

In a jet condensing plant the air introduced by the injection water must also be allowed for.

Leakage of air into the exhaust pipe and condenser should be reduced to a minimum by xercising the greatest care to keep all joints, etc., in good condition.

The amount of air entering the exhaust pipe due to leakage at joints and glands is obviously not proportional to the amount of exhaust steam, nevertheless air-pumps are frequently designed to give an effective displacement proportional to the amount of exhaust steam, and in fact air-pumps for piston engines are frequently proportioned upon the low-pressure cylinder.

Vertical air-pumps are usually single-acting, and low-pressure engine cylinders double-acting. On this basis for ordinary bucket pumps the piston displacement of the low-pressure cylinder is about 6·5 times that of the pump for jet condensing compound engines in this country and 5·5 times for India and hot tropical climates. For surface condensers this air-pump ratio varies from 10 to 12, the lower figure for the smaller and less efficient engines.

Wet-air pumps for jet condensers are frequently proportioned so that their effective displacement is about five times the volume of the water (injection plus condensed steam) which they have to discharge.

Horizontal air-pumps are double-acting, and their volume is therefore one-half that of single-acting pumps.

Air-pumps of the Edwards type usually have about 75 or 80 per cent. as much capacity as the ordinary pumps.

These notes apply particularly to air-pumps for reciprocating engines, and it is tacitly assumed that the vacuum aimed at is about 26 ins. Considerably greater capacity is necessary for higher vacua.

Air-pump bucket speeds rarely exceed 200 ft. per minute unless the buckets are of the solid plunger type. A usual value is 180 ft. per minute.

The vacuum in a condenser ought to maintain itself an hour with a drop of only 2 lbs.

The smallest air-pump found practicable by Sir R. W. Allen had 0·5 cu. ft. of displacement per pound of steam condensed.

With circulation water at 65° to 70° F. a vacuum of 28½ ins. at full load with a single-stage air-pump can be maintained without special accessories. It is not advisable to allow less than 0·75 cu. ft. of air-pump volume per 1 lb. of steam condensed, and it ought to be possible to maintain a 98½ per cent. vacuum.

Circulating Pump.

The pump for delivering the required water quantity to the condenser is nearly always of the centrifugal type. The head against which this pump has to deliver is made up of the static difference in water levels between the inlet and discharge points, plus the pipe and condenser friction. In cases where water is drawn from and returned to a river or canal, the discharge pipe end can be sealed, thus forming a closed or syphon system. In arranging syphon systems care should be taken to ensure that the highest point in the system is never above a vertical distance of 25 ft. from the water level, otherwise the air contained in solution with the water is liable to be released and accumulate, thus breaking the syphon and throwing extra head on the pump.

Jet or Ejector Air-Pumps.

Of recent years great developments have taken place in the design and application of air-pumps in which the vacuum is produced entirely by means of a jet or jets of fluid, which may be water or steam. The air from the condenser mixes with the jet, and the mixture, which just after mixing is at high velocity and low pressure, passes through a 'diffuser' tube of increasing area in which its kinetic energy is as far as possible transformed into pressure energy, so that the mixture may be finally discharged against atmospheric pressure.

Such types of air-pump have the advantage that there are no moving parts in the complete condensing plant, with the exception of a pump for removing the condensate; also they occupy very little space, have little weight, can be located in any convenient situation, and require little attention and maintenance.

The types using steam jets have superseded those using water jets.

It is found advantageous not to carry out the compression of the air from vacuum to atmospheric pressure in one stage, but in two or more stages. In order to reduce the work in the later stages, and hence to reduce steam consumption, frequently auxiliary condensers are used between the stages

Measurement of Condensed Steam.

The condensate may be measured by passing over a V-notch in a suitably arranged tank, the height of the water surface above the apex of the notch being measured at a point at such a distance from the notch that the water is nearly still.

If h is the height in inches, Q the flow in cub. ft. per minute, and the angle of the notch is 90°, then $Q = ch^2\sqrt{h}$, where c is approximately 0·305, but, more accurately, varies from 0·31 at $h = 2$ ins., to 0·301 at $h = 9$ ins. or over. Less heads than 2 ins. should not be used, it being better to increase the head by using a notch of narrower angle; the discharge is approximately proportional to the tangent of half the notch angle.

If one notch will not pass the water, two may be used, and the reading of the instrument doubled.

In the 'closed feed' systems, which are now frequently adopted in power stations, the condensate and the make-up feed-water may be measured by means of Venturi meters included in the pipe system.

Injection Cocks

are usually of the hollow plug type, in gunmetal. One per condenser is sufficient. Two or three standard sizes are generally available to choose from. The minimum size can be checked as in the following example:—

Maximum load under normal conditions	1,000 i.h.p.
Steam per i.h.p. hour	15 lbs.
Steam per second	4·17 lbs.
Condensing water per pound of steam	40 lbs.
,, ,, per second	167 lbs.
,, ,, ,,	2·67 cub. ft.
Vacuum in condenser, worst	24 ins.
,, ,, in feet of water	27 ft.
Vertical height water level to injection cock	11 ft.
Head of water on injection service, 27-11	16 ft.
Assume spent in friction	50 per cent.
Net head at injection cock	8 ft.
Velocity of water at cock $= 8\sqrt{8}$	22·6 ft. sec.
Hence area of opening	0·118 sq. ft.
,, ,,	17 sq. ins.

If in doubt add a margin of 25 to 30 per cent. It is, of course, understood that the above level, steam consumption, etc., must be modified to suit the actual conditions. Thus in tropical countries 60 should be substituted for 40 lbs. of condensing water per lb. of steam.

Force or Feed Pumps.

When the boiler feed-pump is driven off the engine it is usual to allow sufficient capacity for other works purposes.

The following are frequently adopted:

Textile spinning mills	25 lbs. water per i.h.p. hour
Textile weaving sheds	40 ,, ,, ,,
Mixed spinning and weaving	30 ,, ,, ,,
Flour mills	35 ,, ,, ,,
Bleach works	50 ,, ,, ,,

It will be seen that an ample allowance is made, and for economical superheated-steam engines a reduction of about 5 lbs. can be made. The above are based on actual pump displacement. The plunger speed should not exceed about 200 ft. per minute.

Pump Openings.

The velocity of water in pump openings should not exceed 500 ft. per minute.

Cooling Ponds.

Where the supply of water for condensing purposes is limited, it is necessary to cool the condensing water and use it again and again. One method of cooling is to pass the hot water into an open pond and draw off water for condensing from the opposite side of the pond, the water being cooled simply by evaporation from the surface.

Spray Ponds.

An improvement upon the simple pond is to lay a system of piping over the pond and let the water issue from nozzles in a fine spray. A large amount of water is, however, carried away by the wind and lost.

A spray pond should have 2¼ sq. ft. of area per gallon of water to be cooled per minute. This includes the marginal straps necessary for windage, etc.

Water-Cooling Towers.

Water-cooling towers are of two principal types—chimney type and open type. Both act by bringing the water into intimate contact with air currents, and to expose as large a surface of water to the air as possible the water is either broken up by splash bars into fine drops, or made to run down in thin films. In chimney type towers air is admitted at or near the bottom only, and passes up inside the casing usually by natural draught, though sometimes forced draught is used. Forced-draught towers are smaller than natural-draught for the same duty, but require a large expenditure of power in the fans.

Open type coolers have water-distributing arrangements similar to those in the chimney type, but have no external closed casing, the flow of air across the water is dependent upon the action of the wind. To prevent excessive loss of water, the stack is usually surrounded by louvre boarding, but even then the loss of water is large compared with that in the chimney type.

In chimney type towers the water is usually pumped to distribution troughs at a height of 16 to 25 ft.; the height of the chimney is about 70 ft. if of timber, 100 to 120 ft. if of steel (which is less usual). Towers are often of reinforced concrete, up to 150 ft. in height. With wide towers, special means of introducing the cool air to the central parts are necessary. With such means towers may be up to 40 ft. in width, and should not be narrower than about 15 ft., in order that they may have an adequate margin of stability.

In all cooling towers the heat is extracted from the water partly by (1) direct heating of the air, partly by (2) evaporation of part of the water. Under typical atmospheric conditions in this country evaporation accounts for about 75 to 85 per cent. of the cooling.

The amount of evaporation possible depends upon the amount of moisture already contained in the air entering the tower and its temperatures at inlet and outlet.

It is important, in specifying or judging the capacity of cooling towers, to take into account the humidity or the wet and dry bulb readings.

The 'relative humidity' of the atmosphere is the ratio of the weight of water vapour contained in a certain volume of air to the weight required to saturate this volume at the same temperature, or it may be expressed as the ratio of the vapour pressure at the dew-point to that at the actual air temperature, the dew-point being the temperature to which the air must be cooled in order that it may just become saturated, so that further cooling would cause condensation to begin. The greater the humidity of the atmosphere, the less, of course, is its capacity for taking up moisture by evaporation. The humidity is ascertained by reading wet and dry bulb thermometers and referring to humidity tables.

The quantity of fresh 'make-up' water required to compensate losses by evaporation, etc., in cooling plants is about 3 to 5 per cent. of that in circulation.

It is stated that the loss by evaporation only in natural draught chimney type cooling-towers is approximately 1 per cent. for each 12° F. by which the water is cooled in the tower.

(*I. V. Robinson*, '*B.E.A.M.A. Journal*,' *March* 1921.)

The amount of air for which the cooling tower should be proportioned may be calculated as in the following example:—

Let the atmospheric temperature and humidity be 65° F. and 60 per cent. respectively, the atmospheric pressure 14·7 lbs. per sq. in., and let the air leave the tower at 85° F. (saturated with vapour).

From steam tables, the vapour pressure at 65° F. is 0·31 lb. per sq. in., thus the air pressure is 14·7−0·31 = 14·39 lb. per sq. in.; 1 lb. air at this pressure and at 65° F. occupies 13·45 cu. ft.; 1 lb. vapour at 85° F. occupies 990 cu. ft.

$$\therefore \text{ weight of vapour per lb. air if saturated} = \frac{13\cdot45}{990} = 0\cdot0136 \text{ lb.}$$

$$\therefore \text{ weight of vapour at 60 per cent. humidity} = 0\cdot0136 \times 0\cdot6 = 0\cdot00816 \text{ lb.}$$

At 85° F. the vapour pressure = 0·6 and air pressure 14·1 lb. per sq. in.; 1 lb. air at these conditions occupies 14·3 cu. ft.; 1 lb. vapour at 85° occupies 541 cu. ft.

$$\therefore \text{ vapour per lb. air} = \frac{14\cdot3}{541} = 0\cdot0264 \text{ lb.}$$

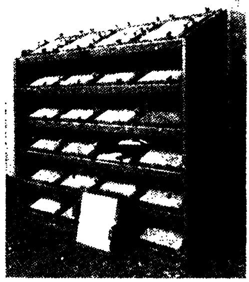
Hence, for each lb. of air passing through the cooling tower, 0·0264−0·00816 = 0·0182 lb. water is evaporated.

Heat to evaporate 1 lb. water from water at 65° F. to vapour at 85° F. = 20 + latent heat = 1·061 B.Th.U

$\therefore$ heat to evaporate 0·0182 lb. = 0·0182 × 1·061 = 19·3 B.Th.U.
Heat absorbed in heating air = 0·237 × 20 = 4·74 B.Th.U.
Total heat taken from water per lb. air = 19·3 + 4·74 = 24·04 B.Th.U.

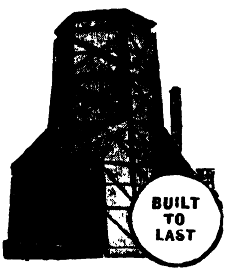
PREMIER

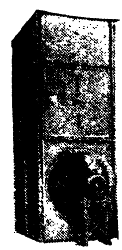
WE have specialised in the production of Air Filters of every type for over 30 years and are always only too pleased to advise as to the best type to be employed for any particular purpose.

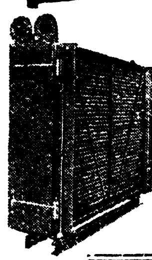


PREMIER ADHESIC AIR FILTER

Is highly efficient; its special design allows it to be built of multiple units requiring no special foundation so that it may be adapted to any available space. There are no working parts, and the filter need never be out of commission even for cleaning.







PREMIER COOLING TOWERS

are being used in all parts of the world under widely varying conditions and giving entire satisfaction. Their special design and construction makes them the most efficient tower of the present day.

PREMIER MECHANICAL WATER COOLER

This cooler has been specially designed to operate in restricted spaces for general industrial work and is suitable for condensing and refrigerating.

WE ALSO MANUFACTURE

LIGHT CONSTRUCTIONAL STEEL AND SHEET METAL WORK

AIR WASHERS
HASTE VALVES

PREMIER CLOSED CIRCUIT AIR COOLERS

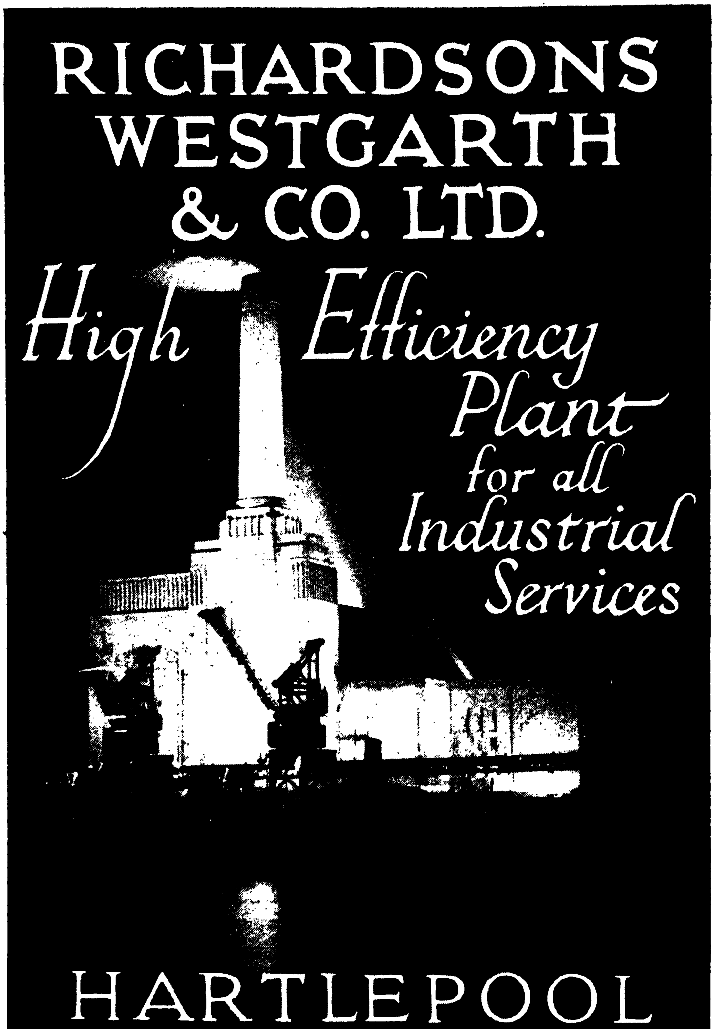
have already been installed in such SUPER POWER STATIONS as Hams Hall, Nechells, Deptford, Poplar, Johannesburg, Adelaide, as well as numerous large and small power stations. They are of tubular construction with no normal connection with the outside atmosphere.

WE ALSO MANUFACTURE

OIL COOLERS
for
TRANSFORMER OIL

HEAT EXCHANGERS OF EVERY TYPE

THE
PREMIER COOLER & ENGINEERING CO., LTD.
Shalford Nr. Guildford Surrey.



RICHARDSONS
WESTGARTH
& CO. LTD.
High Efficiency
Plant

HARTLEPOOL

Ratio of cooling by evaporation to total cooling

$$= \frac{19 \cdot 3}{24 \cdot 04} = 0 \cdot 8 \text{ or } 80 \text{ per cent.}$$

If the water is cooled, say 30°, the weight of water cooled per lb. air $= \frac{24 \cdot 04}{30} = 0 \cdot 801$ **lb.**

Percentage of water lost by evaporation

$$= \frac{0 \cdot 0182}{0 \cdot 0182 + 0 \cdot 801} \times 100 = 2 \cdot 22 \text{ per cent.}$$

Weight of air to pass through cooler per lb. water

$$= \frac{1}{0 \cdot 801} = 1 \cdot 25.$$

It is stated by Mr. W. T. Bottomley that for a typical base-load power station with cooling towers, the economical loading of the towers should be 14,000 B.Th.U. per hour per sq. ft. of base area, with a cooling range of 14° F. The economical rainfall at the tower base should therefore be 100 gallons per hour per sq. ft. of base area.

STEAM ACCUMULATORS.

The function of a steam accumulator is to absorb heat during periods when there is an excess of live or exhaust steam, and to restore the heat in the form of a constant supply of steam at some lower pressure. The employment of accumulators enables a boiler plant to be operated more efficiently because of the greater uniformity of its load, and the economy thus brought about in many kinds of factories amply justifies the comparatively high cost of the apparatus. Accumulators can, of course, only deliver saturated steam.

When engines such as those of collieries or rolling mills, work intermittently, stopping and starting at short intervals, their exhaust steam may be usefully discharged into an accumulator from which a steady supply may be drawn for operating a low pressure turbine or any other purpose. In a few instances accumulators of the gas-holder type have been employed for this purpose, but these are generally too large and costly to be advisable. They have, however, the advantage of great simplicity, and they also work with an extremely slight pressure drop, while the heat loss from their exposed surfaces is not excessive on account of the low ratio of the surface to the volume. Another good feature is the constancy of their discharge pressure, which remains unchanged so long as there is any steam in the accumulator. In one British colliery a steam accumulator of the gas-holder type has been in constant use for more than thirty years.

A much more common type is exemplified by the Ruths accumulator. This consists of a large pressure-tight cylindrical container with spherical ends and nearly filled with water. The charging steam is delivered to the accumulator by a pipe from which it escapes into the water by submerged nozzles. On the top of the container is a steam dome from which steam at some lower pressure is taken continuously or as desired. Automatic valves in the inlet and outlet pipes control the steam flow in accordance with the pressures in the respective mains.

When such an accumulator is installed for the purpose of enabling boiler to be worked at constant load, it is charged directly from the live steam main at times when excess steam is available. When no live steam is entering it, the supply of low pressure steam is maintained by the evaporation of the water at the expense of its own heat. The accumulator therefore works at variable temperature and pressure. The limits of pressure between which it will have to supply steam have therefore to be decided on, for these determine the amount of storage it can provide.

The amount of steam an accumulator can store, or conversely, the weight of water required for a given storage capacity can be calculated in the following manner.

Let the accumulator before charging (*i.e.* when at its lowest permissible working pressure) contain W_0 lbs. of water having a heat content of h_0 B.Th.U. per lb. When charged up to full boiler pressure, let it hold W_1 lbs. of water having a heat content of h_1 per lb. Then, if H is the total heat per lb. of the charging steam, the heat brought in by the charge will be $H(W_1 - W_0)$, and this will increase the heat in the accumulator by $(W_1 h_1 - W_0 h_0)$. By equating these two expressions and simplifying them we obtain

$$\frac{W_1}{W_0} = \frac{H - h_0}{H - h_1}$$

whence we find the weight of steam absorbed by each lb. of the original quantity of water to be

$$\frac{W_1 - W_0}{W_0} = \frac{h_1 - h_0}{H - h_1} \text{ lbs.}$$

The values of H, h_0, and h_1 for any given pressures and temperatures are to be found in Callendar's Steam Tables.

To calculate the quantity of steam that an accumulator can supply before its pressure has dropped to the lowest permissible point is not a difficult matter.

If there are W lbs. of water in the accumulator at any time when it is discharging, and no steam is entering it, a small discharge of dW lbs. of water in the form of steam will abstract an amount

of heat equal to LdW, where L is the latent heat of steam at the pressure concerned. This amount must be equal to Wdh, where h is the heat in a pound of the water, so that by equating these values we have

$$\frac{dW}{W} = \frac{dh}{L}.$$

If, at the beginning of the discharge, the accumulator contains W_1 lbs. of water with h_1 heat units per lb., and at the end of the discharge it contains W_2 lbs. with h_2 heat units per lb., we find by integrating the above equation between these limits, that

$$\log_\epsilon W_1 - \log_\epsilon W_2 = \frac{h_1 - h_2}{L_m}$$

where L_m is the mean value of the latent heat of steam over the range of temperature concerned.

Denoting, for brevity, the expression on the right hand side of the above equation by x the equation can be put into the form

$$W_2 = \frac{W_1}{e^x}$$

in which e^x can be taken as equal to $\left(1 + x + \frac{x^2}{2}\right)$ with more than sufficient accuracy for all practical purposes.

From the above equation we can calculate W_2 the amount of water remaining in the accumulator after a discharge through any given range of pressure, and so get $(W_1 - W_2)$ which is the weight of steam that will have been delivered during the discharge.

It is interesting to observe that, if an accumulator is charged through a given range of pressure and then discharged through the same range, it will contain slightly more water than at first. This is because the low-pressure steam has a somewhat greater latent heat than the charging steam, so that to produce an equal temperature difference in the water, the weight of charging steam must exceed the weight of steam discharged.

Thermal Storage at Constant Pressure.

The system of thermal storage at constant pressure was developed by the late Druitt Halpin to enable boilers to cope with heavy demands for steam by the provision of ample feed-water at the full boiler temperature. A large cylindrical storage vessel above the boiler drum contained water to which the boiler steam had free access. The water was thus raised to boiler temperature and pressure to serve as feed-water at times of the greatest load. The storage vessel thus virtually increased the water capacity of the boiler and so enabled it to deal better with variable demands for steam.

In the Kiesselbach accumulator the same principle is carried out in a more elaborate manner. The storage vessel is placed below the level of the boiler drum, to which its steam and water spaces are both connected. A circulating pump draws water from the bottom of the storage vessel and delivers it to the boiler drum, whence an equivalent quantity flows back to the storage vessel so long as the level in the boiler is above the inlet to the return pipe.

When the demand for steam is small the ordinary boiler feed pump delivers an excess of water to the boiler, with the result that the storage vessel becomes filled by means of the return pipe. At times when the demand for steam is abnormally large the feed pump is stopped, the drum being only supplied then by the circulating pump with fully heated water from the storage vessel.

SECTION XXVIII

THE INTERNAL COMBUSTION ENGINE
(By R. J. W. Cousins, M.I.Mech.E.)

PART I

UNITS AND EQUIVALENTS—GAS LAWS, etc.

Units and Equivalents.

Length
1 metre = 100 centimetres = 1,000 millimetres.
1 metre = 39·37079 inches.
1 inch = 25·4 millimetres.

Area
1 square inch = 6·4516 square centimetres.
1 square centimetre = 0·155 square inch.

Volume
1 cubic inch = 16·387 cubic centimetres (c.c.'s).
1 litre = 1,000 c.c.'s = 61·03 cub. inches.
1 gallon = 8 pints = 277·3 cub. ins. = 4·5435 litres.

Weight
1 gramme = the weight of 1 c.c. of water at maximum density, *i.e.* at 4° C.
1 gramme = 15·432 grains.
1,000 grammes = 1 kilogramme = 2·2046 lbs. (lbs. av.).
1 pound avoirdupois = 7,000 grains = ·45359 kilogramme.
1 British ton = 2,240 lbs.
1 metric ton = 1,000 kilogrammes = 2,204·6 lbs.

Pressure
1 atmosphere = 14·7 lbs. per sq. in. = 1·03375 kilogrammes per sq. centimetre.
1 atmosphere = 30 ins. of mercury (approx.).
1 atmosphere = 760 millimetres of mercury (approx.).
1 atmosphere = 34 ft. of water (approx.).
1 kilogramme per sq. cm. ($kg/cm.^2$) = 14·22 lbs. per sq. inch.
1 inch of mercury = 0·49 lb. per sq. inch.

Mass
1 gravitational pound = 32·2 lbs. weight.
That is the mass (M) of a body equals its weight (W) in pounds divided by the acceleration due to gravity (g) which is 32·2 ft. sec. sec. (approx.).

$$M = \frac{W}{g} \text{ pounds (grav.).}$$

Velocity
1 foot per second = 30·48 centimetres per sec.
1 foot per second = 1·097 kilometres per hour.
1 foot per second = 0·6818 mile per hour.

Acceleration
1 foot per second per second (1 $ft./sec.^2$) means that the velocity increases at the rate of 1 ft. per sec. in every second.
1 $ft./sec.^2$ = 30·48 centimetres per sec. per sec. ($cms./sec.^2$).

Angle
1 complete circle = 4 right angles = 360 degrees = 2π radians.
1 radian = 57·3 degrees.

Angular velocity
1 radian per second = 9·549 revolutions per minute.

Temperature
Freezing point of water = 32° Fahrenheit = 0° Centigrade.
Boiling point of water at 14·7 lbs. sq. in. = 212° F. = 100° C.
Zero absolute = −460° F. = −273° C.
1° Centigrade = 1·8° Fahrenheit.

Heat
1 British Thermal Unit (B.T.U.) = heat necessary to raise 1 pound weight of water through 1° F.
1 B.T.U. = 778 ft. lbs. of work.

Power
1 British Horse Power = 33,000 ft. lbs. per minute.
1 British Horse Power = 42·416 B.T.U.'s per minute.
1 Metric Horse Power = 75 kilogrammetres per second.
1 Metric Horse Power = 0·9863 British Horse Power.
1 Watt = 1 ampere current at an E.M.F. of 1 volt.
1 Kilowatt = 1,000 Watts = 1·34 British Horse Power.

Gas Laws, etc.

The internal combustion engine is a prime mover in which fuel is burnt in the working cylinder or in a chamber directly communicating therewith.

The expansion of the gases resulting from the combustion then acts on the piston or its equivalent, and thus mechanical work is produced. It is therefore essential to know the way in which gases are affected by heat, pressure, etc., in order to understand approximately what goes on in the cylinder, and to make the required calculations.

It will be assumed, unless otherwise stated, that the working fluid behaves as a perfect gas.

***Pressure and Volume.*—Boyles' Law states that the volume of a mass of gas varies inversely as the pressure, provided the temperature is maintained constant.**

$$V \propto \frac{1}{P} \text{ or } PV = c \text{ (a constant).}$$

***Temperature and Volume.*—Charles' Law states that the volume of a mass of gas varies $\frac{1}{273}$ of its volume at 0° C. for every 1° C. change of temperature if the pressure be kept constant.**

$$V_T \text{ (volume at T° C. abs.)} = \frac{T}{273} V_0 \text{ when } V_0 = \text{volume at 0° C.}$$

i.e. the volume is proportional to the absolute temperature T and $\frac{V}{T}$ is constant.

If, however, the volume is maintained, the absolute pressure alters in proportion to the absolute temperature, *i.e.* $\frac{P}{T}$ is constant.

Combining the two $\frac{PV}{T}$ = a constant for any one gas.

If P is measured in lbs. absolute per sq. ft., V in cubic ft. per lb. weight at 0° C. and T in degrees C absolute then $\frac{PV}{T}$ = 96 for dry air.

When P = 760 millimetres of mercury (mm.s Hg) and T = 0° C., the gas s said to be at 'Normal Temperature and Pressure' (N.T.P.).

In practice, air forms the bulk of the working fluid in internal combustion engines, and therefore the behaviour of air under conditions of changing pressure and temperature forms a useful reference, and approximates to that of the charge in the cylinder.

***The Specific Heat* of dry air at constant pressure,**

$$k_p = 0 \cdot 2374 \text{ B.Th.U. per lb. weight.}$$

When allowed to expand as the temperature rises—the pressure being kept constant—work is done against the pressure of the atmosphere. The volume of 1 lb. wt. of dry air at N.T.P. is 12·387 cub. ft. and when raised in temperature 1° F. at constant pressure it expands $\frac{1}{492}$ of its volume against atmospheric pressure, *i.e.*, the external work is :—

$$\frac{12 \cdot 387 \times 14 \cdot 7 \times 144}{492} = 53 \cdot 29 \text{ ft. lbs.} = \frac{53 \cdot 29}{778} = 0 \cdot 0685 \text{ B.Th.U.}$$

When the gas is *not* allowed to expand, *i.e.*, when the *volume* is maintained constant while the temperature is raised 1° F., the pressure rises but the external work is not performed, and the heat required is then less by the amount calculated above, *i.e.* :—

$$0 \cdot 2374 - 0 \cdot 0685 = 0 \cdot 1689 = k_v.$$

This is the specific heat of air at constant *volume*.

The relationship between k_p and k_v is very important in internal combustion engines and compressors. It is usually written γ.

$$\frac{k_p}{k_v} = \frac{0 \cdot 2374}{0 \cdot 1689} = 1 \cdot 406 = \gamma.$$

Compression and Expansion of Gases.

When gases are compressed or expanded in an actual engine, the conditions are somewhat complex, but for simplicity two basic modes are recognised.

(*a*) Isothermal Compression or Expansion.

(*b*) Adiabatic Compression or Expansion.

Isothermal expansion means that the gas changes volume without changing temperature. This is the simple case assumed in Boyles' Law, so that when P alters to P_1 and V to V_1,

$$P_1V_1 = PV = c. \quad \text{(Fig. 1)}$$

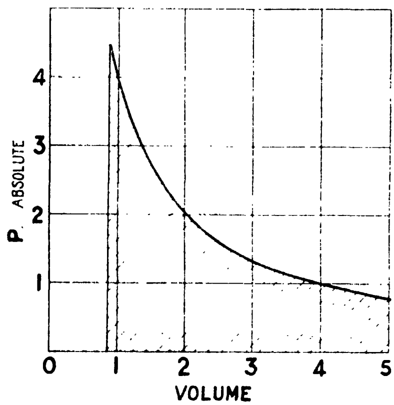

FIG. 1.

This only obtains in practice when the change is made very slowly, and adequate means are provided to maintain a constant temperature. In this mode of expansion, since the temperature is constant, the internal energy of the gas remains constant, as it is proportional to the absolute temperature.

The external work must therefore be supplied from the outside in the form of heat, and conversely in isothermal compression the heat which flows from the gas is equal to the work done in compressing it. This work, represented by the hatched part of fig. 1, is :—

$$144\ PV \log e \frac{V_1}{V} = W \text{ ft. lbs.}$$

P = lbs. per sq. in. V = volume cub. ft.

Adiabatic Expansion or Compression obtains when no heat flows either to or from the gas during the change in volume.

This is a hypothetical condition almost impossible to realise, since it requires a retaining cylinder and piston opaque to radiation and of zero conductivity. It is, however, a convenient and calculable standard.

Since no heat passes, it is clear that the gas must lose or gain internal energy by the amount of external work done by or put into it. This raises the temperature on compression and lowers it on expansion, and so affects the pressure directly ($P = cT$).

The equation then becomes

$$PV^n = P_1V_1^n \text{ where } n = \frac{k_p}{k_v} = \gamma = 1{\cdot}406 \quad \text{(See Specific Heat of Air.)}$$

With Isothermal compression or expansion $n = 1$, and the pressure is modified only by the volume change, but in most practical cases the value of n is between 1 and 1·4, and varies with the conditions governing the heat flow to or from the gas.

The action may be pictured mentally as taking place in two stages, first the pressure rise or fall due to volume change, and second, the additional pressure alteration due to the effect of changing temperature.

If R is the ratio between V and V_1 so that $\frac{V}{V_1} = R$; then

First $P_1 = PR^1$ volume effect only (isothermal change).
Second $P_1 = PR^{0.406}$ temperature effect;
Result $P_1 = PR^{1.406}$ for adiabatic change.

The External work involved is :—

$$\frac{144PV}{n-1}\left[1 - R^{n-1}\right] \text{ ft. lbs.}$$

added on compression and given out on expansion.

The absolute temperature change is :—

$$T_1 = TR^{n-1}$$

Actual Values of 'n.' When air is admitted to the cylinder of an engine, which has been running long enough to warm up, it receives heat from the walls, and even during the early stages of compression this process may continue for a short period. This raises the value of n above $\gamma(1 \cdot 406)$ and gives a more steeply rising pressure and temperature curve.

As the temperature of the charge rapidly approaches that of the cylinder walls the heat flow ceases and then reverses; 'n' then falls below the adiabatic value more and more as heat is lost to the walls, at a rate dependent on the temperature difference between charge and cylinder valves, etc., the ratio between exposed surface and volume, the amount of movement of the gases over the surfaces, and the density of the charge.

An examination of a large number of indicator cards has shown that the mean value of 'n' on compression and expansion varies greatly not only in engines of different design but in the same engine at different speeds and loads.

An extreme case gave a compression pressure rising constantly with speed even after the volumetric efficiency had begun to fall. These results were obtained on a special cell type of oil engine, where heat was given up by the hot throat on compression and taken in when combustion started. The expansion exponent was naturally affected in the other sense.

The difficulty experienced in getting sufficiently accurate cards at the low pressure end, and fixing T.D.C. on the diagrams introduces a source of error, but the recorded pressures and values of 'n' are given below.

Type of Engine.	R.P.M.	Comp. Ratio.	Comp. Pressure abs.	'n' Comp.	'n' Expansion.
Petrol sleeve valve	1500	7·0 to 1	205 lbs. sq. in.	1·35	
" " "	2100	7·0 " 1	212 "	1·36	1·28 approx.
" " "	2600	7·0 " 1	218 "	1·365	
Petrol poppet valve	1500	5 " 1	122 "	1·35	1·28 "
Cell type oil engine	650	16·8 " 1	550 "	1·30	
" " " "	1500	16·8 " 1	640 "	1·34	1·2 "
" " " "	2000	16·8 " 1	693 "	1·36	
Slow speed oil engine	450	15·5 " 1	550 "	1·34	1·24 "
" " " "	400	15·0 " 1	452 "	1·327	—
Poppet valve alcohol engine	1500	6·7 " 1	180 "	1·33	1·26 "
Cell type oil engine, hand turned at 0° C. with brine circulated in the jacket and air intake	100 approx.	19·0 " 1	520 "	1·22	—

The last example illustrates the great difference in the 'n' due to slow speed and a cold engine. This accounts for the difficulty sometimes experienced in starting when :—

1. The speed is slow and the time for heat loss consequently great.
2. The initial temperature is low as both air and inlet passages are cold.
3. There is no heat pick up in the early part of the stroke, but loss all the way.

Owing to the difficulty of determining when burning ceases, the values cannot be given accurately for the early part of the expansion curve.

Compression Ratio.

In spark ignited engines the ratio R between the volumes at bottom and top centres ranges from 4 or less up to 10 to 1, while in compression ignition engines (where the terminal compression pressure is sufficient to ignite finely divided fuel without any external aid) the ratio may be as low

as 11 to 1 and as high as 20 to 1. A rough guide to the ratio suitable for various cases is given in the table below:—

TABLE OF APPROPRIATE COMPRESSION RATIOS.

Note.—The compression ratio is the volume of the enclosed space at bottom centre divided by that at top centre.

Type of Engine.	Speed R.P.M.	Fuel.	Octane No.	Comp. Ratio.
Small commercial or boat engines	Low 750–1,000	Kerosene (paraffin)	45 to 50	3·6 to 3·8
Small commercial or boat engines	Low to Medium 1,000–1,500	Special 'Power Kerosene	55 to 65	4·0 to 4·8
Commercial vehicles (large)	Medium 2,000	Commercial grade petrols	65 to 70	5·0 to 5·3
Commercial vehicles (small)	Moderately high 2,500	Commercial grade petrols	65 to 70	5·3 to 5·5

SPECIFIC VOLUME.

Dalton showed that at the same conditions of temperature and pressure all gas molecules occupied the same volume.

When a charge of air and fuel is burned the atoms rearrange themselves and combine with oxygen to form new molecules which may be more or less in number than those in the original charge.

The nitrogen, carbon-dioxide and water in the air will not be changed, so only the oxygen need be considered at this point.

$$2\,H_2 + O_2 = 2\,H_2O$$
2 volumes + 1 vol. = 2 vols. (at the same T. and P.).
3 vols. = 2 vols.

Benzene
$$2\,C_6H_6 + 15\cdot O_2 = 12\,CO_2 + 6\,H_2O$$
2 vols. + 15 vols. = 12 vols. + 6 vols.
17 vols. = 18 vols.

Nonane
$$CH_3(CH_2)_7CH_3 + 14\cdot O_2 = 9\,CO_2 + 10\,H_2O$$
1 Vol. + 14 vols. = 9 vols + 10 vols.
15 vols. = 19 vols.

Oxygen forms 21 per cent. of the atmosphere by volume, the other constituents being merely diluents as far as combustion is concerned.

The alteration in specific volume of the whole charge is therefore not so great as that of the active constituents :—

e.g.

Nonane	1 vol.		
Oxygen	14 vols.	21 per cent.	} 100
Remaining air . .	52·7	79 per cent.	
Volume . . .	67·7 before burning.		
Carbon dioxide . .	9 vols.		
Water Vapour . .	10 vols.		
Unchanged parts of the air	52·7		
	71·7 after burning.		

Increase, 67·7 to 71·7 = 5·7 per cent.

Water Vapour in the Air.

When vapour is in an enclosed space in contact with the liquid from which it is produced, the pressure of the vapour rises to a point which is dependent solely on the temperature, and this is the same whether the space was originally vacuous or filled with some gas such as air. This pressure is generally called the 'vapour tension.' When fresh air contains the maximum amount of water vapour for the temperature, it is said to be 'saturated,' and as the total pressure remains the same, it is clear that the pressure due to the air alone is reduced by the value of the partial pressure due to the vapour tension. Therefore, in saturated air the weight of oxygen available is reduced below that in dry air at the same temperature and pressure.

Taking dry air at N.T.P. = 0·0807 lb. per cub. ft. as the standard, the weight of dry air per cubic foot of saturated air at temperature T° C. and pressure P is as under :—

$$\frac{P - P_w}{14\cdot7} \times \frac{273}{T^\circ \text{ C. (abs.)}} \times 0\cdot0807 \text{ lb. per cub. ft.}$$

when P_w is the vapour tension for temperature T from the tables. To find the total weight per cub. ft. add the weight of the water vapour (see table, p. 193).

Vapour Tension of Liquid Fuels.

The remarks on vapour tension of water apply also to liquid fuels used in carburettor engines, *i.e.*, drawn in along with the air. These uels are very complex and tend to become more so owing to modern methods of treatment. The boiling points of their constituents cover a wide range, but one of the most important points to the ordinary user, is that the fuel should contain ingredients having a sufficiently high vapour tension at ordinary temperatures to produce an explosive mixture in the cylinder. When the engine is hot the fuel will evaporate, and if special heating means are provided a heavy kerosene will function, but it is impossible to start on it from cold.

EFFICIENCY.

The thermal efficiency of an engine is the relationship between the energy delivered in mechanical work and the total heat value of the fuel used.

The Air Standard Efficiency,

$$E = 1 - \left(\frac{1}{R}\right)^{\gamma - 1}$$

assumes no heat transfer to or from the gas, complete and instantaneous combustion at constant volume, no change in specific volume, and constant specific heat over the whole temperature range.

None of these conditions obtains in practice, but this ideal figure forms a useful comparison and is a guide to the variation which may be expected by change in compression ratio R. It will be clear that the higher the ratio, the greater the efficiency will be, but the rate of increase falls off rapidly and several practical considerations tend to put a limit on the figure which may usefully be employed. Fig. 2 gives the values for ratios 2 to 22.

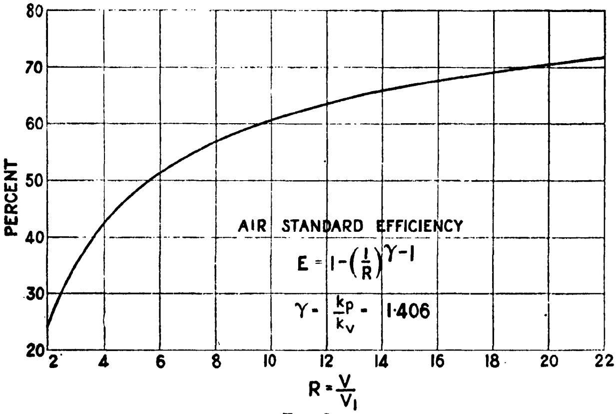

FIG. 2.

THE CONSTANT VOLUME CYCLE.

This cycle follows as far as possible the above conditions, and if they could be realised the diagram would be as fig. 3, with temperatures at the important points as indicated.

The fuel heat is assumed to be added instantaneously without loss at T_2 raising it to T_3. $T_3 - T_2$ then = 100 per cent.

The rejected heat at the end of the cycle = $T_4 - T_1$ and is lost, therefore the efficiency may be written—

$$E = \frac{(T_3 - T_2) - (T_4 - T_1)}{(T_3 - T_2)} = 1 - \frac{T_4 - T_1}{T_3 - T_2} = 1 - \left(\frac{1}{R}\right)^{\gamma - 1}$$

This is the cycle aimed at in the ordinary gas and petrol engines working on the Otto cycle, but there are many quantitative departures from the ideal as under:—

1. Heat is lost in the later stages of compression making T_2 lower.

2. The heat energy is not added instantaneously (the nearest approach to this is violent detonation which soon leads to pre-ignition and cannot be tolerated in practice). The fuel begins to burn before top centre and continues for an appreciable time during expansion.

Since it has been shown that the efficiency is dependent of the expansion ratio, it is evident that the fuel which burns later is not used as economically as that burned at top centre.

3. The specific heat is actually higher at higher temperatures, so that the addition of a certain quantity of heat does not produce the rise in temperature (and therefore pressure) which would result if specific heat were constant.

4. Dissociation of the products of combustion CO_2 and H_2O into CO, H_2 and O_2 occurs at high temperatures. This absorbs heat in the early stages, and recombination later on raises the terminal temperature and therefore the amount of rejected heat.

5. Heat loss, with consequent falling off in pressure, occurs during burning and expansion and as it is greatest at the highest temperature, this loss produces its effects throughout the working stroke.

6. Since the process of evacuating the cylinder takes some time, the exhaust valves or ports must be opened well before the end of the stroke, thus lowering the real expansion ratio.

This all sounds dreadfully disheartening, but the efficiencies obtained are still so good that only the best and largest steam engines can approach the poorest kind of internal combustion engine in fuel consumption.

The Constant Pressure Cycle **consists of an adiabatic compression, addition of heat energy at constant *pressure*, adiabatic expansion and rejection of waste heat at constant volume. The ideal diagram for this cycle is as fig. 4 :—**

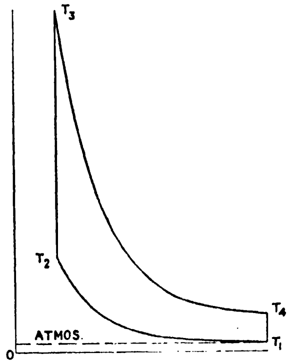

FIG. 3.

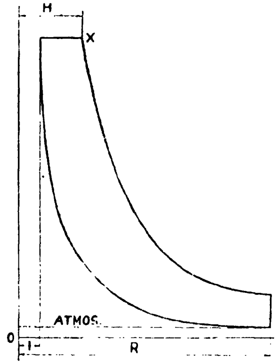

FIG. 4.

The compression ratio is R, the end of heat input X at a volume H (where the clearance equals 1).

The efficiency is $E = 1 - \left(\dfrac{1}{R^{\gamma} - 1} \times \dfrac{H^{\gamma} - 1}{\gamma(H-1)}\right)$

Apart from the inevitable heat losses to the jacket, etc., previously mentioned, this cycle is closely approached in large slow-speed Diesel engines, where the quantity of fuel is sufficiently great to permit the rate of injection to be controlled throughout the burning period, but in the higher speed smaller engines, the departure from the cycle becomes more marked, and in the modern vehicle oil engine there is a rapid rise of pressure above compression pressure, so that the cycle is really a compromise between the two—constant volume and constant pressure.

In the larger engines the maximum pressure and temperature are deliberately kept down for practical constructional reasons, but in the smaller sizes more liberty may be taken, and it is found, as may be expected, that efficiency is improved if the injection timing and rate are such as to give higher peak pressures for the same total fuel per charge.

Naturally the fuel burnt later in the stroke is not used so efficiently, but the compression ratios used in engines working on this cycle, where the fuel is ignited by the heat of compression alone, are so high that even the last of the burning charge is expanded more than in spark ignited engines, and consequently the efficiency of oil engines in general is higher, particularly on lighter loads, where the mean temperature is lowered by reducing the fuel while still admitting a full charge of air.

Producer and furnace gas engines . . .	25 to 28 ,,
Coal gas engines	30 ,,

VOLUMETRIC EFFICIENCY.

The power developed by an engine is in every case dependent on the weight of oxygen it can handle in unit time.

This is particularly the case in petrol engines, which often run slightly 'rich,' *i.e.* with a fuel to air ratio in excess of true chemical balance.

Care must be taken therefore that the valves or ports for admitting air are of sufficient area to pass the required volume without 'wiredrawing' and correctly timed so that the maximum amount of air is retained in the cylinder at the beginning of the compression stroke. Light spring diagrams are very revealing on this point, and should always be taken on engines of new design. In addition to the pressure obtaining, there is also the question of temperature, and in engines where air and fuel are drawn in together the latent heat of the fuel (petrol, benzol or alcohol) has an important effect, as the cooling of the charge offsets to some extent the temperature rise during the suction stroke and thus causes a greater weight of air to be retained when the inlet valve closes. For example, actual tests have shown a rise of from 7 to 10 per cent. in volumetric efficiency when alcohol has been substituted for petrol, thus demonstrating the importance of the temperature effect.

While it is common practice in carburettor engines to heat the incoming charge in order to provide a more homogeneous mixture, and so distribute the fuel evenly to the several cylinders, it is essential that this heating should be kept to a minimum, if maximum power is important.

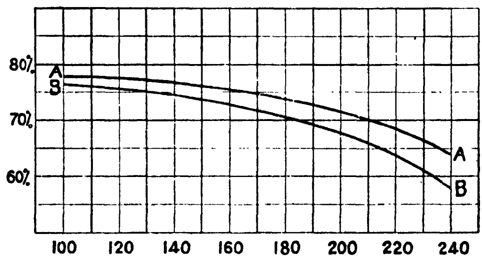

FIG. 5.

Volumetric Efficiency in Terms of Standard Pressure and Temperature.
A. Average of a large number of tests with valves in head.
B. Average of a large number of tests with valves in side pockets.

The following table, giving weights, volumes and latent heats, may be found useful.

SECTION XXVIII

PART II

GENERAL DESCRIPTION OF TYPES OF ENGINES AND FUELS — CONSTRUCTIONAL DETAILS PECULIAR TO LARGE ENGINES—NOTES PARTICULARLY APPLICABLE TO HIGH SPEED ENGINES.

(By R. J. W. Cousins, M.I.Mech.E.)

General Description of Types of Engines and Fuels

Internal Combustion Engines may be classified in several ways of which the broadest are as follows :—

(1) The Heat Cycle.—Constant Volume or Constant Pressure.

(2) The Mechanical Cycle.—Four-stroke, Two-stroke, etc.

(3) Single-Acting or Double-Acting.

(4) Trunk Piston type or Piston Rod and Crosshead.

(5) Method of Cooling.—Air, water, etc.

(6) Cylinder Arrangement.—Line, vee, fan, radial, horizontal, vertical, opposed piston and H types.

(7) Type and arrangement of valves used.—Overhead or side poppet valves, sleeve valves, piston valves or ported cylinders. Also special types using rotary or sliding valves.

(8) Method of Firing.—Spark ignited or compression ignition.

(9) Fuels used.—Gas (town producer or furnace), volatile liquids (petrol, alcohol, benzole and kerosene); non-volatile fuels (heavy oils and distillates).

(10) Method of injection of fuel oil.—Air blast or 'solid' injection.

(11) Design of the combustion chamber for compression ignition engines.—Open chamber, hot bulb low compression, and recent high compression cell types.

(12) High and low speed types.—The former generally being of lighter and more refined design, while the latter are heavy and either of cheaper and simpler construction, or intended for a very long working life.

(1) *Heat Cycle.*

(*a*) *Constant Volume Cycle.*—This includes most engines running on town, producer, furnace or natural gases, petrol and paraffin, but as previously explained the cycle is not followed strictly.

(*b*) *Constant Pressure Cycle.*—The larger oil engines approximate to this cycle when the fuel is injected by an air blast, but the 'solid' injection types, including all the small engines, have a cycle which is a compromise, the pressure of combustion rising above that of compression.

The operations in either case may be concluded in four-strokes (two revolutions) or two-strokes (one revolution).

(2) *Four-Stroke Cycle.*

Engines draw in air on the outward movement of the piston, compress on the next stroke, burning occurs at or near the inner dead centre and expansion follows on the third stroke near the end of which the exhaust valve is opened, the burnt gases being swept out on the fourth stroke.

The question of valve areas to attain the best results is dealt with later under the headings 'Inlet' and 'Exhaust Valves.'

In some large engines working on low value fuel, such as furnace gases, air from a low pressure blower (1½ to 2 lbs. per sq. in.) is admitted towards the end of the exhaust stroke, to assist in clearing the combustion space of dead gases, thus preventing further dilution of the next charge.

The Four-stroke Cycle, first used by Dr. Otto, after whom it is named, is by far the most popular, practically all car, truck and aero engines, as well as the bulk of small and medium commercial engines, being of this class.

The Two-stroke Cycle.—In this the charge is compressed on the inward stroke, burning occurs near the inner centre and expansion follows for a large part of the next stroke. Near the end of this second stroke, large ports or valves are opened and the used gases are allowed to escape, so that the pressure in the cylinder falls to a low figure before the stroke is completed. Other ports are then opened, allowing air from a blower to enter, and the time of opening, size, and direction

of the ports must be such that the residual exhaust is largely swept out and replaced by a clean charge before the piston has travelled far on the next (third) stroke, which then becomes the compression stroke for the second cycle.

The relationship of swept volume, speed and port areas is dealt with later.

Curiously enough, two-stroke engines are usually found either in the very small class, such as is used in light motor cycles, lawn mowers, etc., using the underside of the piston and the crankcase as an air pump and running on a petrol-oil mixture, or in the very large class, mostly marine engines running on heavy oil and with elaborate scavenging arrangements. The reason, no doubt, is that the very simple ported cylinder crankcase compression two-stroke engine, while very convenient in small sizes, is not economical in fuel, and introduces many problems, thermal and otherwise, when made in larger sizes, and it is usually not worth while providing the blower equipment, piston cooling, etc., until such dimensions are reached that a considerable overall saving in weight, etc., is effected by the doubling of the working strokes. The two-stroke engine is now very popular for marine work in both single- and double-acting forms.

(3) *Single- or Double-Acting.*

While most small and medium size engines are single-acting, *i.e.*, use the upper side of the piston only, a large number of marine engines are made with piston rods and lower cylinder covers fitted with glands, so that the underside of the piston may also be used. The glands are formed of nests of contracting rings of the same material as piston rings, each one contained in a rebated distance ring and arranged to have lateral clearance so that they do not carry any force radial to the piston rod. For reasons of accessibility, double-acting engines are generally only found in the larger classes.

(4) *Trunk Pistons.*

which are attached to the connecting rod by the gudgeon or piston pin and carry the side thrust on their skirts are the only form in use on small engines, but many large land engines and most early marine units used piston rods with single-acting engines, the crank chamber being closed by an oil stripping gland and the lower end of the piston rod attached to a crosshead to take the side forces.

This makes a very high, heavy engine, and in consequence there is a swing towards trunk pistons for some marine sets, where the saving of weight and head room are considered of more value than the lower oil consumption of the piston-rod type.

In general, trunk piston engines are of shorter stroke in proportion to the bore, and run at higher revolutions. Many are now under construction in Continental yards for use with reduction gears so as to increase the engine speed without sacrificing propeller efficiency.

(5) *Cooling.*

It is necessary to cool the cylinder walls so that they may be at a sufficiently low temperature to retain the lubricant, and the head and exhaust valve seat must also be cooled to prevent undue thermal stresses and distortion, softening, or burning of the parts.

Air cooling is used on almost all motor-cycle engines, aero radials, and the smaller aero line engines. It is found that the increased powers obtainable from modern fuels necessitate a proportional increase in the fin surfaces, which are now usually fully machined in the form, depth, and pitch found most effective.

Some aero engines use a high boiling point liquid like ethylene glycol on account of the reduction of radiator area rendered possible by the higher temperature (boiling point 197° C.). Steam cooling in radiators fitted with loaded safety valves is also used. The water and steam are separated at the engine outlet, the steam going through to the cooling surfaces so as to be condensed, while the water is circulated rapidly through the jackets again.

Most engines, however, are water-cooled.

Radiators on aero, vehicle and small commercial engines return the same water to the jacket repeatedly, and are to be preferred to the method employed in other cases of supplying new water continuously, for two reasons—

The new water tends to deposit more and more lime, etc., in the jackets if 'fresh.' If sea-water it must be kept below about 55° C. (120° F.) to prevent deposition of salt.

In either case the new water usually enters the cylinder jacket first and keeps it cold, the worst possible condition for bore wear, as it causes the condensation of small quantities of acid products on the cylinder bore.

It is better to use 'fresh' (non-salt) water in a closed circuit with the sea-water passing through a 'heat interchanger.' In this way a very rapid circulation may be kept up in the cylinder head where the greatest differences of heat input exist between the inlet and exhaust valve seats, etc., and where the directing of a large quantity of fairly hot water in the right places prevents great temperature differences in the various parts of the metal.

The jacket round the cylinder should be kept as hot as possible without boiling. This reduces wear by preventing deposition of water vapour and acid products on the walls, and also reduces the viscosity of the cylinder lubricant and thus the frictional losses.

This method is receiving increasing attention as speeds are rising, and wear becoming more important. In large engines the pistons are also cooled, sometimes by water, but increasingly by oil circulation, as corrosion fatigue of piston rods has been experienced with water.

(6) and (7) *Cylinder Arrangement and Types of Valves.*

The first step from single horizontal cylinder engines to vertical cylinder type to save space, was followed naturally by increasing the number of cylinders on the same line. This vertical in-line type now covers most vehicle, marine and power station engines as well as the small commercial class, the number of cylinders ranging from two to ten or even twelve. The crankshaft is one of the main problems, and care must be taken that forces and couples are balanced and that, over the running range, the engine is free from dangerous synchronous vibrations (see crankshafts).

The 'Vee' engine is well entrenched in aero work, and is coming into the field for cars, medium size high-speed generator drives and railcars. It provides two lines of cylinders in practically the same length and very little more width. The crankshaft is of course shorter for the same power, thus simplifying the torsional problem. The member requiring the most attention is the big end, most other parts are as in the line engine.

The fan engine—three banks of cylinders on one crankshaft—is not so well represented The big end, which must be split on a multi-crank engine, presents a difficult problem in design and manufacture. Radial engines of five, seven and nine cylinders on one crank, or fourteen and eighteen on two cranks, dominate the air-cooled aero engine business, except in the smaller powers.

The big advance in power due to the better fuels has been met in the air-cooled radials by more liberal finning and the use of the unsplit big end and built-up crankshaft. One master connecting rod carries a banjo end with side-flanges between which work the wrist-pin connections of the articulated rods. The frontal area of these engines is greater than that of the 'Vee' type for the same output, but by careful design the overall diameter has been reduced while powers have risen, and advanced methods of cooling the cylinders and exhaust ring, and controlling the flow of cooling air, have cut down the head resistance to a very low figure.

The H engine is an aero type of comparatively new development, and consists of four banks of cylinders, usually six in each line. Two banks, one above and one below, act on each of the two crankshafts which are geared to a slower speed propeller shaft in the centre. The basic idea is to get more cylinders of small size on to one engine and thus raise the speed at which the required power is developed, so that the power weight ratio is kept down. In addition to this, small pistons and exhaust valves do not present such formidable thermal problems at high outputs as large ones.

Opposed Piston Engines.—These are made with two pistons back to back forming the combustion chamber. They work on the two-stroke cycle, and one piston is given a slight lead over the other, so that the exhaust ports, which it uncovers towards the end of the working stroke, will open in advance of the scavenge or air inlet ports, which are controlled by the second piston. The Junkers aero engine of this type, has two crankshafts geared together by a vertical train of spur gears, while the Doxford marine two-cycle engine has the upper piston connected to the same crankshaft as the lower by side rods. Swash-plate engines have also been made on this principle. The type in general has its own particular design problems, which have called for a good deal of development work—notably the exhaust piston and the connecting of the two pistons to the point at which power is taken off, but it has two very attractive features, first the elimination of the cylinder heads, which means a reduction of the heated surfaces, and second the long combined stroke to bore ratio which makes for very good scavenging. Excellent efficiencies are obtainable.

Valves.—The majority of engines use the well tried poppet valve. The old T-head engine with the exhaust valve in one side pocket, and the inlet in the other, was a bad detonator and required two camshafts. It is dead and not likely to be resurrected. Both valves in one compact chamber at the side are popular for petrol engines in cars and lorries, also for small commercial engines. Overhead valves operated by push rods are common on vehicle oil engines, and overhead camshafts on aero and fast car engines.

Reduction of deflection and weight of moving parts, careful cam and spring design and the cooling of the exhaust valve seat are the important points.

Large engines use removable valve cages, but these are not found good on small engines, where the separate exhaust seat cannot be properly cooled.

The single sleeve valve engine has many attractive points, not the least being the absence of local hot spots and the high compression ratio rendered possible by this. At least one aero engine is a definite success, and this system may come to the front for particular applications. Wear of the sleeve is remarkably low and high speeds are obtainable.

Rotary valve engines have attracted designers for many years, but their seeming simplicity is deceptive—they usually leak or seize if made in elementary form, and success has only been reached by certain proprietary designs where very thorough work has been put into the elimination of their troubles.

Most two-stroke cycle engines use ports in the cylinder uncovered by the piston with, in some cases, supplementary valves in the exhaust or scavenge belt to give correct timing. Certain large two-stroke engines, both single and double-acting, use piston valves at the end of the cylinder for the exhaust release. These are controlled by very robust gear, as they are subject to full gas pressure and in fact produce quite a respectable percentage of the total horse-power (about 9 per cent. to 10 per cent.). In smaller engines poppet valves may be used in the same way for the exhaust. Centrally placed scavenge ports open alternately above and below the piston in

the double-acting engines of this type, and as the whole circumference is available for air, high outputs and good piston speeds are possible. In all valve systems the first essential requirement is that the area of opening multiplied by the time, shall be enough to pass the necessary weight of gas with the available pressure difference across the port or valve. If this is not satisfied, the engine will be handicapped. Methods of approximating to the areas needed will be given under valve details.

(8) *Method of Firing.*

There are broadly three methods of firing :—

(*a*) Electric ignition by the passing of a spark between two points in the combustion chamber. This is now done by a momentary high voltage of the order of 10,000 volts applied to the points of a sparking plug by a magneto, or by a coil and distributor working from a battery. The latter gives a better spark at starting speeds. At one time a low voltage was applied to a robustly made 'make and break' device in the cylinder, the contact being broken and an arc thus produced by a trip gear working from the camshaft. Before that, an incandescent tube was so arranged that some explosive mixture entered it at the right moment, but this device disappeared very soon.

(*b*) Surface Combustion or Hot Bulb. In this system a comparatively low compression engine is fitted with an uncooled bulb or chamber forming part of the combustion space. For starting, the bulb is made red hot by a blowlamp, and afterwards the heat of combustion keeps it hot enough to fire the charge, although the compression pressure is only about 200 lbs per sq. in. These engines are of low efficiency but cheap, as the low pressures and speeds do not call for advanced design or expensive materials. They are disappearing before the more efficient and higher speed high compression oil engine.

(*c*) The third method is to design the engine with a compression ratio so high that the temperature of the air at the end of the stroke is high enough to fire the fuel when the latter is injected by pump or air blast. A variety of fuels may be used in this way, since their tendency to detonate does not impose a limit as it does in the spark ignited engine.

The long expansion range gives high efficiency and this too on cheap fuels.

Fuels not volatile at ordinary temperatures are used. Engines firing in this way are now made in sizes from about 400 c.c. capacity per cylinder (a four-cylinder taxi engine has recently been produced in this size) up to marine and power station plants with cylinders about 36 bore and several thousand horse-power per line.

(9) *Fuels Used.*

This is perhaps one of the most important ways of classifying engines, since the design must start from this point, and an engine arranged for high duty on a particular fuel may simply not work on a lower grade, while one designed for low-grade fuel will not use the better stuff economically.

In spark ignited engines the fuel and air are mixed on the suction stroke and a homogeneous explosive charge is compressed. When the spark passes, flame spreads through the charge. The combustion of the first part of the charge heats and expands it, thus compressing and further heating the unburnt part. If the shape of the chamber is not compact, or if the unburnt part is squeezed into a hot pocket, for example over the exhaust valve, it may explode spontaneously throughout its mass, causing a detonation wave to go through it at the high speed appropriate to its density and pressure. This causes a sharp noise like the blow of a light hammer and is called 'knocking' or 'pinking' (the noise sounds something like the word 'pink' repeated quickly). This quickly leads to real preignition, rapid loss of power and probably piston seizure from overheating. Therefore, persistent knocking cannot be tolerated. Much can be done by designing the combustion chamber as compactly as possible (a sphere without hot zones and a spark appearing magically in the centre is the unattainable ideal), by firing the charge so that the flame travels towards cooler and not hotter zones, and by giving a certain amount of movement to the gases to facilitate flame spread, but when this has been done, the fact remains that some fuels are more stable chemically and will work under control (*i.e.* without spontaneous detonation) up to very high compression ratios, while others (notably the heavy paraffins) being what are called 'chain' compounds (the construction of the molecule is like that of a long train of heavy waggons held together by weak couplings) break up easily and 'knock' on the smallest provocation. If pre-heating is necessary (as for kerosene) this makes matters worse. The compression ratio in spark-ignited engines must therefore be low enough to prevent the particular fuel from knocking, but if high-grade fuel is used in a low-compression engine, practically no advantage is gained. The heat value of the available hydrocarbons does not vary much. *The real value of a fuel for spark ignition engines lies in its ability to work at a high ratio and therefore at a high efficiency*, and in support of this it is found that greater power may be obtained from alcohol blends, although the heat value is actually less (due to the combined oxygen). This result comes about thus :—

(*a*) The very high latent heat of alcohol cools and contracts the air, so that a greater weight of air is retained at the beginning of compression.

(*b*) A very high compression ratio may be used and the extra air is used at a high efficiency. (See tables of appropriate compression ratios in Part I.)

The 'lower' heat values of some fuels are given below. These do not include the latent heat of the water vapour produced as it is not available at the working temperature.

	Per lb.	B.Th.U.s Per gall.	Sp. Gr. at 60° F.
Petrol (mean of several samples)	18,890	136,600	0·725
Benzene, pure	17,300	153,000	0·884
Heavy aromatics	17,900	158,500	0·885
Pentane (normal)	19,600	122,300	0·626
Kerosene (approx. value)	19,000	154,400	0·812
Cracked spirit (approx. value)	18,400	139,400	0·760
Cyclo hexane	18,800	146,600	0·780
Ethyl alcohol 98 per cent.	11,480	91,600	0·796
Methyl alcohol	9,630	79,900	0·830
Methylated spirits	10,200	83,700	0·820
Gas oil 0·86 sp. gr. (for compression ignition)	18,300	157,200	0·860

It will be seen from this table that if fuel is bought by the gallon, a high specific gravity may be an advantage—provided the knock rating of the fuel is high enough for the engine.

The knock rating was first quoted as the percentage of toluene required to be mixed with a standard non-aromatic petroleum spirit in order to give the same behaviour in a variable compression engine as the sample in question. The system of 'Octane numbers' has since been adopted. In this system pure iso-octane has been taken as 100 and fuels are classified as 73–87–100, etc., according to their approach to this fuel in detonation resistance. The higher the number the greater the compression ratio at which the fuel will work, and consequently the better the efficiency. For compression ignition engines, on the other hand, *a readily disrupted molecule is not only desirable but to some extent necessary.* For example, tar oil and creosote are very difficult to burn well in engines, as their stability is great, and their ignition temperatures very high. Kerosene—a poor fuel in spark-ignition engines, in fact quite at the bottom of the class—is good in a compression ignition engine, but a slightly heavier petroleum distillate—gas oil—is preferable in many ways, being cheaper, less volatile, and a better lubricant for the injection pump, as well as a better starter. Very large engines designed to use tar oils are usually provided with pilot injectors, using from 5 per cent. to 10 per cent. of a more readily ignited petroleum. The delay in starting combustion with certain fuels is followed by a sudden rise in pressure, due to the fact that a considerable proportion of the charge is then in the cylinder whereas if burning starts promptly, the rise is more gradual and the combustion noise is less.

Fuels for compression ignition are sometimes classified according to their 'cetene value' which may be regarded as the direct opposite to the 'Octane number,' but universal standardisation has not yet been attained. Another system aims at defining the ignition delay in crankshaft degrees, and another in compression ratios.

Engines using gases or light volatile fuels are spark ignited, and the compression ratio is normally between 3·6 to 1, and 7 to 1—the figure varying with the fuel. Among the gases used are furnace gases and producer gas, both of low calorific value and much diluted with nitrogen.

Producer gas engines at one time had a great vogue. Plants have been built to make gas from a variety of waste substances, such as wood, sawdust, bark, cocoanut shells, sugar cane refuse, mealie cobs, etc., as well as charcoal, coke, bituminous coal and anthracite, but in spite of the economy of the engines, they have made little progress in this country.

An analysis of a sample of producer gas is given below :—

Out of 100 volumes				
CO_2	4·2 vols.	requiring	0	vols. of oxygen.
C_nH_{2n} (various)	0·6 ,,	,,	2·55	,, ,,
O_2	0·9* ,,	,,	0	,, ,,
CO	20·1 ,,	,,	10·05	,, ,,
H_2	6·8 ,,	,,	3·4	,, ,,
CH_4	3·7 ,,	,,	7·4	,, ,,
N	63·7 ,,	,,	0	,, ,,
Total	100·0 ,,		23·4	
			−0·9*	
			22·5	,, ,,
			=107·0	,, air.

Blast furnace gas has the approximate composition by volume as under :—

CO_2	11 per cent.
CO	27 ,,
H_2	2 ,,
N_2	60 ,,

Heat values for some of the gases used in engines and the air required for complete chemical balance are :—

Gas.	B.Th.lbs. per cub. ft.	Air for 1 volume
Blast furnace gas	84	0·69
Producer (coke) gas	126	1·07
Coal gas	500	4·90
Water (blue) gas	270	2·22
Water (carburetted) gas	458	4·27
Natural oil gas	1,000 to 1,100	11·00 (approx.)

Town gas—once the favourite for small plants—is now being ousted by electric motors or small oil engines, while in large plants this fuel is too dear.

In special cases, for example municipal electric plants operated in conjunction with a gas works, it may pay to use gas for engines driving generators for the evening lighting load, and so level up the demand on the gas making plant, which has its peak for cooking, etc., in the daytime, but the greatest call nowadays in the gas engine trade is for vertical multicylinder machines running on natural gas in the oil-fields, or furnace gas engines which are in general very large, and have horizontal cylinders.

Volatile Liquid Fuels.—The heaviest of this class is paraffin or kerosene, which while not volatile at ordinary temperatures will work in a carburettor engine if an exhaust heated vapouriser is provided.

Its greatest use was in small boats, particularly fishing boats, where the reduction in fire risk was in its favour. Owing to the fact that this fuel detonates readily, low compression ratios must be used. The thermal efficiency is therefore low, and as the preheating in the vapouriser reduces the volumetric efficiency, the power of the engine is also low in relation to its size and weight. Better kerosenes with higher knock values have been produced, but the vapouriser engine is being ousted in favour of the oil engine which is much more efficient, works on a cheaper and still safer fuel, and gives higher mean effective pressures. The really volatile fuels—petrol or gasoline, benzole and alcohol or mixtures of these—have been subjected to intense study and development, so that their qualities as represented by the compression ratio they will stand, freedom from undesirable impurities, ease of starting from cold, etc., have advanced enormously. Cracking and recombination of the simple petroleum distillates is practised extensively, while special fuels capable of working at very high compression ratios and 'boosts' are produced by hydrogeneration, *i.e.* the combination with hydrogen under very high pressures, and the use of small quantities of materials which have been found to inhibit detonation—notably, lead tetra ethyl, $Pb(C_2H_5)_4$.

These fuels enable suitably designed engines to operate at the maximum power/weight ratio yet attained, the remarkable figure of 11 ozs. per horse-power including blower and reduction gear being the dry weight of one racing aero engine produced for a special event. The fuels used in compression ignition engines of the light high-speed class, such as bus and truck engines, are light petroleum distillates of the grade generally known as 'gas oils' with a specific gravity of about 0·86 to 0·87. On account of the very small nozzles sometimes used (holes as fine as 0·008 in.) no sediment can be tolerated, and the fuel must be of consistently low viscosity and free from water and corrosive constituents. Fine filters are commonly fitted.

In the large air-blast injection engines, much cruder fuels of specific gravity 0·89 and higher can be used, but in cold conditions, means may have to be provided for heating the service pipes, as these fuels are very viscous at low temperatures.

The quality and cleanliness of fuel oils available for ships vary in different ports, and cases are reported of erosion of nozzles, etc., by fuels containing water and sediment. This is particularly bad for airless injection engines, which means almost all marine engines, and hence there is a move towards establishing some standards for these oils.

On the smaller plants distillates are generally regarded as practically essential, but experiments now in progress show that centrifugally filtered residuals work well in certain cell type engines of small size, though heating has been necessary to reduce the viscosity.

(10) *Injection of Fuel.*

The early oil engines used the method, still adopted in some large machines using residual oils, of injecting the fuel by an air blast of considerably higher pressure than that of compression. (Compression pressure about 500, blast pressure 800 to 900 lbs. per sq. in.) The fuel is metered into the injector by a controlled plunger pump and the needle valve lifted mechanically at the correct time. The high pressure air (from a two- or three-stage compressor built into the engine) then blows the fuel into the cylinder through the 'flame plate' breaking it up into a fine mist which fires from the heat of compression.

'Solid Injection' engines dispense with the air blast and rely on the very high pressure from pecial fuel pumps (from 3,000 up to 7,000 lbs. per sq. in.) and the fine nozzles to give sufficient

subdivision of the fuel. This system has gained ground very rapidly, as its simplicity makes it the only one for small engines and it has also been applied to the largest sizes. On marine engines it is now universal, and the fuel economy is in some cases as much as 10 per cent. better than blast injection engines driving their own compressors.

(11) *Design of Combustion Chamber.*

In both air blast and direct injection engines there are several ways of ensuring that the fuel shall be intimately mixed with the air.

(*a*) The open chamber (used also with blast air injection) relies on the several jets in the nozzle or flame plate to distribute the fuel, but in modifications of this system the air inlet ports or valves are arranged to give some rotation to the air so that the radial jets from the injector may be swept circumferentially by clean air and so use a larger proportion of the oxygen present.

(*b*) This rotation may be speeded up as much as possible, everything being done to create a rapid 'swirl' and thus maintain a good performance at higher speeds. Both (*a*) and (*b*) usually have the combustion chamber formed by a central cup in the piston head.

(*c*) The air may be compressed into a separate chamber in such a manner as to produce a rapid circulation past the injector. In these cases the nozzle may be of the single hole or preferably the 'pintle' type, which will run for long periods without attention.

(*d*) The piston may be made with a projecting piece on the head, known as a 'turbulence block.' Near the end of the compression stroke this enters and restricts the passage to the combustion chamber, thus setting up high velocity air currents which assist in the distribution of the fuel.

In general the best starting and the lowest consumption are obtained on open chamber engines with low velocity air movement, as the heat losses are lower, but the highest speeds and outputs have been obtained from certain engines of (*c*) type, which also give clean exhausts free from visible smoke and objectionable aldelydes up to high mean pressures.

(12) *High and Low Speed Types.*

In all classes of engines, speeds tend to increase from year to year.

In aero engines the struggle for greater power combined with propeller efficiency, forced a decision in favour of geared engines, even for large radials, and this at once opened the way for much higher rotational as well as piston speeds.

The 1914–18 piston speeds of 1,400 to 1,800 ft. per minute have now been raised to 3,000.

Car engines were originally rated on 1,000 ft. per minute, but present-day speeds reach 3,000 for cars and 2,500 for commercial vehicles.

In these fields there are degrees of speed but no broad division, whereas in marine work there is a definite step from the direct drive where speeds exceeding 120 r.p.m. are not usual, to the geared or electrically driven propeller, where the engines may run 250 r.p.m., in cargo vessels up to 450 r.p.m., as in the German 'pocket battleship' class, which have double acting two-strokes 420 mm. bore × 580 mm. stroke. The piston speed is approximately 1,700 ft. per minute, which is about twice that of the long stroke piston rod type, common in direct drives. In spite of the fact that the blowing engines develop 13 per cent. of the power of the main engines in providing the 5 lbs. scavenge air pressure required, the overall fuel consumption per b.h.p. at the couplings is approximately 0·385 lb., *i.e.*, 0·34 net apart from the blowers.

These engines are of wrought steel welded construction and the bare weight without gear boxes is the somewhat remarkable one of 18 lbs per b.h.p. There are now many ships in commission or building abroad in which single acting two-stroke geared engines with trunk pistons are fitted.

The elimination of the piston rod and the shorter stroke used, make these engines much lower, lighter, and easier to handle. The gear allows the designer to choose the highest engine speed consistent with life and economy, while keeping the propeller speed even lower than in the direct drive, and the gain in propeller efficiency goes to balance the small gear loss. The fast running trunk piston engine uses rather more lubricating oil, and the slow-speed crosshead type has an excellent record behind it, but judging by all the other fields the increase in speed in marine engines will go on. A number of ships' auxiliaries have been installed, running at 900 r.p.m., and 1,800 ft. per min. piston speed. These have given consumptions as low as 0·365 lbs. per b.h.p. hour on long runs, and used in generator drives they save a great deal in weight and cost of the dynamos.

As pointed out in the notes on cooling, cylinder wear is a matter of corrosion as well as erosion, so that increasing the speed does not increase the wear in proportion. In other words, a piston running fairly fast does more work before reboring is necessary than if run slowly under the same temperature conditions. The increase in speed has led more and more to the use of aluminium alloys, both cast and forged, and recently magnesium alloys have also been tried experimentally by several makers. In marine engines wrought and cast steel are taking the place of cast iron

as they are not only stronger and therefore lighter for the same loads, but have a stress strain relationship (Young's modulus) twice as favourable, in other words, stiffness does not suffer by the reduction in section.

Dynamic forces which increase as the square of the rotary speed have now become more important, and every effort must be made to use the advantages offered by the stronger or lighter materials now available to reduce the weight of moving parts.

Constructional Details Peculiar to Large Engines.

While many things are common to all engines, the larger classes have problems of their own, and in particular use constructions not readily applicable to small machines.

General Construction.

Practically all marine and most other large oil engines now have vertical cylinders. Crankshaft bearings are usually carried in cross members of the bedplate to which is attached the column supporting the cylinders. In some cases the cylinder heads form a stiff entablature attached to the bedplate by the transverse bulkheads of the column, and from this entablature the cylinders depend, the water jackets being of light section and unstressed. The lower ends of the cylinders spigot into a deck which takes the side thrust in the case of trunk pistons. This scheme has the great merit of giving a cylinder free from axial stresses, and thus reduces the risk of distortion in the top flange and in the neighbourhood of the piston rings at top centre when gas pressure is greatest.

In another system the water jackets are of strong section and either cast in one piece or have their end faces machined and firmly bolted together to form a stiff upper beam. The main bolts pass up to the top of this beam and may extend farther through the cylinder heads, or the latter may be separately studded to the top face of the jacket section.

The liners in this case spigot top and bottom into the jacket, the bottom joint being made with rubber rings while the top is a slight interference fit.

The cylinder liners are turned all over to ensure uniformity, and are easy to renew if necessary.

In some very large engines forged mild steel has been used for the cylinders, with a thin dry liner of hard cast iron shrunk in. This reduces the thickness required, and in consequence the thermal stress is less in proportion to the ultimate strength of the material. In this connection it must be remembered that in two cylinders of the same thickness—one of cast iron and the other of steel—having the same temperature difference between the inner and outer skins, the stress in the steel is greater because the relationship between stress and strain is greater, *i.e.* 30×10^6 in steel and about 14×10^6 for cast iron (in lbs./sq. in. units), while the thermal expansion is the same approximately. The steel, however, will stand a tensile stress even higher in proportion, thus giving it a considerable advantage. The extreme upper part of the cylinder is sometimes formed with an external helical rib, which, when the jacket is in place, forms a narrow passage through which the circulating water is forced at a high velocity to take away the heat from this part, where the temperature and density of the gases are much higher than lower down, and where in consequence the heat stresses are greatest, particularly as the liner is thickest here. The lower part of the cylinder should be kept as hot as possible, having regard to the cooling system used (fresh or salt water). The cylinder thickness should be calculated for the maximum gas pressure at the top and may be reduced considerably below when the liner is not subject to axial load. For good cast iron the metal may be $0 \cdot 07\ D + 0 \cdot 25$ in. at the top, tapering to $0 \cdot 04\ D + 0 \cdot 25$ in. at the half-stroke and continuing parallel. If steel barrels are used, the stress due to gas pressure may be at least doubled, but it is sometimes advisable to turn ribs on the outside to increase the ring stiffness and preserve the roundness of the working barrel. Due to the temperature difference of the inner and outer faces, a very thick cylinder may be more heavily stressed by heat than a thinner one by mechanical forces, and a stronger material is then the solution.

The maximum gas pressure in the old air blast engines was about 500 lbs./sq. ins., but with airless injection the peak is now about 700 in large cylinders. This only affects the upper part of the cylinder, and the pressure drops very rapidly as the piston moves down the stroke.

Thermal and Mechanical Stresses in Liners, etc.

The percentage heat losses to water do not vary very much with piston speed or size, for the same general design of engine, but different designs and systems differ widely in the amount and distribution of the heat flow. This suggests that the horse-power per square inch of piston may be taken as a rough measure of the rate of heat flow in corresponding parts of engines of the same class.

Local gas velocities together with the temperature and density obtaining at each instant determine the heat flow at any point. The cycle occurs so rapidly, however, that it is unlikely that anything beyond the merest skin is affected by the cyclic temperature change, and the mean value is the pertinent figure, even in comparatively slow engines.

For any given heat flow the temperature difference between the inside and outside surfaces of a containing wall varies directly as the thickness, and inversely as the conductivity. If the wall is constrained to keep its shape, the outer part is intension, and the inner in compression. The thermal stress at the face is therefore—

$$\pm \frac{R \times t \times E \times a}{2C} \text{ lbs. per sq. in.}$$

where R = rate of heat flow in B.Th.U.'s per hour per sq. in.
t = thickness in ins.
E = direct modulus of elasticity.
a = coefficient of thermal expansion per 1° F.
C = conductivity B.Th.U.'s per hour per in. cube per 1° F.

Approximate values for the various factors are as under:—

Cylinder heads high output cell type oil engines .	$R = 700$	B.Th.U.'s per sq. in. per hour
Cylinder heads high output supercharged petrol engines	$R = 700$	,, ,, ,,
Liners for either of the above—top zone . .	$R = 300$ max.	,, ,, ,,
Liners for oil engines, 2-stroke . . .	$R = 150$	for 1,000 ft. min. piston speed.
,, ,, ,, ,, 4-stroke . . .	$R = 125$	

Material.	E.	a.	C.
Cast iron	14×10^6	$6{\cdot}7 \times 10^{-6}$	3·0
Aluminium (normal high expansion alloys, cast or forged)	11×10^6	$12{\cdot}5 \times 10^{-6}$	9·6
Mild steel	30×10^6	$6{\cdot}2 \times 10^{-6}$	2·15

It is clear that the thermal stress increases in proportion to the thickness, while the stress due to gas pressure varies inversely as the thickness, being $\frac{DP}{2t}$ lbs. per sq. in. (D = cylinder diameter, ins., P = pressure lbs. per sq. in., t = thickness inches). Therefore there is in each case an optimum thickness for liners, etc., which gives the lowest combined stress.

Example:—

20-in. cylinder, 4-stroke, cast-iron liner, 1,200 ft./min. piston speed, 700 lbs. maximum pressure, say 600 maximum on liner below the spigot.

Heat flow 150 B.Th.U.'s per hour per sq. in. approximately.

Thickness (inches).	Stress.		
	Thermal.	Mechanical.	Combined.
1	2,350	6,000	8,350
1¼	2,940	4,800	7,740
1½	3,520	4,000	7,520
1¾	4,110	3,430	7,540
2	4,700	3,000	7,700

The addition of the two stresses shows that between 1½ in. and 1¾ in. there is little difference, and allowance for reboring, etc., would suggest that 1¾ in. would be suitable in this case for the upper part of the liner.

Through bolts are often used to tie the heads down to the bedplate. They pass through distance pillars, preferably formed in the bulkheads or A frames of the column, and these pillars have an important bearing on the fatigue stress of the bolts. Since both bolt and pillar are springs in parallel, the variation in bolt stress when each explosion occurs depends on the pillar as well as on the bolt.

Let A_1 A_2 = Areas in sq. ins. of bolt and pillar respectively.
,, L_1 L_2 = Length in ins. ,, ,, ,,
,, E_1 E_2 = Young's Modulus for the materials in bolt and pillar (30×10^6 for steel, 14×10^6 for cast iron).

Then the axial stiffness of the bolt is $\frac{A_1 \times E_1}{L_1} = S_1$ lbs. per inch., and the axial stiffness of the pillar is $\frac{A_2 \times E_2}{L_2} = S_2$ lbs. per inch. Therefore the stiffness of the two together is $S_1 + S_2$ lbs. per inch deflection. And if the variation of the *external force* (in this case the gas force) coming on to each bolt and pillar is F, then the deflection is $\frac{F}{S_1 + S_2}$ inches, the variation in bolt tension is only $\frac{F \times S_1}{S_1 + S_2}$ and the variation in bolt stress is $\frac{F \times S_1}{A_1(S_1 + S_2)}$. This is a very important point and should be applied to connecting rod big end bolt bosses, etc. It shows that the stiffness of the metal round tension bolts carrying varying loads is as important as the bolts themselves, and that the failure of a bolt from fatigue may be due to the flimsiness of its abutment.

The superiority of cast steel over cast iron on account of its higher E value is also clear.

Wrought Steel Construction.

The use of this material for engine columns and bedplates is increasing rapidly. Long through bolts may be dispensed with so that there are no opposed stresses, pattern-making is cut out, and size becomes of less importance as the foundry question never arises. Greater rigidity or less weight, absence of 'wasters' cooling stresses and blow-holes are further advantages. Cast steel bearing housings or ribbed cross members of small individual size and of open section easily cast without cores, may be employed and attached by tennons to the plates forming the bulk of the structure. Electric welding is used to hold all the parts together and fill and key the tennons, but the design is so arranged that direct tension on the welds is not relied upon. Double bulkheads may be used, curved round at the top to bring the stress lines close to the cylinder flange, or separated at the bottom to enclose the bearing housings. Strips are welded on where required for machining. The main bulkheads may be made as U-shaped slings, carrying the bearing housing in the bend, and attaching to the cylinder beam at the two upper ends, thus eliminating the long bolts. Side plates notched and welded in position extend right round under the frames, and project right and left to the cylinder centre line, where they are bolted together on a vertical joint and complete the crankcase. This construction has resulted in a really astonishing reduction in weight. The whole structure should be annealed after welding.

The cost compares very well with the heavier designs, and in ship work it means less dead weight to carry.

In addition to the direct gas forces in line with each crank, the whole engine must be considered as a beam subjected to bending moments set up by the varying dynamic forces along the length of the engine.

These couples depend on the amount of balancing, the crank arrangement, the reciprocating masses, etc., and are given in the crankshaft section, but the engine frame must withstand them without undue stress or deflection, and therefore it is necessary to make an approximation to its strength as a beam. The welded structure lends itself very well to this need for beam strength, as good longitudinal sections can be provided at top and bottom, while quite light side plates, suitably attached, form what is in effect the web of the girder.

Crosshead.—This feature is only found in large engines. The area of the thrust face may be equal to that of the piston or down to 0·75 of that figure. In single guide designs the sliding shoe is T section, and retained by keep plates each side which take the horizontal component of the compression force. This is much less than the working thrust and does not need half the area of the main slide face. Means should be provided in the design for adjusting the face of the fixed guide for both distance and alignment. If distance plates are used for the adjustment, they should be of ample area to prevent any subsequent settling down, and should be screwed or riveted in place. Cast iron forms the best surface for the fixed guide. The shoe may be of cast iron or steel, the latter faced with white metal.

There seems no reason why aluminium, which works so well in aero and car engines (where the piston forms its own crosshead) should not be used for the shoe, and in one experimental engine this has been done with a useful saving in reciprocating weight.

Piston Cooling.—Liquid cooling of pistons becomes necessary as the size increases, because the heat gradient in the piston head becomes too great and the rings will not live. Two-stroke engine pistons are hotter, size for size, than four-strokes.

Salt water is still used in a few cases, but fresh is better, and oil is much to be preferred to either, for two reasons :—

(1) leakage into the crankcase from the telescopic or hinged pipe connections does not matter provided enough oil is reaching the piston.

(2) Corrosion fatigue may be set up by the action of the water, particularly at the edges of holes (in the piston rod for example) through which it passes.

Piston Rods.—Prolonged tests on samples unstressed on the one hand, and subjected to alternating loads on the other, show that the rate of corrosion in weak salt, acid or alkaline

solutions is much more rapid in the case of stressed parts, and the piston rods, especially of double-acting engines, should be made with as little stress concentration as possible, radial holes should be avoided, and oil cooling employed to eliminate this danger.

Internal bushings of cast iron are sometimes fitted to reduce the chances of corrosion fatigue in the rod when water cooling is used. External sleeves of pearlitic cast iron are also in common use in double acting engines to reduce the temperature stress in the rod, and an arrangement used in one very large engine is shown in fig. 1 where the piston cooling oil passes up through the annular space between the rod and the protecting sleeve, thus keeping the former free from any marked temperature differences, while the thermal stress in the sleeve is small owing to its thin section. The outlet is down through the centre of the hollow rod. The sleeve is attached to the top and free to expand below.

The minimum section where the rod is screwed into the crosshead should not be less than 0·04 of the piston area in a double acting engine, and every possible care must be taken to avoid sudden changes of section, sharp corners, etc., which would cause concentration of stress.

Oil Pipes.—Most slow-speed engines employ sliding telescopic pipes for flow and return of the piston coolant, but at high rotary speeds the pulsations and pumping effects become marked, even when large air vessels are fitted. 'Walking pipes' then become preferable, if not absolutely necessary.

Liberal surfaces should be allowed at the hinged joints, and light but stiff *straight* weldless steel tubes used with end fittings welded or brazed on. Any tube having a considerable amplitude of movement should be calculated for strength in bending, and curves should be avoided in these members.

W lbs. = weight of tube per inch (including the oil in it); S = stroke in inches at end.

$R = \dfrac{\text{crank}}{\text{con. rod}}$ ratio.

R.P.M. = revs. per minute.

Then the force per inch varies from zero at the fixed end to—

$$+ 14{\cdot}1\ SW \left(\frac{\text{R.P.M.}}{1{,}000}\right)^2 \times (1 + R) \text{ at Top Dead Centre} = + F_T$$

and

$$- 14{\cdot}1\ SW \left(\frac{\text{R.P.M.}}{1{,}000}\right)^2 \times (1 - R) \text{ at Bottom Dead Centre} = - F_B$$

If L inches equals the length of the pipe the greatest bending moments are—

$$\frac{+F_T L^2}{9\sqrt{3}} = + M_T \text{ at top, and } \frac{-F_B L^2}{9\sqrt{3}} = - M_B \text{ at bottom centre.}$$

The resistance of the tube to bending is $\left(\dfrac{D^4 - d^4}{D}\right) \times \dfrac{\pi}{32} = B$ ins.^{3} (when D and d are diameter and bore of pipe) and the stresses positive and negative are $\dfrac{+M_T}{B}$ and $\dfrac{-M_B}{B}$ lbs. per sq. in. respectively. They should not total more than 18,000 lbs./sq. ins. To lower the stress, increase the diameter D.

Pistons.—These are now often made in the larger sizes with forged steel heads machined all over without ribs or other irregularities, in order to avoid distortion and cracking. Cast steel may also be used, and many are still of cast iron, but the strength of the latter being much inferior it must be thicker for the same load, and hence the thermal stresses are higher.

The older designs with ribs under the head and made of ordinary cast iron, develop cracks in the higher duty airless injection engines now being built. Ribs should be avoided in the head.

The cooling liquid should be constrained to follow the heated surface closely and at a good velocity. Skirts are of cast iron and piston bearings of bronze on case hardened pins.

A special double-acting piston design is shown in which the comparatively thin crowns (upper and lower) are supported mechanically near the edge and at an intermediate diameter by a strong forged steel centre. The piston rod has no radial holes in highly stressed sections. Light baffles of aluminium are used to cause the cooling oil to pass right across the heated surfaces and behind the rings, which are fitted with wear rings. The crowns are of forged Y alloy (aluminium), while the split bolted-on guide ring is of cast iron and registered on the steel centre.

Fairly large four-stroke trunk pistons up to about 22 ins. diameter have been made of cast aluminium with bronze interiors to carry the pin. These are not liquid cooled, but rely on a deep nest of narrow rings. The speed is nearly 1,600 ft./min.

Starting.—The usual method is to admit compressed air from a distributing valve through non-return valves in the heads of a sufficient number of cylinders, but small compressed air engines running fast and geared to a toothed ring on the flywheel are more efficient, and are common on medium sizes.

Engines driving generators may be arranged to be started by using the dynamo as a motor. Dynamometer tests give the torque required to start a high compression oil engine as 40 to 45 lbs. per sq. in. of piston referred to the whole engine. Lifting the valves to release compression reduces the torque at the first movement, but they must be dropped quickly or work is wasted in pumping losses.

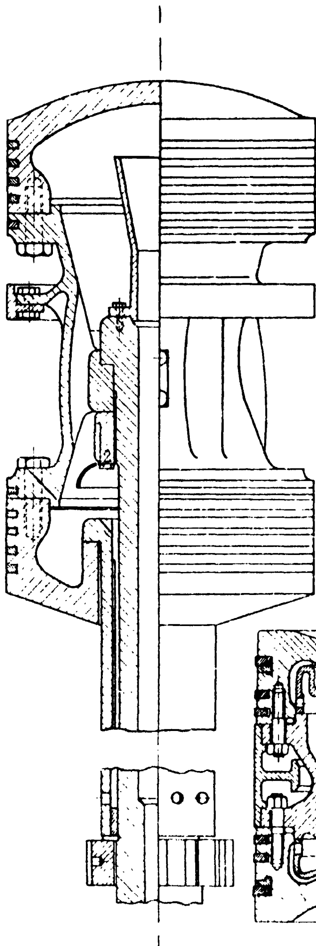

FIG. 1.

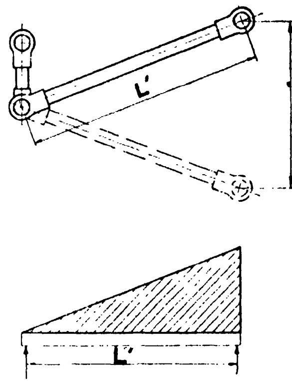

FIG. 2.

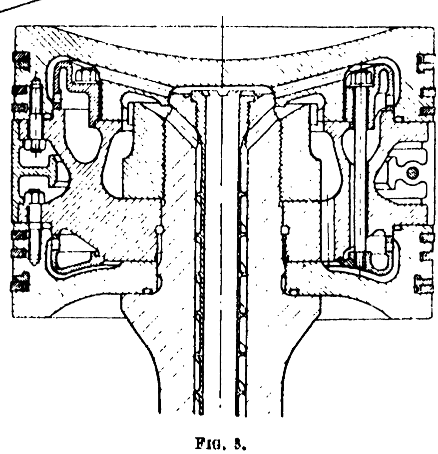

FIG. 3.

Connecting Rods

The bottom ends are almost always of the 'marine' type, *i.e.* two separate halves, of cast or forged steel, white-metalled on the working face, and bolted to the tee end of the shank.

The diameter is dictated by the shaft requirements, but with the higher pressures now ruling, the projected area should be as generous as possible. In large line engines the diameter may be as high as 0·83 of the cylinder bore, with a width of half the diameter, giving a net projected area, exclusive of fillets of about 0·4 of the piston area. This may be reduced to 0·33 of the piston area if necessary. The top end may also be in halves bolted on, but is sometimes integral up to the gudgeon pin centre line, with the top cap or caps (in the case of forked rods) bolted to ears on the shank.

Connecting Rod Bolts.

In single acting two-strokes, these have little or nothing to do, since the pressure is almost always downwards but in double acting engines they must be made to take the full gas load as a recurring stress. The area of the bosses round the bolt should be adequate, so as to limit the stress variation (see note and equations at the beginning of this section, on through bolts and pillars in frame construction).

When running at speed, the gas load is reduced by inertia forces, but at starting and accelerating from low speeds nearly the whole of the gas pressure is realised. In single acting four-stroke engines the periodic pull on the bolts is that due to the inertia of the reciprocating parts at T.D.C. plus the centrifugal load of the upper half of the big end and half the shank.

If r = crank radius, L = connecting rod length, R.P.M. = revs. per min., W = weight in pounds of the piston with all reciprocating parts including the small end and half the connecting rod shank; W_1 = the upper half of the big end plus half the connecting rod shank; then the periodic upward pull on the big end bolts at T.D.C. is :—

$$[W_1 + \left(1 + \frac{r}{L}\right)W] \times 28\cdot2 \times r \times \left(\frac{RPM}{1{,}000}\right)^2 \text{ pounds}$$

and they must take this as a fatigue load.

As much stretching length as possible should be provided, turned well below the bottom of the thread (0·85 the area of the bottom of the threads is a good figure) and the changes of section should be well rounded and absolutely clear of tool marks.

A high tensile steel may be used for the bolts, but a much softer material is better for the nuts, and reduces the stress concentration on the first two threads where fractures usually occur.

Connecting rod bolts must be tightened up initially so that the surfaces of the half caps never separate. A good plan is to make the bolts to a limit gauge length over-all and tighten up until they stretch a specified amount, which is calculated to give the required load, with a margin for errors and settling down of threads and surfaces—say 30 to 40 per cent.

Crankshafts

On account of the size of the forgings required, the shafts of large engines are made in several parts, and a usual practice is to make a pair of webs and one pin in a piece and shrink them on to the journals.

The pins are also sometimes shrunk into separate webs, so that the whole shaft is built up of simple turned sections and slabs bored and faced.

The first method, however, makes a lighter shaft, and what is often much more important, one with smaller unbalanced masses to produce centrifugal loadings on the bearing, and of lower polar inertia.

The thickness of the shrunk band round the shaft may be of the order of 0·35 of the shaft diameter. In better steels than the mild quality usually employed, the yield point is higher and a greater initial interference may be used. The band thickness in one design which has been running for several years was reduced below 0·3 d (d = shaft diameter) without any subsequent trouble.

The interference suggested for mild steel (30 tons ultimate and 18 tons yield) is 0·0015 per 1 in. of shaft diameter, and higher according to the yield of the material. Since the shaft squeezes in a little, the nominal stretch per inch at the bore may be about 10 per cent. more than that given by the yield.

E.g. 18 tons/sq. in. + 10 per cent. = 44,500 lbs./sq. ins.

$$\text{Stretch per inch for this stress} = \frac{44{,}500}{30 \times 10^6} = 0\cdot00148 \text{ in., say } 0\cdot0015 \text{ in.}$$

The grip may be approximated as under for the torque required to *start* the web moving on the journal. Once it has moved from the original position, it goes more easily.

Area of ring section on one side (sq. ins.) × total interference in thous. × 8,000 = lbs. ins. torque.

A generous factor should be allowed for possible torsional oscillations and the peak torque from each cylinder.

A shrink grip is not apparently affected by alternating loads which are below its slipping torque.

If, therefore, the grip torque is such that the corresponding shaft stress would be above the permissible figure for fatigue, the shrink should be safe.

A torque giving between 9 and 10 tons per sq. in. at the journal is suggested.

Dowels were at one time fitted after shrinking, but they cut the most heavily stressed ring of metal, and cause an objectionable concentration of stress above the hole, as well as loosening the grip. They are better left out. Rough surfaces are apparently no advantage. Close limits on journal and hole diameter must be adhered to and careful temperature control is essential.

If a gas furnace is used, a reducing flame helps to prevent oxidation of the surfaces. When heating the web, allowance should be made for sufficient expansion to give clearance for sliding on easily, and preliminary arrangements made to ensure rapid and easy handling, so that no time is lost. With care, 250 to 300° C. is adequate for 1·5 thous. per inch interference, and between 300° C. and 350° C. for 1·75 thous. per inch. Scaling will not occur at these temperatures.

For large shafts carbon steels up to about 37 tons ultimate are preferable to alloy steels, on account of—

(a) Cost.
(b) Ease of production.
(c) Consistent qualities throughout heavy sections.
(d) Ease of heat treatment.
(e) Ductility, which ensures less danger from stress concentrations.
(f) High hysteresis damping.

Size Limit.

The most powerful engine yet built is an 8-cylinder in line double-acting two-stroke 840 mm. × 1,500 mm. giving 22,500 b.h.p. at 115 r.p.m., but larger cylinders are found in blast furnace gas engines, one of which—a horizontal double-acting tandem—had cylinders 51-in. bore.

The limit of power has not been reached by any means. Higher speeds and the increase of the number of cylinders as well as the raising of the overload by boosting will all contribute, and the builders of the engine referred to above, have declared themselves ready to build a unit of 45,000 b.h.p. in 12-cylinders running at 180 r.p.m. It is questionable, however, whether this as a land engine could compete with the modern steam turbine if coal is readily available.

Notes particularly applicable to High-Speed Engines.

The term 'high speed' is somewhat vague and requires qualification.

High rotary figures may be attained by very small engines with stresses no higher than those in large engines running at less spectacular revolutions per minute.

The mean linear speed of the piston is the best figure for comparison, as it can be shown that for similar designs of widely different sizes the same piston speed means the same stress in corresponding parts of the engines.

Theory of Proportionality.—According to this theory, engines of all sizes built to the same design and proportions in all details have the same stress in all corresponding parts when subject to the same gas pressure and run at the same piston speed.

Consider two engines of stroke S and s respectively, everything being in proportion. Then the piston areas will vary as S^2 and s^2. The sections of the connecting rods, the bearing areas, etc., will all vary in the same proportion, *viz.*, S^2 and s^2, so for equal gas pressures the stresses and bearing loadings due to this cause will be equal.

At the same piston speed the rotary speeds of the two engines will be inversely as the linear dimension, *i.e.* 's' r.p.m. for the larger and 'S' r.p.m. for the smaller.

The dynamic forces will vary in proportion to :—

(1) The weight of the parts, *i.e.* S^3 and s^3.
(2) The stroke S and s,
(3) The rotary speed squared s^2 and S^2

the result being $\dfrac{S^3 \times S \times s^2}{s^3 \times s \times S^2} = \dfrac{S^2}{s^2}$

but the cross-sectional areas of all the parts, such as connecting-rod shank, big-end bolts, etc., also vary as $\dfrac{S^2}{s^2}$.

Therefore, the dynamic forces also produce equal stresses at the same piston speed. Similarly, it can be shown that the torsional frequency of the crankshaft, the surging speed of the valve springs, etc., all move in step and are inversely proportional to the linear dimensions S and s. Thermal stresses, however, increase with size and must be considered separately.

It is assumed then that 'high speed' engines are those designed to run at a high piston speed, say 2,000 ft. per minute and upwards.

The highest speed yet attained, as far as the writer knows, was in a racing car engine of 132 mm. stroke, which ran at 5,000 r.p.m., normally aspirated, and reached 6,000 r.p.m., when supercharged—a mean speed of 5,200 ft. per minute on the pistons.

Racing cycle pistons exceed 4,000 ft. per minute at times, but in car engines 3,000 to 3,300 is the usual limit.

Aero engines have run at 3,600 ft. per minute, but 3,000 is the normal figure for both liquid and air-cooled machines.

It must be remembered, however, that the load is much higher and more continuous and that most aero engines are supercharged.

The problems introduced by high piston speeds are :—

(a) Thermal.

(b) Dynamic.

The piston is subjected to higher heat flow, and in consequence all aero and cycle engines and nearly all car engines have aluminium pistons, because its conductivity is so much higher—being about 2½ times that of cast iron. Greater clearances must be allowed, as aluminium expands more than the iron cylinder in which it works. The expansion ranges from 0·0018 of its length per 100° C. for certain alloys, up to 0·0023 or 0·0024 for others. Unfortunately, those of higher expansion are also stronger, and therefore usually used in high duty pistons.

Compare cast iron 0·0012 per 100° C. The top land is given a clearance of about 0·008 D + 0·010 in., and this is reduced progressively to the skirt where the allowance depends on the duty.

It is not possible to give a general rule for piston skirt clearance as this varies with the alloy used, the heat flow, the piston design and the cylinder cooling.

In general, the higher the horse-power per square inch of piston, the hotter it will be, and short pistons with few rings also attain higher temperatures on the skirt and require greater clearance than those with a more generous length above the gudgeon pin centre.

Skirts may be given a slight taper, say 0·0005 in. to 0·001 in. on the diameter per inch of length, and are frequently made oval, so that distortion of the piston pin bosses may not cause binding, while the thrust faces, in the line of the connecting rod swing, may be made a somewhat closer fit.

The increased dynamic forces due to the high rotary speed cause every effort to be made to keep the piston weight down, and for this purpose aluminium is without a real rival.

Mangesium alloys are being tried, but are not yet really in the field, since the mechanical properties at present are much poorer than those of the modern aluminium alloys, especially at high temperatures, and outweigh the gain in weight (specific gravity aluminium alloys about 2·7 and of magnesium alloys as used 1·8) while the mean thermal expansion is 0·00275 per 100° C. against aluminium 0·00235.

Die cast or chill cast pistons are in great demand for all except the highest class aero engines where all machined forgings of 'Y' or similar alloy are used. These are of course very expensive by comparison. 'Upset' forgings with piston pin bosses and internal head ribbing all complete are being made in America in special die forging machines. The external turning, ring grooves, and boss boring are the only machining operations required. The mechanical properties of the metal are improved by this method of production.

Grinding of the skirts is giving way to diamond turning as a finish, high speeds and fine feeds being used. A beautiful surface is produced which is very true.

As a guide to weight, one well tried modern 5 in. aero piston body weighs about 2·5 lbs. bare or 3·75 lbs. with pin and rings.

The head thickness is about 0·1 D (D = diameter).

Three rings are usually used, two gas and one slotted oil scraper ring with the groove freely vented by drilling at the back.

Oil engines usually have three gas rings and one scraper, all above the pin. Sometimes provision is made for a second scraper ring near the bottom of the skirt. This is fitted when the oil consumption begins to rise, owing to wear. Gas rings made taper (5° to 10°) on the top side, and with sufficient side clearance to prevent binding when bottoming in the groove, will remain 'alive' (i.e. not stuck with carbon) for longer than parallel ones.

Two representative pistons are shown in figs. 4 and 5. The pins vary from 0·25 D for petrol to 0·36 D for oil engines.

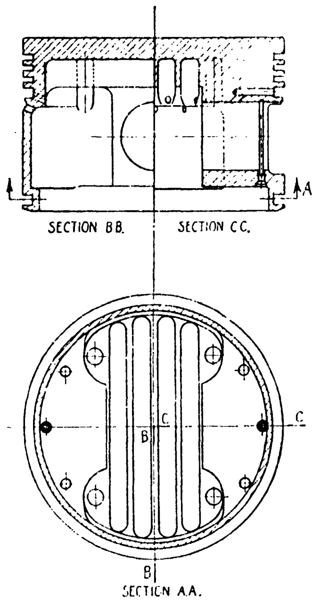
Where very high heat flow is anticipated, as in a supercharged oil engine, extra rings with sufficient metal behind them to conduct the heat, should be used, otherwise the pin bosses will become too soft at the bearing surface and will wear very rapidly. Attention should be paid to the support of the pin bosses, thin ribs overstressed at the inner edge are worse than useless. (See T section ribs in fig. 5.)

Proprietary pistons are being used more and more, and nearly all rings are now made by firms specialising in their production. Narrow rings are now general, the width being 0·025 to 0·03 D (D = piston diameter).

Other parts subjected to severe heat flow are the exhaust valve and its seat.

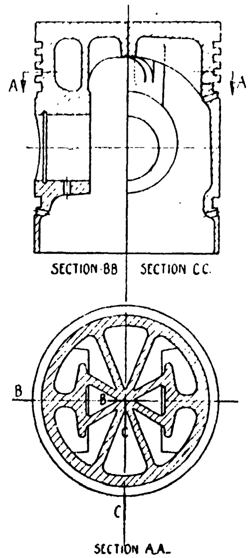
Various heat resisting steels, tungsten alloys and others are used, but for special cases of really high output the most recent development is the hollow valve, in which about half the internal

space is filled with metallic sodium. This melts at about 97·5° C., and being shaken rapidly up and down transmits the heat to the large diameter hollow stem whence it is taken away by the guide (the boiling point of sodium at atmospheric pressure is 825° C., so that it forms an excellent medium). Note that extra care must be taken to see that the guide boss has a good flow of air or water round it, and has ample cooling area to deal with the extra heat in this case. Welded on 'stellite' faces are also employed, usually on the valve and give excellent results, while inserted seats of special iron, corrosion resisting steel, aluminium bronze (in aluminium heads) or monel metal are now always used in aero work and nearly always for the exhaust valve seat of commercial vehicle oil engines, as the seat erosion is aggravated by the free oxygen present in the gases from this latter class of engine. In heads of iron or steel, the seats may be simply pressed in with an



HIGH DUTY AERO PISTON

FIG. 4.



PISTON FOR LIGHT LORRY OIL ENGINE

FIG. 5.

interference of 0·0025 per 1 in. of diameter. It is worth remembering that an increase in the stem diameter and lengthening of the guide have been found sufficient to cure some cases of over-heating in exhaust valves, as the extra area for heat flow kept the temperature below the critical point. The guide may also be continued downwards as a shroud, clear of the stem, to protect the working surface from the gases.

Connecting rods are sometimes stampings of aluminium alloy for car engines, but steel stampings are more general.

Aero rods are machined all over and of material too hard to stamp to finished section.

The cross-section under the small end, *i.e.* the minimum section, should be large enough to take the maximum gas pressure on the piston as a recurring fatigue load because, although the compressive load due to gas is reduced on the working stroke by the upward inertia pull, the latter appears as a tensile force on the next revolution, so that the fluctuation is between—

Downward force (gas − inertia) and upward force, inertia,

i.e. the range is equal to the gas force.

The cross-section will vary with the material from 1/60 to 1/25 of the piston area for high tensile alloy and medium carbon steels respectively. The shape of the shoulders running down to the bolt bosses should be designed to spread the load over the pin.

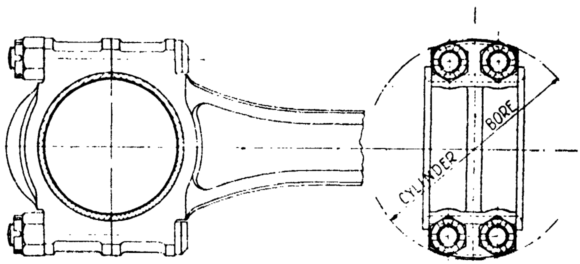
The cap should be stiffened by a deep arch-shaped rib to take the top inertia pull, and there should be a fair balance of area inside and outside the bolts at the joint face.

For connecting rod bolts see note, p. 209.

An upper limit for 60 ton steel bolts is 10 tons per sq. in. referred to the inertia pull at T.D.C. and maximum speed. This is for well-designed bolts without sudden changes of section and surrounded by symmetrical bosses of sufficient area. The rod length centre to centre may be very short in 6-cylinder engines, but in 4-cylinders it is not advisable to use less than four cranks long, as the secondary forces are unbalanced and rise rapidly, being proportionate to $w^2r\left(\frac{r}{l}\right)$; r = crank radius; = connecting rod length, centre to centre; w = angular velocity radians per second.

In many small engines it is necessary to remove the pistons from the top, and to do this the connecting rods must be (*a*) small enough in the big end to pass through the cylinder bore; or (*b*) long enough in the shank to allow the gudgeon pin to be slid out over the cylinder top face when the head is removed and before the big end bolt bosses foul the lower end of the cylinder.

A four-bolt big end turned on the longitudinal axis and using T head bolts, allows of the largest crankpin and may be used to satisfy (*a*).



TYPICAL HIGH SPEED BIG END

FIG. 6.

Fig. 6 illustrates this construction, which is useful when the crankpin must be the maximum possible size for torsional reasons. Steel is preferable to brass for the backing of the white metal bearing, and may be very thin. Better adhesion is obtained with low carbon mild steel. Thorough de-greasing is essential. It is most important that bearings should be a tight fit and take a good bearing in the big end bore, otherwise fretting will occur and local overheating with consequent cracking of the white metal. 2,500 lbs. per sq. in. is about the maximum *peak* loading for white metal, 2,000 lbs. per sq. in. is a safer figure.

Pressed strip steel bearings $\frac{1}{16}$ in. thick are now being produced with about 0·010 in. to 0·015 in. of white metal on the face. The technique of production is difficult, but the saving in diameter and weight is useful and the cost ultimately much less.

Centrifugally cast lead bronze on a steel backing is now used in many aero engines and oil engines for heavily loaded connecting rod big end bearings, but it is more expensive and needs a high carbon or alloy steel shaft, as it wears soft steel quickly.

Small end bearings use a hard bronze bush, which in hard tensile steel rods may be made to float in the bore of the small end. In this case a very small shallow groove should be turned outside the bush at the centre, and several oil holes drilled from it to connect with the inner surface.

A suitable bronze centrifugally cast is :—

Copper	88 per cent.
Tin	10 ,,
Zinc	2 ,,

Floating gudgeon pins are almost universal on high speed engines. They are always hardened in some way, the materials used for the carburising process being ordinary low carbon case-hardening steel, 3 per cent. nickel steel, or for aero engines nickel chrome.

Special steels, usually containing a little aluminium, are used when a nitrided surface is adopted.

Air hardening steel has also been used, but is not common.

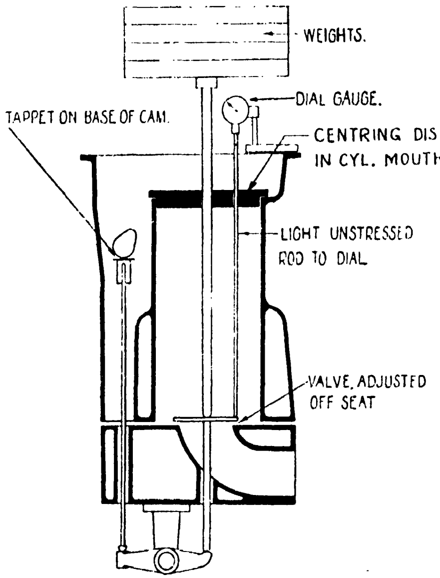
The advantage of the nitrided surface is that it is not affected at quite high temperatures which would begin to soften a carburised case.

Dynamic Troubles.

High speed engines have very low cyclic irregularity and phase variation (see next section) and arrangements of cylinders giving irregular firing angles may be employed if desirable on other grounds, but, on the other hand, they are much more prone to exhibit forced or synchronous vibrations, particularly in the following ways which must always be looked into carefully before the design is allowed to go through :—

(*a*) *Crankshaft*, torsional vibrations due to synchronism.

(*b*) *Frame*, bending vertically due to the combination of free centrifugal and inertia forces, and horizontally due to centrifugal forces only. Vee engines should have each bank treated separately and the resultants obtained. (See 'Crankshaft Balance,' p. 227, for forces involved.)



TEST RIG FOR VALVE GEAR DEFLECTION

FIG. 7.

(*c*) *Valve Gear*.—(1) Bouncing of valves due to faulty cam design or inadequate spring pressure in relation to speed' (see Cam Design). (2) Surging of springs (see 'Valve Springs,' p. 223) (3) Deflection of valve gear. Rockers are the worst offenders, then inadequately or improperly attached fulcrum brackets, then push rods. The deflected parts allow the valve to seat too soon and at too high a velocity, then the stored energy in the parts flips the valve open again, causing it to bounce on the seat. Fracture of the stem and irregular functioning are the results of this weakness. The only way to avoid this trouble and at the same time keep down weight, is to shorten the stress lines, and the overhead camshaft is obviously at an advantage. Rockers should be of I section, and as deep and as short as possible. Fig. 7 shows a simple test for overall deflection, which can be applied to existing parts.

The weight is equal to the positive acceleration force exerted by the flank of the cam at the maximum speed, and can be calculated by the method shown in the section on Cam Design.

SECTION XXVIII

PART III

DESIGN OF I.C. ENGINES — TORSIONAL VIBRATIONS OF CRANKSHAFTS—SCAVENGING AND SUPERCHARGING—MOUNTINGS — FOUNDATIONS — MAINTENANCE, etc.—STANDARD SPECIFICATIONS—B.S.I. AND LLOYD'S RULES

(By R. J. W. Cousins, M.I.Mech.E.)

Design of I.C. Engines

Cylinder Head.

Since the primary purpose of the head is to close the end of the cylinder, it must be strong enough for the maximum explosion pressure, but as it also often forms the support for the valve seats it must be stiff enough to carry the gas load without serious deflection. It should, therefore, be of considerable depth and sufficiently ribbed internally to ensure local stiffness as well as overall strength as a beam. In particular the design should be examined to see that the bottom deck is supported against doming in the centre. When the head is held down by four through bolts, the general outside shape should be rectangular, with straight walls joining the bolt bosses, and when a circular spigot joint is used in conjunction with this bolt arrangement, the corners, where the joint is farthest from the walls, should be reinforced by ribs and generous fillets.

Internal dwarf walls, allowing plenty of space above for coring and water circulation, are also useful in some cases for stiffening the bottom deck.

Where possible a ring of bolts, spaced as regularly as the valve elbows, etc., allow, should be employed, as the smaller span means a more easily made joint with probably a shallower and lighter head.

Aluminium Heads.

When aluminium is used for cylinder heads, valve seats of aluminium-bronze, or a high expansion heat-resisting steel must be fitted. They are usually screwed in (the heads are sometimes heated to about 100° C. for this purpose) and the internal castellations into which the spanner fits are machined away. The guides are made of bronze. The holding-down bolts should be of *high-expansion steel* turned down over the greater part of their length to give plenty of stretch, and the bolt bosses must be of large cross-section, say six times the area of the reduced part of the bolts, otherwise the high expansion of the aluminium will lead to crushing of the bosses or permanent lengthening of the bolts, so that the joint will blow when the engine is cold, and continual tightening only causes further stretching of bolts or crushing of bosses until failure occurs.

In large two-strokes, a water-cooled pad with thin decks is sometimes interposed between the pressure-carrying head and the combustion space so as to reduce the thermal stresses. Cast steel is also used for the same reason, as the greater strength permits the use of thinner sections.

Pistons and Connecting Rods.

See notes and sketches in Part II.

It should be remembered that the piston of the internal combustion engine has usually three functions :—

(*a*) To form a gas-tight plug ;
(*b*) to take away the heat which is unavoidably fed into the piston crown ;
(*c*) to form a crosshead for the small end of the rod (except in certain large engines).

While many designs and proportions are found, there is a growing tendency to use a piston on the following lines, for vehicle and industrial light engines :—

(1) A moderately deep top land—say $0 \cdot 1d + \frac{1}{8}$ in. (d = cyl. diameter).
(2) Three narrow gas rings, $\frac{3}{32}$ in. to $\frac{5}{32}$ in. wide, with $\frac{1}{8}$ in. to $\frac{3}{16}$ in. between.
(3) An oil control ring immediately below the gas rings.
(4) An evenly balanced crosshead portion with the gudgeon pin centrally placed between the oil vent groove and the lower oil control ring at the bottom of the skirt.

The length of this crosshead portion will be cut down to $0 \cdot 35\ d$. for high speed engines and increased to $0 \cdot 7\ d$., for industrial machines where long life is essential, but it should be realised that extending the length on one side only of the pin must lead to asymmetrical loading, and do more harm than good. For this reason the extension shown in fig. 2, Part II, p. 208 though found occasionally, is in the writer's opinion not good practice.

The heat is taken away in most cases by a fairly thick crown (relying on the high conductivity of the almost universally used aluminium) assisted by ribs cast, or pressed, on the underside.

In some cases oil-cooling via the connecting rod is now being introduced, even in small high speed engines, care being taken to get it to the zone behind the rings, since the time required to 'gum up' the latter is largely dependent on the temperature at the grooves. If this is of the order of 230° C. or over, gumming and carbonisation are rapid, but at 200° C. an enormous improvement is effected.

Piston bosses should be well supported from the crown at their inner ends by thick struts, to prevent bending of the walls which would occur with overhanging bosses. Thin ribs over the bosses are no use, they only provide an overstressed part to start cracks.

Gudgeon pins may be from $0 \cdot 25\,d$ for petrol to $0 \cdot 33\,d$ for oil engines, and are almost invariably full floating.

Valves.

Inlet valves used to be made with cast-iron heads and steel stems, screwed and sometimes welded in place, but they are now usually stamped or forged in one piece. Case-hardened stems are not uncommon. Guides are generally of cast iron in iron cylinder heads, and bronze in aluminium—on account of the expansion. Malleable iron guides have also been used and are reported to do well with hard stems. Stems may be made the nearest standard size to $0 \cdot 2\,d + 0 \cdot 125$ in. (d = throat dia.). Stem clearance should not be too tight, particularly in oil engines where slight air leakage does not matter, and sticky stems may cause intermittent action if too close a fit is used. Materials used include 32–37 S.M. steel, silicon-chromium, and 3 per cent. NiO.H.

See notes on Exhaust Valves in Part II, p. 199.

Gas Velocities.

Analysis of a large number of petrol engine results over many years has shown that maximum B.M.E.P. (brake mean effective pressure) occurs at an empirical inlet gas velocity of 130 ft./sec., maximum thermal efficiency at about 150 ft./sec., and maximum power at from 210 to 240 ft./sec., the higher figure applying to larger engines.

Oil engines hold their torque rather better, giving the maximum at about 145 ft./sec., but they have no carburetter restriction and the manifold may be made more generous, as distribution troubles do not arise.

The empirical gas velocity is reckoned as:

$$\frac{\text{piston area} \times \text{piston travel ft./sec.}}{\text{valve throat area}}$$

Valve Lift

Tests show that volumetric efficiency increases with valve lift up to about $0 \cdot 35\,d$ (d = throat diameter), but the gain becomes small towards the end. It is, however, worth going to $0 \cdot 3d$.

Most engines could be improved by a higher lift than the conventional $0 \cdot 25\,d$ and many fall short even of this figure.

Exhaust Valves may be made smaller than the inlets, and when the total space is restricted and the maximum output is aimed at, the relative velocities may be inlet 3, exhaust 4, or even inlet 2, exhaust 3, *i.e.* the exhaust throat diameter may be $0 \cdot 87$ to $0 \cdot 82$ of the inlet throat.

See notes in Part V on Exhaust Valves for high outputs.

Timing.

Inlet Opening.—In oil engines the inlet may open well before top centre. 10° to 15° early is quite common, and with 'blown' (supercharged) engines a greater lead is of advantage in conjunction with a late closing exhaust (say inlet opens 25° before T.D.C., exhaust closes 35° after T.D.C.) as the residual gases are then largely cleared out. This 'overlap,' as it is called, also tends to reduce slightly the pumping losses on the exhaust and inlet strokes as the valve opening is greater all the way.

In normally aspirated multi-cylinder petrol engines too much overlap affects the carburation at low speeds; single-cylinder motor-cycle engines, however, usually have very early opening inlets and late closing exhausts as the total opening periods are thus increased and greater time is given, thereby easing the cam action.

In the case of 'Buchi' exhaust gas driven turbines operating centrifugal blowers, the mean temperature of the exhaust gases is lowered by having an exaggerated overlap of 150° to 160°, so that a large quantity of cool air is passed through the engine and thence through the turbine blades, thus keeping them at a safe temperature.

Inlet Closing.—In hand-started oil engines the maximum quantity of air must be retained, so as to give sufficient temperature rise for starting at hand cranking speed, say 120 r.p.m. For these small commercial engines 25° to 30° after B.D.C. is usual, but in oil engines where other means are provided for starting, or in the spark-ignited engines, the valve may be closed later, so as to obtain the best volumetric efficiency at the running speed. The exact timing depends on the mean inlet gas velocity chiefly, and the following values are suggested:—

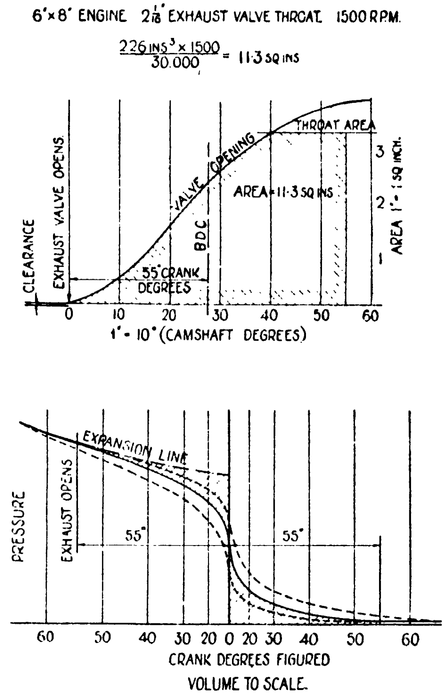
130 to 150 ft./sec.	35° after B.D.C.
170 „ 180 „	40° „ „
200 „ 230 „	45° „ „

Where maximum power is the chief aim the latest timing is the one to use, but if low-speed torque is important 35° to 37° is advisable.

Exhaust Opening.—The exhaust takes place in two stages, first the rapid discharge of the bulk of the weight of gas due to its own pressure, and secondly the mechanical sweeping out of most of the remainder by the rising piston.

The first portion is accomplished while the piston is near the bottom of the stroke and travelling slowly.

If the expanding charge could be retained until the end of the stroke and the pressure then instantly dropped to atmospheric, there would be no work thrown away on the down stroke and no negative work done on the up. This is impossible, but the minimum loss is incurred if the necessary period for the first stage of evacuation is arranged equally each side of B.D.O., because



FIGS. 1 AND 2.

the piston movement is the minimum for the time. The period in crank degrees required depends on (*a*) the swept volume of the cylinder, (*b*) the revolutions per minute, (*c*) the integrated value of the exhaust valve opening area. A simple method which has been applied to a number of engines with success is as follows (see figs. 1 and 2).

Plot the exhaust valve opening area on a base of 1 in. = 10° camshaft movement, and 1 in. vertically = 1 sq. in. valve opening. Then, at some point along the base, the pressure in the cylinder will have fallen to a value near atmospheric. A vertical line at that point cuts off an area of the diagram which in petrol engines is equal to:—

$$\text{A sq. ins.} = \frac{\text{Swept volume of cylinder cubic inches} \times \text{r.p.m. (crankshaft)}}{30{,}000}$$

hence find the position of the vertical line, and half-way between this and the opening point is B.D.O. (See fig. 1.)

In oil engines a devisor of 27,000 may be used to allow for the lower internal energy of the gases due to the impossibility of burning all the oxygen, and the greater expansion ratio.

It is evident that a high lift valve and a cam giving rapid acceleration on the flank, reduce the period required.

Although, as previously stated, the exhaust valve may be made less than the inlet when space is restricted, it should be as large as possible as a few useful pounds mean pressure may be picked up by reducing pumping losses and also by cutting down the period required for the preliminary evacuation. This enables the valve to be opened slightly later, thus increasing the mean pressure near the end of the stroke.

Light spring indicator diagrams should be taken at various speeds and examined critically to find whether any improvement may be effected in either filling up or evacuating the cylinder, by modification in the timing. The cylinder pressure should reach atmospheric when the inlet closes. The exhaust at full load should drop to within a pound or two of atmospheric pressure in a period after bottom centre approximately equal to that between valve opening and bottom centre.

The total lost work represented by the hatched area of the diagram will then have the minimum value. (See fig. 2.)

Two-stroke Ports.

In two-stroke engines the exhaust gases must be evacuated down to a pressure approximating to scavenge pressure by the time the air ports open, and the air and exhaust ports must have sufficient area to allow the scavenge air to drive out the residual exhaust before the piston has risen too far on the up or compression stroke.

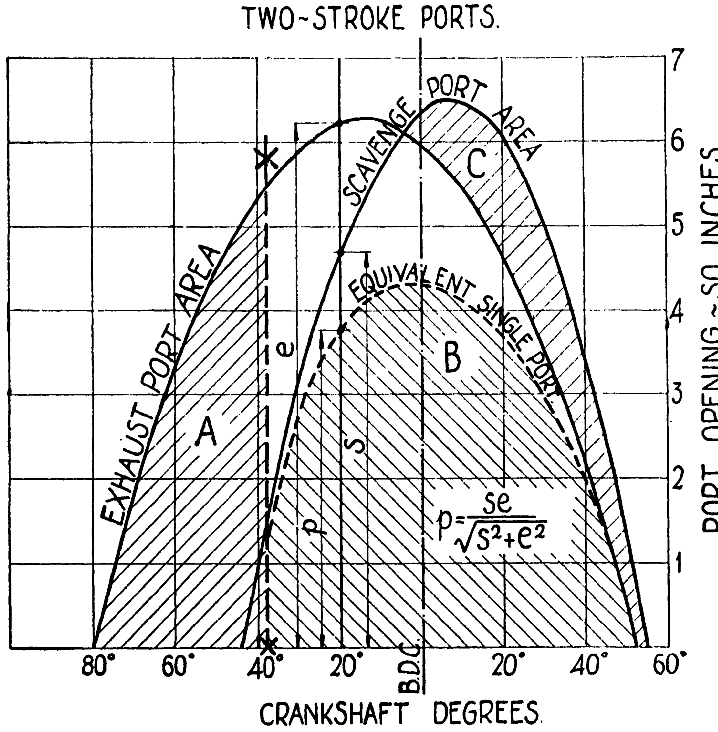


FIG. 3.

The following method, apparently empirical but in reality taking cognisance of all the variables, has been developed and checked from many experimental results.

Draw a diagram of exhaust and air port areas on a basis of 10° = ½ in. horizontally, and 1 in. vertically = 1 sq. in. port area. Then at some point a vertical line X–X will cut off an

area A, such that the integrated value of the port opening with respect to time will be sufficient to discharge the exhaust down to scavenge pressure. Make the area 'A' equal to :—

$$\frac{\text{Swept volume (cub. ins.) of 1 cyl.} \times \text{r.p.m.}}{44{,}000} = \text{A sq. ins.}$$

when using the scales mentioned. The divisor 44,000 is suitable for scavenge pressure 15 ins. Hg, say $7\frac{1}{2}$ lbs. per sq. in.

For low scavenge pressures, 3 to 4 lbs., use 40,000. The time of exhaust port opening and its rate of increase should be such that the line X–X does not encroach more than 5° or so on the scavenge port opening—otherwise blow-back into the air belt will become serious.

The dotted line enclosing area 'B' is the graph of a single port having the same resistance to flow as the combined scavenge and exhaust, and is found as follows :—

At any instant, *i.e.* on any vertical line, let s and e equal the scavenge and exhaust opening areas ; then the equivalent single port is :—

$$p = \frac{se}{\sqrt{s^2 + e^2}}$$

and the enclosed area B (the integrated value of the 'blow through' area) should be such that the available scavenge pressure will be able to pass about 1·1 cylinder volumes per revolution.

Since the scale is $\frac{1}{2}$ in. = 10°, 1 rev. = 18 ins. Then $\frac{B}{18}$ is the mean value of a constantly open port.

$$\frac{\text{Swept vol. (cu. ins.)} \times \text{r.p.m.} \times 1{\cdot}1}{12 \times 60} \times \frac{18}{B} = \text{speed ft. sec. through the equivalent single port, } p.$$

The mean speed is approximately $200\sqrt{P}$ when P = scavenge pressure in lbs./sq. ins., and the air volume is measured at N.T.P. In each case it must be considered whether the pressure or the port areas should be adjusted to suit the desired speed and volume.

Independent control of the timing of exhaust and scavenge ports is practically essential for high-speed two-stroke engines, and some ringing of the changes with the above diagram will enable the designer to cater for each phase of the operations. The last point is that the scavenge area must predominate towards the end, so that the cylinder pressure may be raised to scavenge pressure by the time the ports close. The area O is not critical—20 per cent. of B will suffice.

Cams.

To understand the action of the cam it is necessary to divide its functions into successive phases as under :—

(*a*) Radially outward or positive acceleration of the tappet, etc., up to a maximum velocity which depends on the lift, period and r.p.m.

(*b*) Deceleration, *i.e.* radially inward or negative acceleration of the parts by the valve spring or springs, which must exert sufficient force to keep the tappet in contact with the cam nose, and bring the parts to rest at the full lift.

(*c*) Continuation of the radially inward thrust of the springs until the point of maximum inward velocity is reached where the cam nose joins the flank.

(*d*) Slowing down of the tappet, etc., by the action of the cam flank.

(*e*) Final easy curve which reduces the velocity to a very low figure so as to seat the valve gently.

Taking these in detail :—

(*e*) Where silence is of great importance as in car engines, a gentle connecting curve is arranged between the base circle and the flank of the cam at both beginning and end.

For small car engines which run fast, a slope of 0·0003 in. to 0·0005 in. radial lift per cam degree is satisfactory, and may cover a total lift of 0·010 to 0·015 in. from the base circle. Of this 0·004 in. to 0·008 in. will be clearance.

Larger engines may have 0·001 in. per cam degree, and where silence is not of primary importance this 'approach' curve may be dispensed with. There is now sufficient experimental evidence that the noise due to the contact between tappet and valve at the beginning of lift is negligible, and that the most clatter comes from rapidly seating valve heads. It seems unnecessary therefore to employ an easy approach at the leading side but only at the trailing flank.

Another reason for this is that a smart opening of the exhaust valve helps to prevent the burning and scouring which occurs if the agony be prolonged by allowing the high temperature gases to continue at high velocity through a very small opening.

(*a*) and (*d*) : The flank proper is that part of the cam, joining the base circle to the nose, where the radial velocity continually increases.

The rate of increase or acceleration depends on the period available and the lift required, but it should be greater than the spring force, *i.e.* the time should be divided so that the two sides of the nose have more than the two flanks. This reduces the spring force required.

Constant acceleration cams are sometimes calculated and constructed, but there is no reason why the outward acceleration force should not rise, as in the well-known tangent cam, used with a roller or curved tappet. Rounded flanks *must* be used with the popular flat-ended tappet

otherwise there is violent shock and the gear will be horribly noisy and will not live. Very high maximum accelerations up to about 200g. (6,500 ft. sec. sec.) may be used on cam flanks, but the hollow flank with its violently rising curve is not recommended except for short-lived 'stunt' engines.

(*b*) and (*c*): The shape of the nose determines the deceleration, and the springs must be adequate to keep the tappet on the cam and prevent 'bouncing' at the maximum designed speed.

The spring or springs necessarily exert most pressure when fully compressed, *i.e.* when the valve is full open and the tappet is on the apex of the cam, and less pressure when farther down. It is, therefore, reasonable so to design the cam nose that advantage is taken of this, by having a higher negative acceleration at the apex than at the junction of nose and flank. The spring may then exert a force proportional to that required to follow the cam, over the whole of the nose period.

When R/L is not greater than unity this condition is satisfied (see accompanying graphs, figs. 5 to 8, for cam calculation), *i.e.* the *required* force is greatest at the apex where the *available* spring force is also at a maximum. Graphic differentiation of the valve lift curve (on a time base) gives the velocity curve, and a second differentiation of this gives the acceleration. The points on each successive curve are given by the value of the tangent of the angle of the slope of the preceding curve at each point.

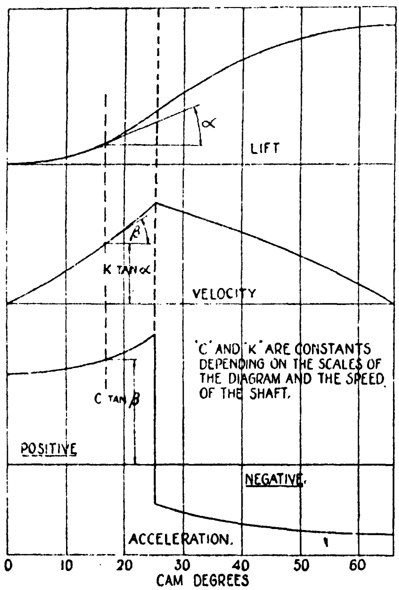

FIG. 4.

This method, however, calls for a very high degree of accuracy in draw ng and is not recommended.

The graphs given (figs. 5 to 8) cover noses and flanks of cams of normal proportions, constructed of circular arcs and having flat tappets, or followers with rounded ends, or rollers.

R is the radius in inches from camshaft centre to centre of curvature of cam profile.

L in every case equals the radius in inches from the centre of curvature of the cam to the centre of the tappet or follower.

In the particular case of tangent flank cams, R equals the distance from the camshaft centre to centre of tappet end when the latter is on the base circle (see small diagrams, fig. 8).

R.p.m. is the crankshaft speed, *i.e.* twice cam speed.

C is a constant from the graphs depending on the $\frac{R}{L}$ ratio and the angle from apex for nose acceleration, or the angle from the base circle for flank acceleration.

Then the acceleration $= \dfrac{R \times C \times \text{r.p.m.}^2}{100{,}000} =$ A ft. per sec. per sec.

If W lbs. is the effective weight of the parts, and the acceleration of the cam apex is A ft. sec. sec., the spring pressure must be not less than—

$$\frac{A \times W}{g} \text{ lbs. } (g = \text{gravity} = 32 \cdot 2).$$

Allow a margin for overspeed, manufacturing errors and friction, say 30 to 50 per cent.

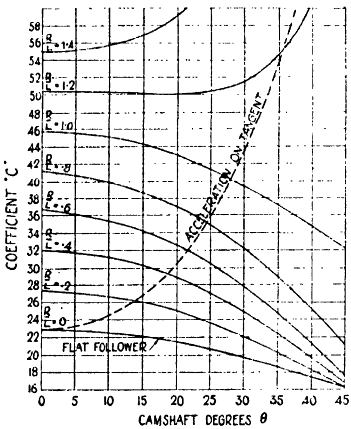

FIG. 5.—Circular Noses and Tangent Flanks.

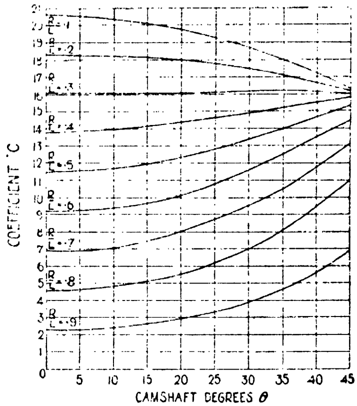

FIG. 6.—Round Flanks.

Acceleration $= \dfrac{C \times R \times N^2}{100{,}000}$.

C = coefficient from table according to angle and proportions of cam.
R = Radius in inches. See fig. 8.
N = Revs. per min. of crankshaft assuming camshaft runs half engine speed. Dotted curve gives acceleration on tangent.
θ = Angle in camshaft degrees.

When $\frac{R}{L} = 0$, **then L = ∞ equivalent to the case when a flat follower is used.**

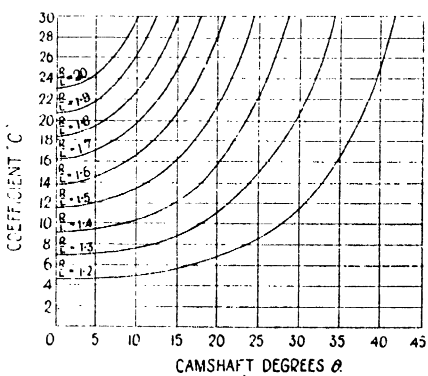

FIG. 7.—Hollow Flanks.

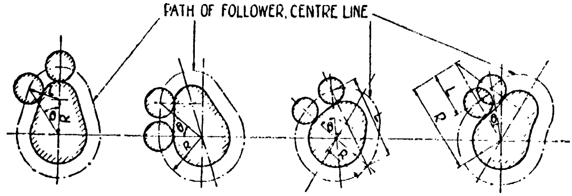

FIG. 8.

The equations for the instantaneous value of the acceleration at any point in the cases covered by the curves are as under:—

Straight line tangent to base circle:—

$$W^2R\left(\frac{1 + 2\tan^2\theta}{\cos\theta}\right) \text{ ft. sec. sec.} \qquad (1)$$

Round nose and round or hollow flank—circular arcs:—

$$W^2R\left(\cos\theta + \frac{n^2\cos 2\theta + \sin^4\theta}{(n^2 - \sin^2\theta)^{\frac{3}{2}}}\right) \text{ ft. sec. sec.} \qquad (2)$$

Simple harmonic cams (circular arcs) with flat followers—

$$W^2R\cos\theta \text{ ft. sec. sec.} \qquad (3)$$

R = radius in feet from shaft centre to centre of curvature for (2) and (3), and shaft centre to roller or tappet centre for (1).
W = angular velocity of the camshaft in radians per second.
θ = Angle moved through by cam from base circle (or origin of the cam) in the case of flanks in (1), (2) or (3), and in the case of the nose (2) or (3) the angle from the apex = $180 - \theta$.
$n = \frac{L}{R}$ when L is the radius of curvature in feet.

To use r.p.m. of the crankshaft instead of radians per second of the cam, and R and L in inches instead of feet, multiply the results by 0·000228. In all tappets, and in flat followers particularly, be careful that the head is large enough to cover the maximum eccentricity of the point of contact, which occurs at the junction of nose and flank.

Effective Weight of Valve Parts.

In directly operated valves when the cam lift equals the valve lift, simply take the weight of valve, cotters, spring carrier, tappet, etc., and add one-third of the spring weight (a rough estimate of the latter must be made and corrected later if far out).

When an unequal rocker of ratio R to 1 is used, the acceleration on the parts at the valve end is in direct proportion to that at the cam (or tappet) end. The force per pound for the valve end parts is therefore increased in the ratio R.

Assume acceleration Ag at the valve, *i.e.* A times gravity. Then the acceleration a the cam is $\frac{Ag}{R}$.

Take the weight to be W_c and W_v for cam and valve ends. Then the force directly applied to the parts at the cam end is $W_c \times \frac{Ag}{R}$ but, since it is usually done through the rocker from the spring at the valve end, it is reduced $\frac{1}{R}$ of this amount by the leverage, *i.e.* $\frac{W_c\,Ag}{R^2}$. This means that to find the *effective weight at the valve*, the weight of the moving parts at the cam end is divided by the *square of the rocker ratio* and added to the parts at the valve end.

This total weight is multiplied by the cam acceleration and by the rocker ratio to find the forces at the valve.

Flat Followers.

Chilled cast iron is sometimes used; reports vary as to its behaviour. If hard enough it is very good, but if not, it 'rings,' *i.e.* develops deep circular grooves, badly and quickly. (Incidentally all tappets and valve gears seem either to wear very well or tear up in the beginning. Good hardening and oil in the places where it will be drawn between the loaded surfaces, seem to be the chief desiderata.)

Probably the quickest way of arriving at a suitable cam is to try it out on the drawing-board. Determine the timing first—giving as long a period as possible considering the engine speed, etc. Then lay off the gentle approach curve if used, remembering that since it opens the valve so little it does not account for much gas flow and the period may therefore be extended a little. Next fix the cam apex, giving the desired lift and period, and then fill in with tangent or cuved flanks, varying the nose radius until a profile giving reasonable spring pressures, etc., is found. A 'hammer headed' tappet with fixed curved end not only works well but gives great latitude in design because, by increasing the radius of the curved end, the nose acceleration may be reduced and the flank acceleration increased or *vice versa* without altering the cam. For any given period and lift smaller camshafts and base circles are also possible with curved followers as compared with flat ones, as with the latter the nose acceleration depends directly on the radius from shaft to nose centre, while with a curved follower it may be twice this figure.

The radius of the nose itself (*i.e.* from nose centre to cam face at the apex) may be very small indeed, and it is often necessary with flat followers to reduce it to 0·075 in. to get the requisite lift without increasing the overall diameter of the cam.

At speed the nose is practically unloaded, while when running slowly the spring pressure is all it has to sustain. The flanks do the positive acceleration and take the gas pressure when opening the exhaust valves.

Valve Springs.

The principal cause of valve spring failure is fatigue, due to the actual stress *range* being too great. (Not the maximum stress, but the difference between maximum and minimum.) Usually this is not due to the stress range accounted for by the normal valve lift, but by the extra relative travel of the coils when surging takes place.

This surging is more likely to occur at high speeds when the natural frequency of the spring tunes in with one of the harmonics of the cam profile, usually starting when the camshaft speed is as high as one-tenth to one-twelfth of the spring frequency and being bad at one-eighth. As the engine speed is usually fixed, the best thing to do is to keep the spring frequency as high as possible.

This frequency is approximately—

$$F = 0{\cdot}213 \times 10^6 \times \frac{d}{R^2N}$$

where,

F = frequency vibrations per minute.
d = diameter of wire.
R = Mean radius of coils.
N = number of active coils.

or—

$$F = 590\sqrt{\frac{S}{W}}$$

where,

S = stiffness in lbs. per 1 in. axial deflection.

W = weight in pounds of the active coils. (Do not count the two end coils as they are dead. Now, since W (the weight) is proportional to the number of coils (N), and S (the stiffness) is inversely proportional to N,

$$F \propto \sqrt{\frac{S}{W}} \propto \sqrt{\frac{1}{N^2}}$$

i.e. frequency varies inversely as the number of coils, other things being equal.

It is clear that for a fixed valve lift the working deflection per coil, and therefore the norma stress range, also varies inversely as the number of coils.

Therefore the *Spring Frequency is proportional to the Stress Range for a fixed working travel.*

The situation then is this:—

(*a*) If a low stress range is used for the normal lift there is a danger of surging of the coils and fatigue failure from this cause, because the spring frequency is too low.

(*b*) If too high a stress range is employed, failure may occur from the normal travel.

The best solution seems to be to use the highest *safe* range possible, thus keeping the frequency high and avoiding surging, without incurring the risk of failure from the second cause.

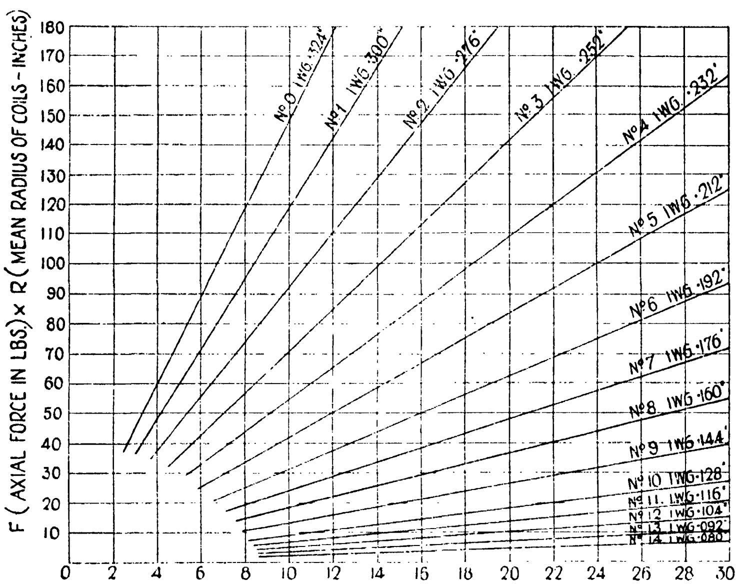
If the *maximum* stress is not too great a larger *range* may be allowed, and from the experience of a number of cases, the following stresses are suggested:—

Maximum . .	24 to 28 tons/sq. in.	
Range . .	14 ,, 12 ,, ,,	(the higher range with the lower maximum).

This is for good quality commercial springs.

The maximum force required (F) having been found from the cam form and valve gear weights, the spring may now be calculated.

Generally the design suggests a convenient outside diameter, and from this a mean radius R to the centre of the coils may be assumed. The stress graphs (fig. 9) give the stresses for



PARALLEL HELICAL SPRINGS ~ ROUND WIRE.

FIG. 9.

different standard gauges of wire for any value of F × R, and from this the correct wire may be chosen at once to come within the maximum permissible stress decided upon.

The deflection per coil is then found from the second graph (fig. 10), multiplying the deflection for 1 ton per sq. in. by the actual maximum stress employed. To find the number of *useful* coils, divide the *total* deflection required by the deflection per coil as found above. Add two for the dead coils at the ends.

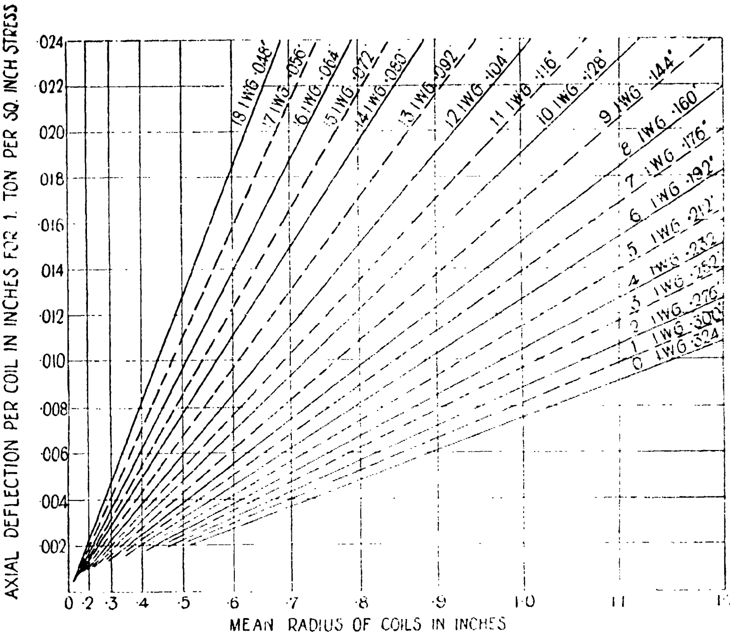
$$\text{The } \textit{total deflection} \text{ from free length to valve open} = \frac{\text{Maximum stress} \times \text{working lift}}{\text{Working stress range}}$$

The minimum working length (valve open should be just a little longer than the solid length. This helps to discourage surging, as it causes the coils to touch, and introduces some interference with the wave motion every time the spring is compressed. The free length is the minimum working length plus the total deflection.

The spring force must exceed the nose acceleration force at all points from the apex to the junction of nose and flank, and as the spring force decreases from the apex, it is important that the acceleration force should also decrease—see 'Cams' (p. 219).

With a curved or roller follower, the cam motion must be measured at the *centre of the follower*, not on the cam surface. Similarly with flat followers the radial motion of a point on the tappet centre line gives the correct reading.

Springs should not be too small in the mean diameter compared with the thickness of the wire, as an additional stress is thereby introduced. The graph (fig. 11) gives the addition, which should be allowed for if appreciable.



DEFLECTION - PARALLEL HELICAL SPRINGS - ROUND WIRE

FIG. 10.

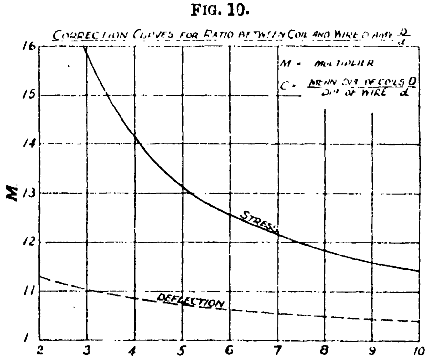


FIG. 11.

The equations for stress and deflection in ordinary parallel helical springs of round wire are:—

$$\text{Stress (lbs./sq. in.)} = \frac{16FR}{\pi d^3}$$

$$\text{Deflection} \quad . = \frac{64\ FR^3 n}{C\ d^4}$$

F = axial load lbs., R = mean radius of coils inches, d = wire diameter inches, n = number of free coils, C = transverse modulus of elasticity = $11 \cdot 8 \times 10^6$ approx. for spring steel.

Since the stress due to surging of helical springs is greatest at the ends (theoretically twice, practically about 1·5 times at the point of reflection of the wave) and breakages almost always occur in the first free coil, it would be an advantage to bring the two ends in to a smaller diameter, provided the ratio $\frac{\text{coil diam.}}{\text{wire diam.}}$ is not already so small that the modification will cause an even greater increase to offset the gain. Reported failure to derive any great advantage from 'barrel' springs may possibly be due to this cause (see graph, fig. 11, showing this effect).

Investigation by the N.P.L. has shown that the great discrepancy between the fatigue range of polished laboratory specimens and that of actual springs is due largely to the decarburising of the outer skin by heating in the presence of free oxygen during manufacture. This leaves in effect an outer layer of mild or low carbon steel, much weaker than the core, at the most highly stressed zone. Minute cracks form in this layer and the stress concentration at the bottom of each small fissure soon destroys the underlying part. Grinding of the wire between draws and tempering in an inert atmosphere have enabled springs to be made for aero engines which will stand a very much increased range, but at present this is hardly economic for commercial engines.

If the crankshaft speed r.p.m. be multiplied by the valve lift in inches, a figure of merit is given which is a measure of the tendency to surge. If the product is over 1,250 (say ½" lift at 2,500 r.p.m.) some surging may be expected, and at 1,500 it is certain, even with a high stress range, while 2,000 is usually destructive. The manufacturers of racing motor cycles (which generally have only two valves per cylinder, and consequently large lifts in proportion to the speed) have been driven to revive the old 'hairpin' spring, in which the wire is stressed in bending, and the coils do not move bodily as in the usual helical spring.

With the popular duplex arrangement the maximum force is divided between four wires.

The bending moment is this force (negative acceleration force divided by 4) multiplied by the radius from point of application on valve to centre of coil.

The bending stress is maximum and uniform in the coils, and varies from this figure to zero at the ends of the arms forming the abutment as well as those engaging with the valve.

Force required F lbs.

Force on each wire, $\frac{F}{4}$.

Bending moment $M = \frac{FR}{4}$ (R ins. = radius from coil centre to end of arm).

Wire diam. d ins. stress $= \frac{32\ M}{\pi d^3}$ lbs./sq. in. (round wire).

$\frac{6M}{d^3}$ for square wire of side d ins.

The maximum stress should not exceed 45 tons/sq. ins., and the range 20 tons for this class of spring.

The total deflection aimed at may be from twice to three times the valve lift—2·5 being a usual figure. The deflection of the spring depends on the length of wire in the coils—the arms accounting for very little as under :—

Length of arm to valve = R ins. deflection $= \frac{MR^2}{3\ EI}$.

Length of arm to abutment = A ins. deflection $= \frac{MA^2}{3\ EI}$.

$E = 30 \times 10^6$ for spring steel. I = moment of inertia of wire in bending.

$$I = \frac{d^4\pi}{64} \text{ for round wire.}$$

$$I = \frac{d^4}{12} \text{ for square wire.}$$

Take these two deflections from the total required and the remainder must be the deflection of the coils. The length of wire necessary (L ins.) is found from :—

$$\text{deflection of coil} = \frac{MRL}{EI} \text{ or } L = \frac{\text{def.} \times EI}{MR}$$

The mean diameter of coils is then chosen to give $n + \frac{1}{2}$ coils so that the arms are in the correct relationship. The diameter of coil has no bearing on the stress or deflection. Springs of this design have been run up to ½ in. lift at 4,000 r.p.m. crankcfaft speed without any sign of surging —a figure quite impossible with helical springs.

Crankcases.

In some engines the upper part of the crankcase also forms or contains the cylinders, while in others separate cylinder blocks or individual cylinders are bolted on.

In the latter case especially it is advisable, for the sake of vertical longitudinal stiffness, to carry the crankcase walls below the shaft centre, thus giving extra depth, while a wide flange at the bottom joint (where the crankcase or column joins the sump or bedplate) will stiffen the structure horizontally. Where the cylinders or jackets are formed integrally with the crankcase the latter may end at the shaft centre line where it bolts to a light sump. The stress lines due to the gas forces should be made as direct as possible, so that the flow of stress from cylinder base to the bearings on each side may be free from sudden alterations in direction which introduce heavy stress concentrations and deflections.

Crankshafts.

One of the most important members and one which presents some of the most interesting problems in design is the crankshaft.

The principal questions arising are:—

(1) Materials.
(2) Balance.
(3) Torsional resonance.

(1) *Materials.*—In very large engines mild steel, or recently rather better S.M. steel of 35 to 37 tons/sq. in. ultimate, is used almost exclusively, as the large sections demand a steel easily manufactured and heat-treated, and of sufficient ductility to accommodate itself without damage to the internal stresses consequent on its thickness.

As smaller sizes are reached, stronger and harder steels, such as tempered high carbon, are used, while in most car engines high tensile alloy steels are used—so as to provide a harder surface for pins and journals.

Aero engines use the highest class alloy steels up to 70 tons tensile, and are bored out for lightness.

In automobile work cast shafts of steel or special iron have been introduced recently, and the latter particularly are very cheap to produce, and not only wear very well, but have very high hysteresis or internal friction, which, combined with a low stress/strain modulus, gives heavy damping and reduces resonance.

These special irons such as 'acicular' and 'nodular' irons, are held to a close specification, particularly for carbon content, and ladle additions are made which become finely divided and well distributed in the metal, each particle forming a nucleus about which the graphitic carbon collects. This prevents or reduces the formation of the characteristic laminae or thin plates of crystalline graphite which weaken the metal by preventing continuity over large areas.

Cast-iron shafts must be of generous proportions, particularly web thicknesses, and while flying webs may be used in petrol engines the use of bearings between all cranks is imperative in the case of compression ignition engines.

Pins and journals should be cored out to give more uniformity of metal section and balance weights of any reasonable shape may be cast integrally.

The torsional frequency is lower than for a similar steel shaft in the ratio of the square roots of the respective moduli of rigidity, *i.e.*

$$\sqrt{\frac{8 \cdot 25 \times 10^6}{11 \cdot 8 \times 10^6}} \text{ say } \underline{0 \cdot 835.}$$

Another development is the hardening of steel crankpins when the shaft is practically complete

Two methods are employed :—

(*a*) An oxy-acetylene flame is directed on to the slowly rotating pin, followed immediately by a jet of water, both flame and water jet being just the width of the pin. A very hard carburised skin is obtained. The job is done in a special machine, and the technique has called for considerable development work.

(*b*) A suitable steel is used which will harden sufficiently by quenching, and the pin is surrounded by heavy coils (made split for ready dismantling) through which very high frequency alternating current is passed. The magnetic hysteresis produces a high surface temperature, and after the necessary time water is forced through slots between the coils, quenching and hardening the surface. The object is to produce a very hard surface to resist wear, particularly when using lead bronze bearings.

Balance.—All the masses forming or attached to the crankshaft may be separated into :—

(*a*) Revolving masses.
(*b*) Reciprocating masses.

The connecting rod may be represented by two masses, one revolving with the crankpin, and the other reciprocating with the piston. These masses when in motion give rise to revolving or reciprocating forces and couples, the latter occurring when one force is balanced by another not in the same plane (*e.g.* in a two-cylinder engine with crank at 180°).

These forces and couples may be primary, *i.e.* at crankshaft speed, or (due to the obliquity of the connecting rod acting on the reciprocating masses) secondary, *i.e.* at twice crankshaft speed.

Forces or couples of a higher order are too small to be troublesome.

If the connecting rod be suspended horizontally by the crankpin and gudgeon pin centres, from suitable balances, the weights recorded are the revolving and reciprocating components respectively, and the latter is added to the piston (complete with pin and rings) to give the total reciprocating mass = W_1 pounds. The big end mass is added to the crankpin and the equivalent unbalanced mass of the webs to give the total unbalanced revolving mass = W_2 pounds. These two figures W_1 and W_2 with R ins. crank radius, L ins. connecting rod length, O distance from centre to centre of cranks longitudinally, and the r.p.m. enable the forces and couples to be calculated :—

$$\text{Reciprocating force at TDO} = 28 \cdot 2 \left(1 + \frac{R}{L}\right) R\, W_1 \left(\frac{RPM}{1{,}000}\right)^2 \text{ lbs.}$$

$$\text{BDO} = 28 \cdot 2 \left(1 - \frac{R}{L}\right) R\, W_1 \left(\frac{RPM}{1{,}000}\right)^2 \text{ lbs.}$$

Revolving force—radially outward at all points—

$$= 28 \cdot 2\, R\, W_2 \left(\frac{RPM}{1{,}000}\right)^2 \text{ lbs.}$$

The vertical component is $28 \cdot 2\, R\, W_2 \left(\frac{RPM}{1{,}000}\right)^2 \cos\theta$ lbs.

θ = angle from T.D.C.

The reciprocating force may be separated into :—

Primary, $28 \cdot 2\, R\, W_1 \left(\frac{RPM}{1{,}000}\right)^2 \cos\theta$

and Secondary, $28 \cdot 2\, R\, W_1 \left(\frac{R}{L}\right) \left(\frac{RPM}{1{,}000}\right)^2 \cos 2\theta$

(This is a close approximation—the error is not of practical importance.
Tabulate the values of θ and $\cos 2\theta$ from T.D.C. to B.O.D.

θ	2θ	$\cos 2\theta$
T.D.C. 0°	0°	+ 1
45°	90°	0
90°	180°	− 1
135°	270°	0
B.D.C. 180°	360°	+ 1

The secondary force is therefore upward at both T.D.C. and B.D.C., and downward at 90°, its value depending on the crank to connecting rod ratio. With an infinitely long rod $\frac{R}{L} = 0$ and there would be no secondary forces. This is the case with the 'Scotch Yoke' used in boiler feed pumps, where the connecting rod is replaced by a block on the crankpin sliding at right angles to the piston rod.

A simple method of finding the forces and couples of a crankshaft is as under :—

Primary Forces and Couples.

Draw the end view diagrammatically, placing the centre crank or the two centre cranks vertically.

Project horizontally and vertically as shown in fig. 12. The horizontal view will normally be symmetrical, showing that no unbalanced couples are present tending to displace the shaft in that plane.

The end view in all except single cylinder engines should be an equiangular star, showing that there are no free translational primary forces shaking the engine bodily, but the vertical view gives the opposing couples which may now be worked out by multiplying the projected length of each crank by its distance from the longitudinal centre line. In this way the best crank arrangement for any number of cylinders may be found by a few simple sketches, and the balance weights necessary to neutralise the larger couple can be determined. Note that only the *revolving* masses can be balanced by revolving balance weights, but *half* the reciprocating masses may be included, in which case *two couples at right angles*, but each of half the value, will replace the single one.

To find the secondary forces and couples, draw the same views with the centre crank or pair of cranks vertically, but double *all the angles* between the cranks as in fig. 13.

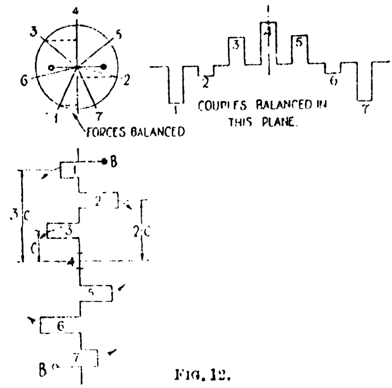

FIG. 12.

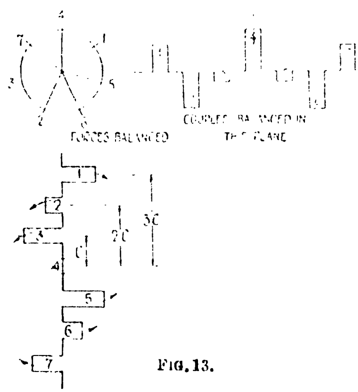

FIG. 13.

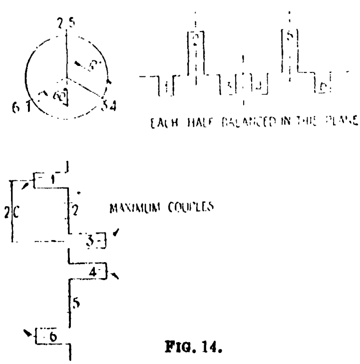

FIG. 14.

The secondary out of balance couple in fig. 13 is not observable in practice, as the polar inertia of the whole engine is so great in proportion to the small unbalanced secondary couple.

The idea is thus :—

(1) Free forces, if any, will show in the end view.

(2) If the horizontal view is drawn so that no *couple* is shown, *i.e.* so that the cranks form a symmetrical figure about the centre of length, then the vertical view at right angles will contain the maximum couple if any exists.

In the four-cylinder engine the primary forces and couples are balanced, but the secondary diagram is bad, as all the virtual cranks come to the top together, showing that all the secondary forces are added. They total about 1 crank in the primary $\left(\frac{R}{L} \times 4 = 1 \text{ approx.}\right)$ and shake the engine bodily in a vertical direction. In cars the secondary forces are now usually circumvented, by allowing the engine to move up and down on its rubber or spring mountings.

Frame Couples.

With four, six, eight cranks (or any even number) one-half usually forms a mirror image of the other so that the couples are balanced against each other. Though no free couples are present, the balancing is done through the bearings and frame, and therefore the latter must be strong and stiff enough to stand them.

Take a six-cylinder engine with symmetrical shaft arrangement consisting of two 3 throw cranks forming right- and left-hand helices (see fig. 14).

Since the two halves do not show any couple in the horizontal view, it will be maximum in the vertical, and is equal to $2\,C \times \sin 60° \times W_F$ lbs. ins. Where W_F = the centrifugal force in lbs. due to one crank weight W_1 at the running speed, *i.e.* $28 \cdot 2\ W_1 R$ ins. $\left(\frac{\text{RPM}}{1{,}000}\right)^2$. The frame must stand this bending moment horizontally, and for the vertical forces add W_2 (the reciprocating weight) to W_1 (the revolving). Treat other numbers of cylinders similarly.

Flywheels.

The function of the flywheel is to form an available store of kinetic energy for the following purposes :—

(1) To assist starting.
(2) To prevent sudden run away due to cutting off the load so that the governor may have time to act.
(3) To reduce speed variation and prevent flicker of lights, etc.
(4) To limit phase variation, *i.e.* advance and retard with reference to uniform angular velocity, thus enabling several generating sets to run in parallel on alternating current.

The energy stored in the flywheel is proportional to the mass of the rim multiplied by the square of its linear velocity, *e.g.*—

Weight W lbs., velocity at mean radius v ft. sec.

Energy in ft. lbs. $= \frac{Wv^2}{2g}$ (g = gravity = $32 \cdot 2$).

This may also be expressed as polar inertia (mass by radius ²) multiplied by angular velocity and divided by 2.

The polar inertia of a flywheel of outer diameter D, inner diameter d and face f (all in feet) is :—

$f(D^4 - d^4)\,\frac{\pi}{32} \times \frac{w}{g}$ when w = weight of 1 cu. ft. of the material and g = gravity.

Multiply by the square of the angular velocity in radians per sec. and divide by 2 to get the energy in ft. lbs.

Cyclic Irregularity and Phase Displacement.

The diagrams show the method of finding these, given the total polar inertia of the revolving mass (including flywheel, crankshaft with balance weights if any, and any rigidly attached mass, such as a generator) together with the torque curve.

The latter may be developed from an indicator card by multiplying the available pressure at any point by the piston area, and by the instantaneous value of the effective crank radius (fig. 15).

FIG. 16.

The first integration of the torque curve gives the velocity, and the second integration the phase alteration or angular movement fore and aft of a point at uniform velocity (see diagrams, fig. 16).

Method.—Divide the torque diagram (on a time base) into any number of equal divisions by vertical ordinates and dot in the mid ordinates, the time for each division is t secs. The height A at each mid ordinate, above or below the mean torque line, is a measure of the velocity V gained or lost by the *end* of that division, and the velocity curve will rise or fall by that amount in that division (use any convenient scale for each curve). Similarly the height of the mid ordinate V_M in each section of the velocity curve above or below the mean velocity for the whole cycle, gives the advance or retard S by the end of the section on the phase or displacement curve.

The actual value may be computed as under—the letters refer to fig. 16 :—

t = time (seconds) for 1 division.

A = mean angular acceleration force (*i.e.* torque lbs. ft.) in each division above or below mean torque line.

I_p = polar inertia $\frac{\text{lbs. ft.}^2}{g}$ of flywheel, etc.

V = velocity increase or decrease at *end* of time t.

$$= \frac{At}{Ip} \text{ radians per sec.}$$

V_M = difference between mean velocity during time t and mean velocity for the whole cycle.

S = space moved through during time t

$$= V_M t \text{ radians.}$$

The curves have been worked out for a number of engines from one to six cylinders, and the results are given below :—

V = swept volume of one cylinder in cubic inches.

Ip = polar inertia of the whole system (flywheel, crankshaft, generator, etc.) in lbs. mass × ft².

i.e. $\frac{\text{Weight}}{g} \times (\text{radius of gyration in ft.})^2$

g = gravity 32·2.

R.P.M. = revolutions per minute.

N = number of pairs of poles in the alternator (for phase alteration).

O = positive or negative values of constant for percentage cyclic irregularity, giving rise above or fall below the mean speed.

K = positive or negative values of constant for phase displacement in electrical degrees.

Then cyclic speed variation above and below mean speed—

$$= \frac{V \times O}{Ip \times RPM^2} \begin{array}{l}\text{per cent. up (O positive)}\\ \text{or down (O negative)}\end{array}$$

and phase displacement—

$$= \frac{V \times N \times K}{Ip \times RPM^3} \text{ electrical degrees fore or aft.}$$

Add the positive and negative values of O or K in each case for total variation.

Note the advantage of high revolutions in reducing the cyclic irregularity as the *square* of the speed and the phase displacement in effect as the *cube*, since (for the same electrical frequency) N (the number of pole pairs) decreases as the designed speed is raised, thus reducing the displacement in electric degrees.

Thus on the National 'grid'—50 cycles per sec. = 3,000 cycles (min.).

500	r.p.m.	= 6	pairs	of poles	in the	alternator.
600	,,	= 5	,,	,,	,,	,,
750	,,	= 4	,,	,,	,,	,,
1,000	,,	= 3	,,	,,	,,	,,
1,500	,,	= 2	,,	,,	,,	,,

CONSTANTS.

No. of Cyls.	Cyclic Irregularity. Per cent.		Phase Alteration in *Electrical* Degrees.	
	'O' Pos.	'O' Neg.	'K' Pos.	'K' Neg.
1	$+ 4{\cdot}35 \times 10^4$	$- 7{\cdot}85 \times 10^4$	$+ 3{\cdot}42 \times 10^4$	$- 5{\cdot}5 \times 10^4$
2	$+ 6{\cdot}62 \times 10^4$	$- 7{\cdot}36 \times 10^4$	$+ 5{\cdot}5 \times 10^4$	$- 5{\cdot}75 \times 10^4$
3	$+ 3{\cdot}75 \times 10^4$	$- 5{\cdot}7 \times 10^4$	$+ 1{\cdot}65 \times 10^4$	$- 1{\cdot}9 \times 10^4$
4	$+ 1{\cdot}08 \times 10^4$	$- 1{\cdot}43 \times 10^4$	$+ 0{\cdot}23 \times 10^4$	$- 0{\cdot}38 \times 10^4$
5	$+ 2{\cdot}8 \times 10^4$	$- 3{\cdot}83 \times 10^4$	$+ 0{\cdot}66 \times 10^4$	$- 0{\cdot}76 \times 10^4$
6	$+ 1{\cdot}88 \times 10^4$	$- 3{\cdot}25 \times 10^4$	$+ 0{\cdot}35 \times 10^4$	$- 0{\cdot}41 \times 10^4$

The favourable figures for four-cylinders are due to the fact that the reciprocating inertia of *all* the pistons is available to reduce the negative work on *each* compression and absorb positive work on each explosion. For moderate speeds an allowance of $4{\cdot}0 \times 10^4$ *total* cyclic variation should be made.

Water Pump.

The volume delivered on radiator or heat interchanger jobs should not be less than 15 gals. per b.h.p. per hour. This will give a temperature rise of from 12° to 18° F. according to the type and design of the engine. The flow should be definitely directed to the parts of the head—exhaust valve seats, etc.—where heat flow is greatest, and the injector or sparking plug boss should also be well cooled.

From actual measurements on small pumps with cast vanes, the volume delivered against $0{\cdot}8\ h$ head corresponds approximately with v_r (radial velocity at eye) $= v_e \tan \frac{\alpha}{2}$ (see fig. 17) when v_e = tangential velocity of the eye, while the stalled pressure is :—

$$\frac{v_w^2}{2g} = h \text{ feet head (1 ft.} = 0{\cdot}434 \text{ lb./sq. in.)}$$

v_r is the radial velocity and v_t the tangental velocity at the vane tip.

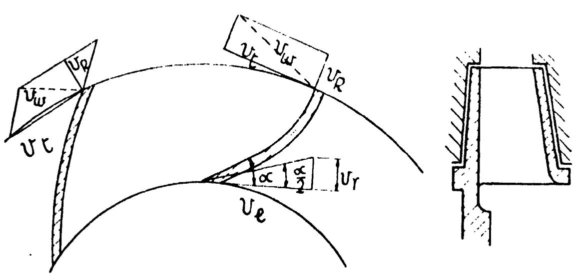

FIG. 17.

The right-hand parallelogram of velocities is drawn for a radial end to the vane, and the left hand for a backward sloping vane. The difference in the maximum water velocity, and therefore the pressure, is apparent. Larger pumps should be dealt with more faithfully by hydraulic engineers.

Oil Pumps.

These may be of many forms, but the most favoured is the gear pump, which when made with the special tooth forms developed for this work can deliver very large quantities from a small machine. As few as 7 teeth may be used, very deep in proportion to the diameter. If ordinary gears are used they should not be fully meshed, but set so that there is a little tangential play,

thus providing a vent at the centre, where otherwise severe 'lock-up' pressures will be generated forcing the gears apart.

The volume delivered per revolution is from 0·55 to 0·6 of the volume of one annulus between bottom and top of the teeth. Obviously the coarser the pitch the greater the volume from the same size pump.

From 2 to 2·5 gals. per hour should be allowed for every b.h.p. for small and medium high-speed engines.

For very large engines less oil is needed per b.h.p. for the bearings, etc., but for piston cooling about 1 gal. per hour per b.h.p. should be available. The specific heat of lubricating oil is 0·5 compared with water, and its specific gravity about 0·95. The temperature rise is therefore about twice that of water under similar conditions.

Sizes of Filters for Engines and Compressors.

To use the following table the filter manufacturer needs to have a table of the C.F.M. which his own range of filters will pass. This formula then tells him the size suitable for the engine or compressor in question.

$$\text{C.F.M.} = \frac{\text{L.A.N.}}{\text{C.}}$$

Where L = Length of stroke in inches.

A = Area of one (L.P.) cylinder in square inches.

N = R.P.M.

C = Constant (from accompanying table)

Torsional Vibrations of Crankshafts.

This is a very wide subject and it will not be possible to do more than touch on the major points.

An elastic structure is one which will return to its original shape if a force which has distorted it is removed. If the force be too great it may cause permanent distortion or rupture at once, but we are here concerned with forces of a smaller magnitude, easily withstood by the body under consideration if applied steadily. When the disturbing force is removed the restoring force or 'spring' of the material under stress brings the parts back to normal, but with this important difference, that they are now moving at a considerable velocity because the potential energy of the stressed material has been converted into kinetic energy of the moving masses.

These continue to move in the opposite direction until they are gradually brought to rest by the stress produced in the reverse sense as the body is distorted the other way, and the parts oscillate backwards and forwards at a speed depending on the inertia and stiffness of the structure. This speed is known as the 'Natural Frequency' and is independent of amplitude, *i.e.* it is the same for large or small swings of the one structure. This process would continue indefinitely were it not for the fact that some energy is dissipated at each oscillation by the parts of the structure moving in a viscous medium, air, water or oil, and also by the internal friction of the particles of the metal over each other (this latter effect is known as 'Hysteresis').

A harmonic force is one which varies as the projection on the diameter of a point moving round a circle at uniform angular velocity.

Its graph on a time base is a sine curve forming waves, equally above and below the zero line, and *the force is proportional to its distance from that line.* This is the essential property of a harmonic force and is very important, since the force required to deflect an elastic structure also varies with the deflection (up to the elastic limit of the material), and this agreement accounts for synchronous vibrations.

When an elastic structure is subjected to a recurring alternating force of this character *at the same frequency* as the natural oscillating frequency of the structure, the disturbing force is always in the same direction as the motion and causes the swings to become larger and larger every time until rupture occurs or the loss of energy at each cycle is equal to the energy put on at each cycle by the applied harmonic force. Take the sample case of a steel shaft fixed to an infinite mass at one end, and to a flywheel at the other.

Let the stiffness of the shaft be such that it requires S ft. lbs. to twist it through 1 radian, while the mass of the flywheel is M gravitational lbs. $\left(M = \frac{\text{Weight lbs.}}{32 \cdot 2}\right)$, and its radius of gyration R ft.

Then the polar inertia of the flywheel is MR^2, and the time for 1 complete oscillation is:—

$$\text{secs.} = 2\pi\sqrt{\frac{MR^2}{S}}$$

i.e. the frequency (vibrations per sec.) $= F = \frac{1}{2\pi}\sqrt{\frac{S}{MR^2}}$

In order to form a mental picture of what happens when a crankshaft is subjected to varying recurring torques, consider first the moving coil of a loud speaker. This can only be in one place at one instant, *i.e.* its movement on a time base is a single line, yet a full orchestra, with all the widely varying frequencies of vibration, is reproduced, and the ear can pick out the different instruments.

If several different harmonic curves are drawn and then combined, a peculiarly shaped wave is produced which repeats itself at intervals—the least common multiple of all the vibration times (see fig. 18).

The reverse process, though much more difficult, is also possible and, as pointed out by Fourier, any recurring wave form, however irregular, may be resolved into a fixed quantity (its mean height) and a number of simple harmonic waves, the largest of which has one pitch in the time required for the irregular wave to complete its cycle. Any simple multiples may be present in different amplitudes and phases. The ear analyses the exceedingly complicated movements of the loud speaker by means of numerous filaments, each one of which only responds to its own frequency.

In the same way a shaft of a certain natural frequency only responds to vibrations of the same frequency as its own, but these may be contained in a complex torque curve in such a way as not to be recognised easily. Since the torque curve repeats every cycle for each crank, the shaft is subjected *at each crank* to a number of concealed harmonics of every multiple of the cycle from one upwards, *i.e.* every multiple and half multiple of the revolutions in four-cycle engines.

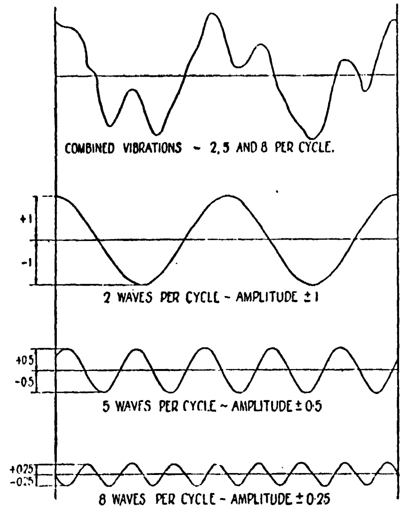

FIG. 18.

The approximate values of the amplitudes of all these harmonics from ½ to 12 are given in the accompanying table. Full torque is assumed, and the values are in pounds per square inch on the piston, so that to find the actual torque in lbs. inches, multiply the piston area in square inches by the crank radius in inches by the suitable figure from the tables. The number of vibrations per revolution is called the 'order.' When the engine speed multiplied by any integer or half integer equals the natural frequency of the crankshaft system, vibration will be present in some degree depending on the extent to which the impulses from the different cranks are in phase with each other. If two equal impulses are a half-pitch apart, they will cancel, and no perceptible vibration will result. If, however, they are not exactly opposed, some fraction of the impulses remains operative, and the simplest way to find the value of the unopposed forcing torque is as follows:—

If several sine waves of the same frequency but with their crests at different places (*i.e.* not in the same phase) are drawn, the resultant wave will be of the same frequency, and may be found by adding a number of ordinates, but this is a slow and cumbersome method, and a much better way is to draw a 'vector diagram.' In this method each harmonic forcing torque is represented by a vector or radial line from a common centre, the *length* of the line being the half amplitude, and the *angle* the phase of each individual sine wave.

The resultant, found either geometrically or by simple trigonometrical calculation, as for a number of forces, will again be a radial line and will represent by its length and angle the amplitude and phase of the resulting vibration. One circle represents the time for a complete vibration, and therefore the angle on the vector diagram between two harmonic forces associated with two cranks on the engine will be the angle between the firing points of those cranks multiplied by the 'order,' *i.e.* the number of vibrations per revolution of the crankshaft.

Now imagine a shaft (with six cranks and one flywheel) of such stiffness that when vibrating about one node (stationary point) the different cranks move through the amplitudes shown on the curve (fig. 19). This curve is called the 'elastic' curve, and the method of plotting it will be described.) Then the vibratory energy input at each crank will be in proportion to the ordinate of the elastic curve at that crank.

Now draw a 'vector diagram' for each order, in which one revolution equals the time for one *vibration* and each crank is shown in its proper firing sequence by a vector or radial line at the *angle* corresponding to the crank angle multiplied by the 'order' of vibration under investigation, and of a *length* equal to its ordinate on the elastic curve. It will be found that several orders have the same diagram, *e.g.* 3, 6, 9, — 1½, 4½, 7½, etc., for a six-cylinder engine and then the only difference is in the value of the applied harmonic torque for each order (see table).

It will be seen that in some orders (in this case 1½, 4½, 7½ and 2½, 3½, 5½, 6½) an alteration in the firing sequence makes a considerable difference in the result, and sometimes this alteration alone is a complete solution to the problem.

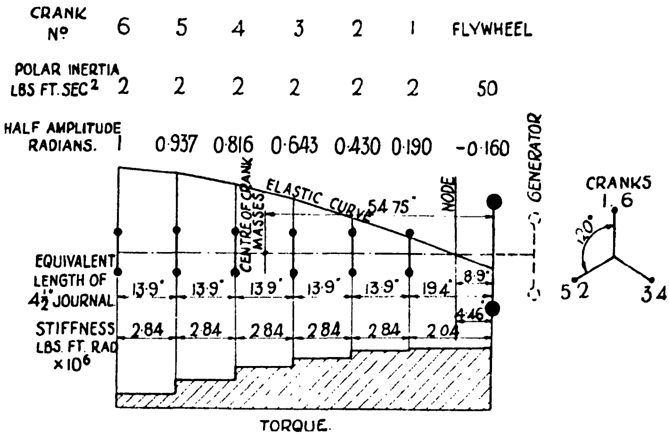

FIG. 19.

In eight-cylinder line engines several firing sequences are possible with the normal crankshaft and all should be investigated before deciding. A quick approximation may be made in simple

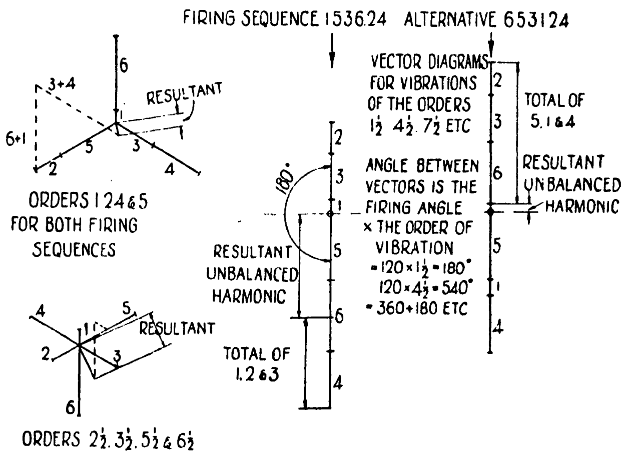

FIG. 20.

cases by numbering the cylinders from the flywheel end and reckoning the cylinder number as equal to the amplitude.

Thus for an eight cylinder running between the $5\frac{1}{2}$ and $6\frac{1}{2}$ orders the question of firing 1, 6, 2, 5, 8, 3, 7, 4, or 1, 3, 2, 5, 8, 6, 7, 4, may be settled by a rudimentary sketch.

Firing angle, 90°. Vector angles $90° \times 5\frac{1}{2}$ and $6\frac{1}{2} = 360° + 135°$ and $360° + 225°$
The diagrams for the two vibrations will therefore be the same, but in reverse directions.

1.6.2.5.8.3.7.4. FIRING SEQUENCE. 1.3.2.5.8.6.7.4.

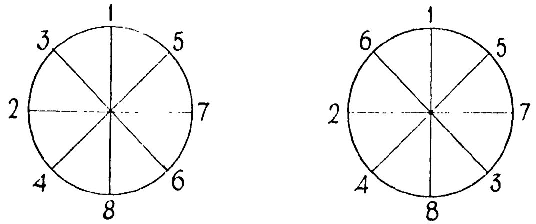

FIG. 21.

The second firing sequence is obviously much better in this case. The 6th order is approximately zero for both.

EFFECT OF RECIPROCATING MASSES.

Quite apart from the *mean* effect of the piston, small end and other reciprocating masses (which can be allowed for by adding half their value to that of the revolving mass with which they are associated) these parts introduce inertia forces which in turn resolve themselves into recurring torques having a number of harmonic components which affect the value of the corresponding gas torque components. The inertia torque components of sufficient value to be considered, are the 1st, 2nd, 3rd and 4th. They are all symmetrically disposed about the top dead centre, *i.e.* zero phase angle, while the gas forces tend to group further forward. Therefore it is impossible to add or subtract them directly, a vector sum is the only solution. Moreover, the gas forces alter slightly in amplitude and phase with I.M.E.P., but the inertia forces are proportional to the square of the angular velocity (or R.P.M.).

The approximate values of these orders are therefore given as sine and cosine values for the gas components and the sine values only for the inertia (the cosine values are zero).

To find the vector sum for a particular order, proceed as follows:—

Work out the weight in pounds of the reciprocating parts and divide by the piston area. This gives the weight per sq. in. Call this W. t_n is the torque coefficient (sine value) for the n^{th} order taken from the table below; g is the gravitational unit 32·2; R is the crank radius in inches and the angular velocity ω is in radians per second. Then the inertia sine component is S_I and equals

$$\frac{t_n \times W \times R^2 \times \omega^2}{12g}$$

Note that t_n may be of *negative* value, thus cancelling part of the gas sine component. Call the gas sine and cosine components S_G and C_G. Then the resultant value T_n of the harmonic component of the n^{th} order for this particular engine is :—

$$T_n = \sqrt{(S_G + S_I)^2 + C_G^2} \text{ lbs. per sq. in. of piston and 1 in. crank radius.}$$

The Elastic Curve.

The first step is to find the stiffness of each section of the system, conveniently expressed as a length of journal of equal stiffness.

To do this from first principles is almost impossible with a complex structure such as a crankshaft, but several empirical formulæ have been suggested.

The simple one worked out by Major Carter gives good agreement with torsion tests on very widely differing proportion of shafts, and is as under:—

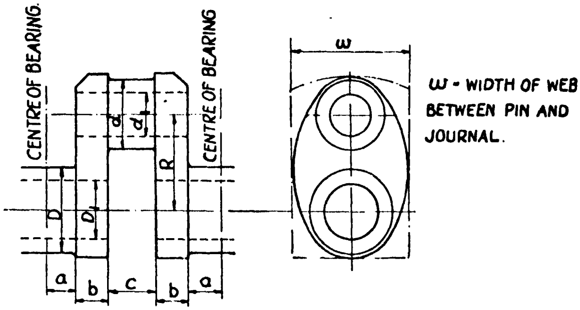

FIG. 22.

$$2a + 0{\cdot}8b + \frac{0{\cdot}75c \times (D^4 - D_1^4)}{d^4 - d_1^4} + \frac{1{\cdot}5R \times (D^4 - D_1^4)}{b \times W^3} = l''$$

i.e. the length of a shaft of diameter D, and bore D_1 (*i.e.* the journal size) equal in stiffness to a crank unit from centre to centre of bearings. Add the necessary amounts at either end from the drawing of the crankshaft, and fill in on the diagram (fig. 19).

The next thing is to fill in the polar inertia of each crank (including the big end and half the reciprocating mass) the flywheel and the auxiliaries, if the latter are driven from the free end. The calculations for one crank mass may be taken in the order given below, the letters as for the crank stiffness:—

Each moving part must be multiplied by the square of its radius of gyration, *i.e.* the radius at which the mass would have to be concentrated to have the same inertia. As the dimensions are almost always given in inches and the weight in pounds, these units will be used for the separate parts, and the total corrected to pounds per feet per second² by dividing by 144*g*., *i.e.* 4630.

Part.	Radius of Gyration.
Piston and Small End (*i.e.* total reciprocating weight).	Allow half the total weight × crank radius² = R^2 = polar inertia lbs. ins.
Big End.	Total weight × crank radius² = R^2 = ,,
Crankpin.	Total weight × $\left(R^2 + \frac{d^2 + d_1^2}{8}\right)$ = ,,
Rectangular Webs.—Total weight, length L, width *w*, centre of gravity C″ from shaft centre.	Weight of 1 pair × $\left(C^2 + \frac{L^2 + w^2}{12}\right)$ = ,,
Eccentric Disc Webs.—d''_w dia., C″ eccentric.	Weight of 1 pair × $\left(C^2 + \frac{d_w^2}{8}\right)$ = ,,
Concentric Disc Webs.—d''_w dia.	Weight of 1 pair × $\frac{d_w^2}{8}$ = ,,
Elliptical Webs.—m'' major axis, m''_1 minor axis, C″ eccentric from shaft centre.	Weight of 1 pair × $\left(C^2 + \frac{m^2 + m_1^2}{16}\right)$ = ,,
Journal	Total weight × $\frac{D^2 + D_1^2}{8}$. = ,,
Balance Weights.—These can generally be reduced to an equivalent sector of a disc or annulus of radius *r* outer, r_1 inner.	Weight × $\frac{r^2 + r_1^2}{2}$ = polar inertia lbs. ins.²

Divide the total pounds weight × ins.² for each crank by 4,630 to give the result in pounds ft. sec.², and insert in shaft diagram (fig. 19).

Flywheel rim outer dia., D_r inner D_d

$$\text{Weight of rim} \times \frac{D_r^2 + D_d^2}{8} = \text{polar inertia lbs. ins.}^2$$

Flywheel disc, dia. D_d

$$\text{Weight of disc} \times \frac{D_d^2}{8} = \quad ,,$$

Now using the inertia values as weights, and treating the equivalent lengths as giving their positions on a beam, find the point of balance—multiplying each inertia figure by its equivalent distance from the flywheel, and dividing the total by the total inertia including the flywheel.

Moment of crank inertias about flywheel (see fig. 19) $= 6 \times 2 \times 54 \cdot 75 = 657$.

Total inertia, 62 lbs. ft. sec.^{2}.

$$\text{Point of balance} = \frac{657}{\text{total inertia}} = 10 \cdot 6 \text{ ins.} = \text{ins. from flywheel.}$$

Then find the frequency of the flywheel oscillating about the point of balance as a stationary point or node, thus :—

$$\text{Shaft stiffness from node to flywheel: } \left\{ \begin{array}{l} \text{dia. of shaft } D \\ \text{bore of shaft } D_1 \\ \text{length from node } L \end{array} \right\}$$

$$= S = \frac{(D^4 - D_1^4)\pi \times 11 \cdot 8 \times 10^6}{32 \times L \times 12} \text{ lbs. ft. per radian}$$

$$= \frac{(D^4 - D_1^4) \times 10^6}{10 \cdot 35 \times L} \text{ lbs. ft. per radian.}$$

Time of oscillation

$$= t \text{ secs.} = 2\pi \sqrt{\frac{I_p}{S}}$$

where I_p = polar inertia of the flywheel $= MR^2 \dfrac{\text{lbs. ft.}^2}{g}$

Frequency $= F = \dfrac{1}{t}$ vibrations per second.

This figure will be too low and should be corrected by dividing by a factor varying with the number of cranks as under :—

1	2	3	4	5	6	7	8	number of cranks.
1·0	0·95	0·94	0·93	0·92	0·92	0·91	0·91	divisor.

Stiffness of 10·6 ins. of $4\frac{1}{2}$ shafts $= 3 \cdot 73 \times 10^6$.

$$\text{Frequency} = 2\pi \sqrt{\frac{3 \cdot 73 \times 10^6}{50}} = 43 \cdot 8. \quad \text{Corrected} = \frac{43 \cdot 8}{92} = 47 \cdot 5 \text{ per sec.}$$

In many cases this is sufficiently accurate and the frequency may be found to be too high to be dangerous (say more than six times the r.p.m. in a six cylinder), but for an accurate determination of the frequency and the value of the ordinates of the elastic curve, proceed as follows :—

Let F vibrations per second be the approximate frequency as found by the method just explained. Then the harmonic torque in pounds feet, required to oscillate a mass of polar inertia 1 lb. ft. sec.^{2} through an amplitude of $\pm$ 1 radian is $4\pi^2 F^2 = 39 \cdot 4 \ F^2$. Starting from the end opposite the flywheel where the movement will obviously be greatest, assume a half amplitude of 1 radian at the end crank and make a table as in the worked example below.

Assumed frequency 47·5 per sec. Acceleration torque per lbs. ft. sec.^{2}

$$39 \cdot 4 \times 47 \cdot 5^2 = 89 \times 10^3 \text{ lbs. ft.}$$

1.	2.	3.	4.	5.	6.	7.	8.
Mass.	Inertia Lbs. Ft. Sec.^{2}	Half Amplitude $\pm \theta$ Radians.	Acceleratn. Torque T_A Lbs. Ft. $\times 10^3$.	Total Torque T_T Lbs. Ft. $\times 10^3$.	Stiffness of Section Lbs. Ft. Rad. $\times 10^6$.	Deflection of Section ϕ Radian.	Remaining Angle $\theta - \phi$.
Crank No. 6	2	1	178	178	2·84	0·063	0·937
,, 5	2	0·937	167	345	2·84	0·121	0·816
,, 4	2	0·816	145	490	2·84	0·173	0·643
,, 3	2	0·643	115	605	2·84	0·213	0·430
,, 2	2	0·430	76	681	2·84	0·240	0·190
,, 1	2	0·190	34	715	2·04	0·350	0·160
Flywheel	50	0·160	715	715	4·46 Between flywheel and node = 8·9″ of $4\frac{1}{2}$ shaft.	0 160	—

Column 4 is the product of the unit acceleration torque (89×10^3 for the assumed frequency of 47·5 per sec.) by the inertia (column 2) by the half amplitude (column 3).

Column 5 is the addition of the acceleration torque in column 4 and the previous entry in column 5.

Column 6 is from the shaft diagram.

Column 7 is column 5 divided by column 6.

Column 8 is column 3 minus column 7.

The *stiffness* to the node is found by dividing the torque in that section by the half amplitude of the flywheel movement:—

$$\frac{715 \times 10^3}{0 \cdot 16} = 4 \cdot 46 \times 10^6.$$

The *distance* from flywheel to node is given by dividing the stiffness per inch of the shaft by the actual stiffness between flywheel and node:—

$$\frac{39 \cdot 5 \times 10^6}{4 \cdot 46 \times 10^6} = 8 \cdot 9 \text{ ins.}$$

If the last section does not balance, *i.e.* if the flywheel acceleration torque at the calculated amplitude is greater or less than the total torque of the cranks, then the assumed frequency is also greater or less than the true figure, and a second approximation must be made. When practical agreement is reached, the figures in column 3 are the ordinates of the elastic curves for the mode of vibration under consideration, *i.e.* one node in the crankshaft, and column 5 gives the total periodic torque in each section, from which the stress is readily calculated.

Note.—The mean useful torque should be added to the periodic torque when calculating the maximum stress.

The Resultant from the Vector Diagram for any order of vibration n is called the Vectorial Sum, and is written $\Sigma\theta$. When multiplied by the value from the table of Harmonic Components T_n (for the order under consideration) and by the piston area square inches and crank radius inches, the product is the harmonic torque in lbs. ins. for that order.

$$\Sigma\theta \times T_n \times A \times R = T_h.$$

and the energy input for $\pm$ 1 radian movement at the free end of the shaft is:—

$$\pi T_h \text{ lbs. ins. per cycle.}$$

Damping.

This is very indeterminate, and no hard and fast rules can apply. Internal energy loss or hysteresis of the material, piston friction, bearing friction, air resistance, deflections of the engine frame, propeller effect, all tend to damp out synchronous vibrations. However, it is safe to assume that the amplitude of movement for hysteresis damping alone will be at least twice the actual deflection.

The hysteresis energy in each section of shaft depends on the stress, f lbs. sq. inch, radius r ins. and length l ins. of the section, and is approximately as under—

$$f^{2 \cdot 3} \times 2r^3 \times l \times 10^{-10} \text{ lbs. ins.}$$

For hollow shafts use $2 \times \dfrac{r^{4 \cdot 3} - r_1^{\,4 \cdot 3}}{r^{1 \cdot 3}}$ instead of $2r^3$.

Work out the value for each section and find the total H lbs. ins. per cycle for the shaft with $\pm$ 1 radian movement at the free end.

The amplitude for hysteresis damping only is then—

$$\pm\, a = \sqrt[1 \cdot 3]{\frac{\pi T_h}{H}} \text{ radians}$$

and from experimental evidence this may be halved to give the actual amplitude to be expected.

The stress in the various sections will be that worked out for 1 radian (fig. 19) multiplied by $\frac{a}{2}$.

Generator Sets.

When a generator is directly coupled to the flywheel with no appreciable length of shaft between, the generator inertia may be added to that of the flywheel and the two considered as one body.

Usually, however, the shaft has sufficient length to make a considerable difference in the natural frequency of the system and its equivalent length and stiffness should then be calculated and (with its polar inertia) added as an extension of fig. 19, the new point of balance being reckoned in the same way by moments about the generator in this case.

When a very long flexible shaft connects the engine to a mass, such as a propeller, two frequencies are to be dealth with.

The two-node frequency will be practically the same as that for the bare engine and flywheel, with one node in the crankshaft near the flywheel, and the other near the propeller.

The periodic torque in this condition of vibration is high in the crankshaft and low in the propeller shaft, which need not therefore be considered on this count. There will, however, be a much lower frequency due to the whole engine system, cranks and flywheel oscillating against the mass of the propeller and its entrained water.

For long propeller shafts regard the crank masses as added to the flywheel.

Then if the engine polar inertia is I_e and the propeller with the entrained water is I_p while the length of the shaft reduced to a uniform diameter is l ins., then the node will be l_e from the engine and l_p from the propeller, when

$$l_e + l_p = l$$

and

$$I_e l_e = I_p l_p$$

hence

$$\frac{I_e l}{I_e - I_p} = p.$$

From this find the frequency, using either the propeller inertia or the total engine inertia, and the stiffness of the shaft between the mass and the node.

The elastic curve (neglecting the inertia of the shaft which is small) is a straight line through the node, and the amplitudes are inversely as the inertias.

For this form of vibration (one node in the whole system) the amplitude of movement of all the engine cranks is substantially equal. All the minor orders therefore cancel and only the major orders are troublesome.

Major orders are those in which all the vectors are in phase and additive.

If there are n cylinders, then all orders which are a multiple of $\frac{n}{2}$ are major orders in 4-stroke engines, and multiples of n in two strokes.

Vee Engines.

Find the resultant or vectorial sum $\Sigma\theta_A$ for one bank and then the resultant for the whole engine, by combining two of these at the angle, separating the *firing positions* of the two banks. Note that this is not usually the vee angle, but 360° more on the engine, *e.g.* in a 60° vee, 16-cylinder, B.1 does not fire 60° after cylinder A.1, but 360° + 60° = 420°. This does not make any difference on integral orders, but on the half orders it is very important.

Take the $5\frac{1}{2}$ order with firing sequence on each bank, 1, 6, 2, 5, 8, 3, 7, 4. The vectorial sum for A bank will be approximately 1·45 for 1 radian at the free end. The vector for B bank will be at 420° × $5\frac{1}{2}$ = 2310° to A, *i.e.* (6 × 360°) + 150°, *i.e.* nearly opposite, so that the final resultant is quite small, 0·74 approximately. Whereas, if 60° (the vee angle) is taken, the result is 60° × $5\frac{1}{2}$ = 330°, which means that the vectors for the two banks are at 30° to each other, and the resultant is almost the arithmetic sum of the two—actually 2·8.

The most serious cases of torsional vibration are usually those involving one node in the crankshaft itself.

In general, orders of higher number than the 6th are not destructive, but may be very objectionable and intolerable with gearing. Modern large diameter crankshafts will stand running through the 6th and $4\frac{1}{2}$ orders in 6- and 12-cylinder engines, but must not be held on them.

Flexible Couplings.

Great care must be taken in choosing and specifying these. The coupling must be as strong in torsion as the shaft and must have the specified stiffness. This must be such that when the coupling is represented in the diagram of the system as a shaft of equivalent stiffness, the frequency of the whole plant is favourably placed with regard to the running range of speed.

The construction of the flexible coupling must be such that its torque/torsion diagram departs considerably from a straight line, so that with increasing amplitude the natural frequency rises and puts the system out of tune with the exciting harmonic.

Dampers.

These are, broadly, of two kinds:—

(*a*) Those which absorb work when vibration occurs, and convert it into heat by solid or viscous friction.

(*b*) Those which put the system out of tune by altering the frequency at short intervals or when vibration occurs.

The first type consist of a fairly heavy rim frictionally attached to a light driving plate, so that when alternating torque occurs it will slip, and so absorb energy and limit the building up of vibration. The driving plate must be very rigidly attached to the shaft to stand alternating loads without developing play, and the friction torque should be enough to hold the rim without slip during the ordinary cyclical variations of the engine, otherwise the device will wear rapidly.

It must not be used at a steady speed at which vibration occurs. Some modification in mass or stiffness should be made to alter the vibratory speed in that case. A modification popular in car work is to attach the rim to the driving plate by a thick pad of rubber vulcanised to both. The very high hysteresis of the rubber then absorbs the vibratory energy, and the device, when not overloaded, runs without lubrication or attention.

A further variation uses oil trapped in pockets between the vanes of the inner and outer members, small channels allowing relative motion and the viscous friction dissipates the vibratory energy.

The second class does not really damp out the vibration, but alters the frequency, so that the system no longer responds to the exciting force. This is fundamentally a much sounder scheme.

One form consists of inner and outer members, the latter of considerable inertia, and driven by oil between fitting radial vanes. By means of a stationary valve about which the device rotates, the oil is alternately locked in the spaces or allowed to flow from one to another, so that in effect the crankshaft has a large mass attached to its free end at one instant, and only the light inner mass the next. This occurs several times in each revolution. The frequency is, therefore, constantly varying and no building up can occur.

Another form is the adaptation of a well-known flexible coupling, the light member driving the free heavy mass by means of 'gridiron' springs, arranged in curved slots, so shaped that the frequency rises rapidly with increasing amplitude. This does not produce heat and appears to last without attention for long periods.

The friction types are only palliatives and cannot be recommended for large plants, where steps must be taken in the design stage to arrange that the various frequencies (one, two or even three node) shall not produce heavy stresses in the running range.

Measurement of Actual Stresses.

Torsiographs of several makes are available which consist essentially of two parts, first, a very light pulley driven from the engine shaft under examination and following all its speed fluctuations; secondly, a heavy flywheel driven from the light pulley by a very soft spring, so that it maintains a steady smooth speed sensibly constant over short periods and the mean of the engine speed.

The differences in angular position of these parts show the fluctuations of the shaft. A light rigid pen mechanism draws a graph of the variation on a moving strip of paper in the Geiger machine, while a stylus draws a similar diagram on a celluloid band in the Cambridge instrument.

The drive must be from an antinode where movement is greatest, and for vibration over 3,000, a steel belt must be used.

Where possible a direct drive through a short tubular cardan shaft, flexible in bending but rigid in torsion, is recommended, especially for vibrations of 4,000 per minute and upwards. The graph drawn by the instrument, multiplied by suitable constants, represents the twist of the shaft at the driving point, taking the node as stationary. A second pen or stylus marks time intervals and a third marks the engine cycles on the same strip. The frequency and order of the vibrations may therefore be checked.

It is to be noted that the record from the instrument is in itself no use in calculating stresses. The necessary shaft diagram of stiffness, etc., and the table of torques in the several sections, must be done first in order to interpret the graph.

High-Speed Electrical Torsiographs.

As rotational speeds increase and crankshaft stiffnesses are put up, it is found that in spite of every refinement—small overall size, light pen mechanisms, restricted travel (afterwards photographically magnified), etc., the various forms of mechanical torsiograph fail to give correct amplitude readings and something fundamental must be done to record the real movements of the shaft.

One device consists of a simple electro-magnetic machine of very small size in which the armature is firmly attached to the shaft, while the field magnets revolve at a sensibly uniform speed. Multiple brushes (to ensure continuous contact) running on slip rings, pick up the varying voltage due to the constantly changing relative velocity of the field and armature. This is fed to a valve amplifier and, after integrating by a suitable electrical circuit to give displacement, is shown on a cathode ray tube in which the vertical component is the shaft movement and the horizontal component is controlled by a 'time sweep' which by suitable means may be divided into crankshaft degrees, and either read directly or photographed for record.

To assist in interpreting the somewhat complicated diagram 'harmonic analysers' have been devised, by means of which each component may be separated from the rest, using a resonant circuit which may be tuned over a very wide range of frequencies.

On account of the very small potentials generated, possible brush losses, etc., other methods are now being investigated, for example—photo electric pick-ups which do away with sliding

contacts and give a much stronger 'signal' needing less amplification and reading directly in displacement without the intervention of an 'integrator,' which, particularly at low frequencies, is a possible source of error and better eliminated where possible.

Rapid strides are being made and a choice of really good pick-ups should soon be available. Reliable frequency analysers are already obtainable, and reduce enormously the labour of interpreting the diagrams. It should be emphasised that the greatest *apparent* amplitude measured from the unfiltered diagram is seldom the amplitude of the fundamental vibration. This only occurs when a slightly damped system is running right on a violent synchronous vibratory speed, showing almost perfect sine waves without any interference. In all other cases, at least a rudimentary harmonic analysis must be made, and this tedious process is done quickly and thoroughly by the electrical analyser.

For important and complicated cases the reader is advised to look up the more extended works devoted solely to this subject, or to obtain expert advice.

Scavenging and Supercharging.

With the great increase in the number of large two-stroke engines for marine work and the practically universal adoption of super-charging or 'blowing' for aero engines, these subjects have become more important.

Timing and port area for two-strokes have been touched on in Part III, and it will be evident that as speeds rise, it becomes important to hold a nice balance between the power lost by a somewhat exaggerated timing (exhaust opening very early so that it may get away and allow time for the scavenge operation) and the power expended on the fan or blower, since the pressure required varies inversely as the square of the time for equal ports. In general, the port area will also be smaller if the period is smaller, so that a careful preliminary survey is essen-

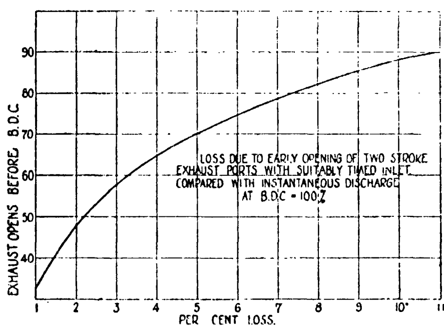

FIG. 23.

tial. The graph, fig. 23, gives the approximate value of the loss due to exhaust release, and will help in deciding the timing. Fig. 24 gives the approximate power for the blower.

Blowers for marine work are often of the rotary displacement pattern. These, though noisy, are efficient when working at the designed pressure, and are particularly suitable for the steady speed at which these engines usually run.

In some forms the volume enclosed between the vanes reduces before the delivery port opens, thus compressing the air to delivery pressure and avoiding back surge through the ports. This makes for a very high efficiency at the designed pressure.

The simple 'Rootes' type is common when driven from its own engine, for direct reversing marine plants, the air inlet and outlet being interchanged by valves connected to the reversing control, so that the air goes into the cylinder whichever way the blower runs. This avoids reversing gear.

The gear-driven centrifugal blower has an inherent advantage for two-stroke variable speed engines, in that, while the volume delivered per minute varies in direct proportion to the speed, the pressure varies as the square of the speed, which is just what is required for forcing the air through the ports. The power expended is therefore in proportion to the cube of the speed, but the output follows the engine requirements in volume and pressure over a wide speed range. The adiabatic efficiency, however, is not so good anywhere as that of some displacement blowers at their designed pressure.

Exhaust turbine-driven blowers are, of course, centrifugal fans, and run up to a very high speed. This form is found on four-cycle engines rather than on two-strokes, since back pressure on the exhaust of the latter is not popular, but there does not seem to be any fundamental reason for the discrimination. The percentage of surplus air, above that needed for complete chemical balance, should be greater if an exhaust turbine is used, so that the mean exhaust temperature will be lowered by distributing the heat over a greater weight of air, thus making conditions easier for the turbine blades, which otherwise may fail. This entails a greater 'port area × time' integral and, in the four-stroke, a very large overlap between inlet opening and exhaust closing—as far as 160° total has been employed.

Supercharging obtains to a slight extent on two-strokes, but usually as a result of the scavenge pressure required to displace the residual gases in the available time, so that, when the cylinder ports close, the charge is well above atmospheric pressure. By that time the piston has, however, reached a point in the stroke which reduces the enclosed volume so much that there is no appreciable gain in the weight of air charge compared with a full cylinder volume at atmospheric pressure. Supercharging proper may therefore be thought of as applying to the four-cycle engine.

HORSE-POWER, ETC., FOR SUPERCHARGING FOR 100 CU. FT. PER MIN. AT 30 IN. MERCURY AND 15° C. INLET.

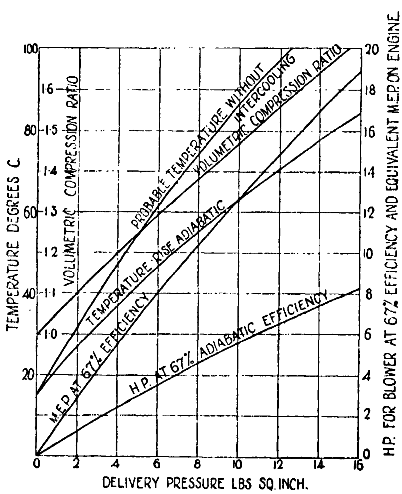

FIG. 24.

The practical limit to the boost pressure is not yet reached, as experimental work has been done up to approximately 4-atmospheres absolute with brake mean pressures of 530 lbs. per sq. in. referred to the whole stroke. This figure does not allow for the work of compressing the air, which was supplied from an outside source, but illustrates what can be got out of an engine. This work was done in a sleeve valve engine, as the absence of the hot exhaust valve gave it a great advantage, and the only trouble experienced was with plugs in the early stages. This was overcome. Incidentally, the exhaust pipes burnt out until made of 'Staybrite' steel.

In aero work 3 to 4½ lbs. above atmosphere at ground level is common, while for 'stunts' or high altitude work, blowers have been used giving over twice the external pressure.

Attention is now being paid to two-stage blowers with some inter-cooling, and to two-speed centrifugals. Either system is intended to give a greater altitude range by maintaining the ground level power at a lower external pressure than is possible with a single-stage or single-speed fan. The measured mean temperature rise for moderate pressure superchargers is 4° C. per 1 in. of mercury (Hg), *i.e.* approximately 8° C. per 1 lb. sq. in. gauge pressure with blower inlet at 30 in. Hg (atmospheric pressure). The more efficient the machine, the less the temperature rise. A curve is given below showing the effect of inlet temperature on power (fig. 25).

In a four-cycle engine the supercharge or 'boost' pressure helps the piston on the downward induction stroke, although some portion of the pressure is used up over the greater part of this

stroke in pushing the greater weight of charge through the valve port. The remainder, however, does useful work on the shaft, and in effect reduces the blower **loss. As a rough estimate, 0·6 of** the pressure is useful. **In comparing** multi-cylinder engines **with single cylinder experimental** sets, it has been observed that the latter with separately driven blowers at 4 to 5 lbs. gauge pressure give results almost identical with the multi-cylinder driving its own blower—the difference in the mechanical efficiency being sufficient to supply the power for the fan.

The permissible compression ratio (R) is reduced as the boost is raised—because the higher induction temperature leads to a still higher compression temperature in the ratio of $R^{0\cdot 35}$ approximately; *e.g.* at 7 to 1 ratio every 1° rise of the charge at B.D.O. becomes 2° when

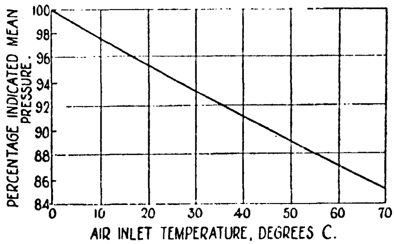

FIG. 25.

compressed. The actual ratios depend to some extent on the engine speed, but mostly on the fuel used, which recently has altered and is still altering rapidly in detonation quality.

Intercooling of the boosted air, when possible, is of value therefore, as it permits the compression ratio to be raised with gain in power and efficiency.

Altitude.

The pressure, temperature and density at any given altitude vary considerably in different places and at different seasons, but mean values have been agreed for what is known as the 'International Standard Atmosphere.' These are given in the graph printed below (fig. 26).

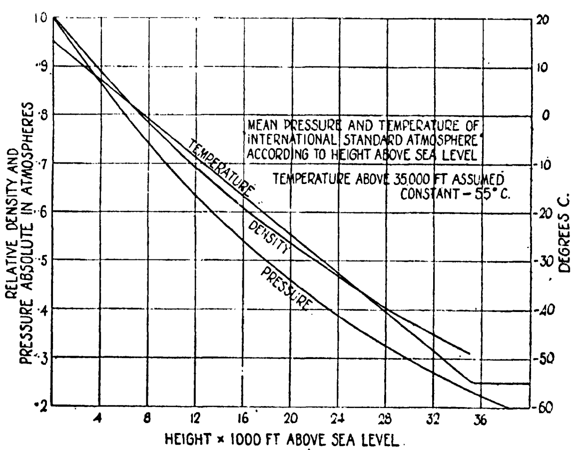

FIG. 26.

Mountings—Foundations—Maintenance, etc.—Standard Specifications—B.S.I. and Lloyd's Rules.

It is customary to put in large masses of concrete to which the engine is bolted by heavy holding-down bolts.

While the addition of this inertia to the engine reduces the amplitude of movement due to torque reaction, unbalanced forces and couples, or engine bed deflections, the rigidity of the arrangement causes vibration waves to be transmitted to the soil, and they may be felt at remarkable distances and have often been the cause of litigation and considerable expense. For some time now there has been a tendency to apply the lessons of the car and aero engines (which run on the flimsiest supports) to heavier work, and foundations now often take the form of a reinforced concrete raft or slab sufficiently deep to form a strong stiff bed for the engine, and also for the generator if close coupled, the whole unit being suspended elastically on a series of springs, or on a generous thickness of some resilient material, so that the bed may move through its vibratory amplitude without any appreciable alteration in the force exerted on the surrounding soil or floor.

Springs should be roughly in two lines parallel to the crankshaft, and as far as possible from it so as to give good resistance to torque reaction (see later paragraph) while being soft (*i.e.* of low rate lbs. per inch) vertically.

If the weight of the whole plant deflects the springs d inches, then the vertical oscillatory frequency of the system will be :—

$$\text{F/min.} = \frac{188}{\sqrt{d \text{ ins.}}} \text{ vibrations per min.}$$

This should be well below the lowest running speed in r.p.m., so as to be clear of vibrations set up by the primary forces on the pistons, etc.

Special felts and rubber in various forms are also used, but in these cases it is most important that an *adequate thickness* should be used—a mere layer is practically useless. The material must have sufficient depth in the direction of vibration to absorb all the probable engine movement and return to its normal dimension continuously, so that the pressure on the ground is almost constant.

In car work the secondary vibrations of four-cylinder engines are now catered for by spring or, more usually, rubber mountings.

Torque reaction is also absorbed to some extent, but as this increases with *decrease* in speed, the mounting is likely to tune in at some low speed near the desired idling speed. It is therefore advisable to make an approximate estimate of the polar inertia of the engine body (cylinders, crankcase and all fixed parts) and see that the stiffness of the rubber or spring mounting is sufficiently low to respond only to impulses below those at the desired idling speed.

If the engine weight exclusive of crankshaft and flywheel is W lbs., and the radius of gyration is r ft., then the polar inertia is :—

$$I_p = \frac{Wr^2}{g}$$

If the supporting springs have a total rate of R lbs. per in. deflection at a distance of r_1 ft. from the centre of the engine, the stiffness of the mounting to resist torque is :—

$$S = 12Rr_1^2 \text{ lbs. ft. per radian,}$$

and the frequency of the whole system oscillating round the shaft is :—

$$\text{F/sec.} = \frac{1}{2\pi}\sqrt{\frac{S}{I_p}} \text{ vibrations per sec.}$$

This frequency should be less than the number of firing impulses per sec. at the idling or lowest running speed, *i.e.* for n cylinders in a four-stroke engine—

$$\frac{n}{2} \times \frac{\text{R.P.M.}}{60}$$

In designing the springs, first choose a suitable diameter of wire and radius of coil to give a reasonable stress in the wire (say under 30-tons/sq. in.). Then make the number of coils sufficient for the deflection (see calculation for Valve Springs, page 223.).

Pads of felt may be arranged just clear of the supporting raft in its normal running position, to check the swing which may occur when stopping and starting.

Attention must be paid to all pipe connections, etc., and flexible sections should be introduced where necessary to allow of the slight engine movements.

Rubber has a fairly even stress strain modulus up to a certain point and then the resistance rises rapidly. This makes it an excellent material for vibration absorbing mountings, but the

pressure per square inch should be kept low, and the thickness as generous as circumstances permit in order to get satisfactory damping and long life.

The oil engine in vehicles calls for very careful mounting. The severe torque reaction due to the high compression ratio and the full air charge, together with the low idling speed which is demanded, make the angular swings of the engine on a flexible mounting very large indeed, and it becomes necessary to provide really flexible pipe connections which can move through big amplitudes continuously without distress.

Controls, etc., must be so arranged that their adjustment is not altered by the engine movements.

A separate gear-box with short cardan shaft connection to the engine is a luxury which is also indicated if competition permits. Steel springs of tapered helical form (in which the large end coils sit down on the support under load and stiffen the rate) have been used with success for this mounting, as greater amplitude can be provided than would be possible with rubber of reasonable bulk.

Maintenance.

The principal points which should be looked to constantly are:—

(1) The supply of clean filtered oil and fuel. Any attention paid to the former will be repaid in bearing life. A constant bleed from the pressure system through a fine filter, returning the oil to the suction side of the pump, will continually remove undesirable matter which may pass the other filters, and the whole of the oil in the system passes through in a short time.

(2) Exhaust thermometers should be provided for each cylinder, as they show very quickly the beginning of any deterioration of the engine, and indicate the line in which it is located.

Routine observation of the temperatures will give warning of the need for periodic attention to such parts as piston rings, and exhaust valves in poppet engines, and head rings and sleeves in sleeve valve engines.

It is absolutely essential that pistons should not be run long with their rings stuck and packed with carbon as the next stage is overheating and possible seizure.

Bearings.

A well-tested design should not give trouble, but wear will occur and should be taken up as opportunity offers.

As crankpins wear most on the inside, they become oval, and big ends should be tried all round to make sure they are not too tight on the large diameter. The shells should bed well in the rod and be hard together at the joint. Tighten the bolts to the makers' instructions, so that the tension is greater than the maximum top inertia, otherwise the joint will open at each cycle, with almost certain breakdown.

Main bearings must be let up very carefully. Although torsional stresses are the most frequent cause of crankshaft failure, many cases have occurred in which alternating bending loads on the shaft, caused by uneven wear-down of bearings or unwise scraping and letting up, have been to blame either by themselves or as forming an aggravation of the previous conditions.

Every effort must be directed to maintaining a straight line through the bearing centres. In well made and properly erected engines the bores of the bearing housings will be aligned, and uneven thickness of the bottom shells is an indication of uneven wear-down.

Where 'hard' water is supplied to an engine, hard scale forms at the hot points, and when possible such places as the insides of the head near the exhaust valve and injector, and all restricted water passages and vent holes should be cleaned.

Injectors should be inspected frequently to see that the nozzles are clear of carbon craters and are not eroded (this occurs when acid products or fine grit are present in the fuel), that the needles are free and the springs correctly adjusted.

Standard Specifications.

The British Standards Institution (B.S.I.) issue booklets containing standard specifications or internal combustion engines of various kinds, and these should be obtained from the offices of

the Institution at 28 Victoria Street, London, S.W. 1, as they will be of assistance in arranging contracts. The chief items of technical interest are as follows :—

(1) *Cyclic Irregularity.*—The angular speed variation shall not exceed 1 in 75 for engines of 1 or 2-cylinders, and 1 in 150 for 3-cylinders or more. This irregularity shall be calculated as $\frac{\text{maximum speed}-\text{minimum speed}}{\text{mean speed}}$ during 1-engine cycle, and is independent of the number of poles in the generator. The engine maker may assume that the armature has 10 per cent. of the flywheel inertia.

(2) *Angular Deviation* shall not exceed $2\frac{1}{2}°$ electrical degrees fore or aft of a point revolving at uniform angular velocity.

Calculations for these two items have been given in Part III.

(3) *Governing.*—5 per cent. for A.C. parallel generators and $3\frac{1}{2}$ per cent. for D.C. or A.C. singly, is specified as the total permanent speed variation.

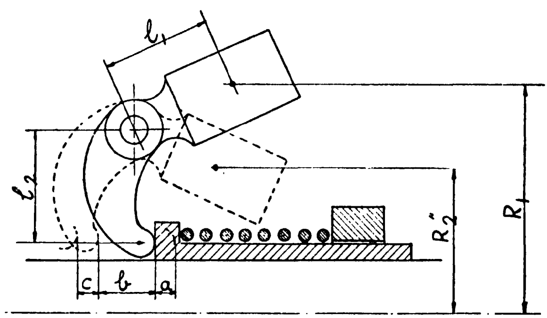
In designing the governor ascertain how much movement of the control rod on the fuel pump is required for :—

(*a*) Idling to shut off.

(*b*) Idling to full load.

(*c*) Full load to maximum overload or extra fuel starting position.

They lay out the weights and connecting gear to cover a total travel = $(a + b + c)$ and calculate the spring stiffness by finding the force required to balance the centrifugal pull of the weights, first at the idling position with a speed of S − $3\frac{1}{2}$ per cent., and secondly at the full load position with a speed S (S = rated speed). These two points cover the distance b and the spring rate is fixed by the difference in load divided by the travel b. Calculate the actual spring as for a valve spring (see page 223) allowing the full travel $(a + b + c)$ with a maximum stress not over 30-tons/sq. in., and a range not exceeding 15 tons/sq. in. Note that if the spring does not move the same distance as the centre of gravity of the weights, the necessary correction must be made for the leverage. See fig. 27.



WEIGHTS SHEWN AT ENDS OF NORMAL GOVERNED RANGE "b"

a = DISTANCE FOR SHUT OFF

C - DISTANCE FOR OVERLOAD.

FIG. 27.

Total of all weights, W lbs.
Rated speed S revs. per min.
Force on Spring at R_1 in.

$$= R_1 \times W \times \left(\frac{S - 3\frac{1}{2}\,\%}{1{,}000}\right)^2 \times 28\cdot2 \times \text{lbs.}$$

and at R

$$= R_2 \times W \times \left(\frac{S}{1{,}000}\right)^2 \times 28\cdot2 \times \text{lbs.}$$

The engine should then settle down with a variation of $3\frac{1}{2}$ per cent. from idling to full load.

All connection should be as free and direct as possible. Any friction or sluggishness in the governor gear will cause hunting, because the delay will be followed by over-correction. Use ball races for the fulcrum pins, and make the governor sufficiently powerful to overcome the pump resistance easily. In big plants a small governor may work a relay, such as a piston valve controlling an oil pressure cylinder which in turn adjusts the speed.

Allowances in engine output are laid down for differences in temperature and pressure conditions as under:—

Standard pressure 30 in. mercury = 760 mm.
,, temperature 62° F. (16·7° C.).
Allowances 4 per cent. per 1 in. of mercury = 1·6 per cent. per cm.
,, 3 ,, ,, 10° F. (5·6° C.).

The lower the pressure and/or the higher the temperature the less the engine output. Humidity is not specified and should be agreed between the manufacturer and purchaser.

Lloyd's Register of British and Foreign Shipping has drawn up rules for the survey of marine internal combustion engines and the auxiliary plant connected with them. While many of the rules concern the installation in the ship and the provision of safety devices, rather than the engine itself, particular attention has been given to the crankshaft and detailed dimensional limitations laid down, in accordance with the cylinder diameter, stroke, bearing span and maximum gas pressure,

It is also required that the plant shall not run at a dangerous synchronous speed.

These rules cover petrol and oil engines of low and high compression and may be obtained from the offices of the Registry, 71 Fenchurch Street, London, E.C. 3.

Particular cases and special designs will always be considered by Lloyd's, and other underwriting bodies, and allowance made for the use of superior materials.

SECTION XXVIII

PART IV

GAS TURBINES.

(Contributed by B. Wood, M.A. (Cantab.), A.M.I.Mech.E.)

Types and Principles of Operation.

A gas turbine is one in which the working substance is a gas rather than a condensible vapour as in the steam turbine or a liquid as in water turbines. A turbine can utilise gas from any source in hot or cold state where available under sufficient pressure and in suitable quantity to make the installation worthwhile. Cold air turbines have been used in torpedoes and in other applications. Hot waste gas from chemical processes has occasionally been utilised. A turbine was also employed in the German V2 rocket projectile to drive the fuel pumps. These are gas turbines in the sense above defined though they rely on stored energy. However, major technical interest lies in self-contained gas turbine sets designed to produce power by burning fuel as in oil engines. Such a self-contained plant must produce its own compressed gas. The gas can be atmospheric air, compressed and heated by burning fuel in it, then passed through the turbine and finally exhausted to atmosphere (the open cycle): alternatively, it may be air or any other gas in a closed circuit, in which case a further operation of cooling back to the initial temperature must be added to complete the process. The surplus of power generated in the turbine above that required to drive the compressor, representing only a fraction of the whole, is the useful or coupling output.

It will be understood that expansion and compression can also be carried out in reciprocating machines but these are usually heavier and more costly though able to withstand higher temperatures intermittently.

Three different ways of carrying out the process have been tried :—

1) Compression in a rotary compressor followed by constant pressure heating and subsequent expansion in a turbine: examples, Brown Boveri, Escher Wyss, Whittle (in the application to jet propulsion of aircraft).

(2) Compression in a piston compressor followed by constant volume or constant pressure burning with partial expansion in the cylinder and final complete expansion in a turbine: examples, Büchi and Pescara.

(3) Partial compression in a rotary compressor followed by explosive burning at constant volume in a chamber and subsequent expansion in a turbine: example, Holzwarth.

The first method, sometimes referred to as the 'combustion' cycle to distinguish it from the explosion cycles, is the oldest in conception and is that used in most plants to-day. It was tried out experimentally in the early years of the century, but with the low efficiency of the centrifugal compressors then employed and the moderate temperatures that turbine blade materials were capable of withstanding, the sets were unsuccessful, producing little or no surplus power. Consequently interest shifted for some time to the other two methods which seemed to offer a way out of both of the difficulties of high temperature and poor compressor efficiency. Holzwarth worked on the problem over a long period of years and succeeded in installing sets of 1,000 H.P. and 2,000 and 5,000 kW in Germany, running on blast furnace gas, but it is not clear to what extent they were really a success or what efficiencies were attained. Büchi and Sulzer Brothers, experimenting with pressure charging of a Diesel engine, carried the charging pressure up to several atmospheres. The proposal was made to drive the compressor from the engine and to arrange that it should absorb all the engine output, leaving the external work to be generated in a separate turbine taking the hot exhaust gas from the engine. Götaverken and Malone have proposed to use this scheme for the propulsion of ships. Pescara proposed to employ a 'free piston' engine, in which the force of the explosion in the engine cylinder is transmitted direct to the compressor piston, without the need for a crank shaft, in the manner of the Junkers compressor. A plant of this nature was run experimentally in France just prior to the war, and appeared to offer promise of commercial success. It is now being further developed in France in the form of the equipressure boiler.

The Combustion Gas Turbine.

Since this is the type which has recently come into industrial, military and naval use, it merits discussion in detail. The cycle employed in the simplest case is the constant pressure cycle referred to in the U.S.A. as the Brayton cycle, and in England as Joule's air engine cycle. This cycle without refinements such as intercooling, reheating or heat recuperation, permits only a moderate efficiency to be attained when utilising practical temperatures but serves as a basis for preliminary

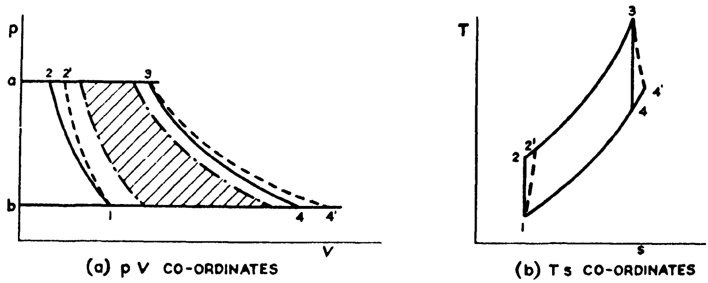

FIG. 1.—Diagram of Simple Cycle.

consideration. The diagram (fig. 1) is the same whether the circuit is open or closed. Fig. 1 (*a*) refers to pressure—volume co-ordinates, and fig. 1 (*b*) to entropy—temperature. In the ideal process shown in full line, the curve 1–2 represents isentropic compression (*i.e.* compression without losses internal or external). The line 2–3 represents heating at constant pressure either by burning fuel in the air or by passing the gas over a surface heater. Curve 3–4 represents isentropic expansion in the turbine. The line 4–1 represents rejection of the exhaust heat to the atmosphere in the open cycle or cooling at constant pressure in the closed cycle. The area a21b shows the work of drawing in, compressing and delivering the air and the area a34b the work done in the turbine or engine. The area of the 'indicator diagram' 1 2 3 4 is the net work output in the ideal case. In practice, compression follows another curve 1–2′ (shown dotted). This is due to stage inefficiency which causes the gas to become hotter and progressively of greater volume than in isentropic compression. The work applied is also greater by the amount of the stage inefficiency, so that a line shown in chain dot can represent the actual compressor work. Similarly, stage inefficiency in the turbine results in only a part of the available work being extracted at each stage so that the volume is increased and expansion follows the dotted line 3–4′. The fraction of the available work extracted is shown by the chain dotted line. The area between the two chain dotted lines shown hatched is the practical work output neglecting any pressure drops in resistances.

Performance.

The approximate performance of gas turbine cycles can be calculated in different ways. The compressor and turbine overall efficiencies e_c and e_t are often assumed, by which means the turbine and compressor work can be derived from the adiabatic work. This may be calculated from the well-known adiabatic expansion law

$$pV^k = \text{constant, where } k = \frac{C_p}{C_v} = \frac{\text{specific heat at constant pressure}}{\text{specific heat at constant volume}}$$

Denoting the absolute temperature by T, etc., and writing

$$\frac{p_2}{p_1} = \frac{p_3}{p_4} = r$$

Then $T_2 = T_1 r^{\frac{k-1}{k}}$ and $T_4 = T_3\left(\frac{1}{r}\right)^{\frac{k-1}{k}}$

The ideal compressor work

$$= \int_{T_1}^{T_2} V dp = C_p T_1\left(r^{\frac{k-1}{k}} - 1\right) \quad \text{or } C_p(T_2 - T_1)$$

The ideal turbine work

$$= \int_{T_4}^{T_3} V dp = C_p T_3 \left(1 - \left(\frac{1}{r}\right)^{\frac{k-1}{k}}\right) \quad \text{or } C_p(T_3 - T_4)$$

The corresponding values of compressor work and turbine work in practical turbines can be obtained by dividing and multiplying the ideal values by the efficiency ratio e_c or e_t respectively and by using appropriate values of C_p according to the mean temperature, making allowance for the extra weight of fuel w added per pound of air.

The cycle efficiency can be readily calculated as

$$\frac{\text{net work}}{\text{heat input}} = \frac{C_{p34}(1 + w)e_t(T_3 - T_4) - C_{p12}\frac{1}{e_c}(T_2 - T_1)}{C_{p23}(1 + w)(T_3 - T_2)}$$

An objection to this method is that e_c and e_t are not actually invariants but depend on the pressure ratio, the stage efficiency and the number of stages.

It is more rational to assume a constant stage efficiency and to take into account the influence of pressure ratio. This can be done readily mathematically if the stage efficiency e_s is taken to be that of an infinitely small stage called the 'polytropic efficiency.' Expansion then follows the polytropic law pV^n = Constant

$$\text{where } \frac{n-1}{n} = e_s\left(\frac{k-1}{k}\right) \text{ in expansion and } \frac{1}{e_s}\left(\frac{k-1}{k}\right) \text{ in compression.}$$

Temperatures are related as above writing n instead of k.

The temperature rise of the compressor then becomes

$$T_2 - T_1 = T_1\left(r^{e_s\left(\frac{k-1}{k}\right)} - 1\right)$$

Similarly the drop in the turbine

$$T_3 - T_4 = T_3\left(1 - \left(\frac{1}{r}\right)^{e_s\left(\frac{k-1}{k}\right)}\right)$$

The cycle efficiency can be worked out as above allowing for variations in k if desired but for many purposes this variation can be ignored. The calculation can also be made readily on a 'polytropic chart.'

The efficiency obtainable with this plain cycle depends in a marked degree on the temperature adopted before the turbine and that before the compressor. Fig. 2 shows in full line how the

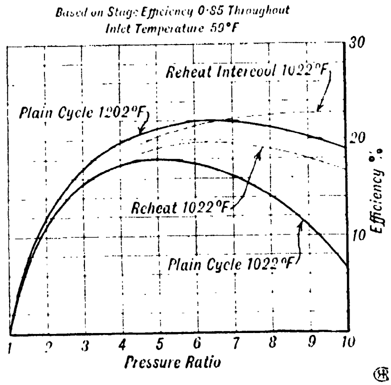

FIG. 2.—Efficiencies of Various Cycles without Heat Exchangers.

calculated efficiency varies with pressure ratio for initial conditions of 1,022° F. (550° C.) before the turbine and alternatively 1,202° F. (650° C.), the air temperature being taken as 59° F. and the stage efficiency in both turbine and compressor as 85 per cent. The lower temperature was considered to be about the limit for continuous operation when a 4,000 kW emergency generating unit was installed at Neuchâtel in Switzerland in 1939. This gave a test efficiency of 17·4 per cent. at the terminals with an air temperature of 78° F. The higher initial temperature might now be accepted as permissible with the same type of turbine. It is clear that the moderate efficiency attainable restricts this cycle to duties where fuel cost is of lesser account than low capital cost, simplicity and independence of water supply as, for instance, in the case of peak load

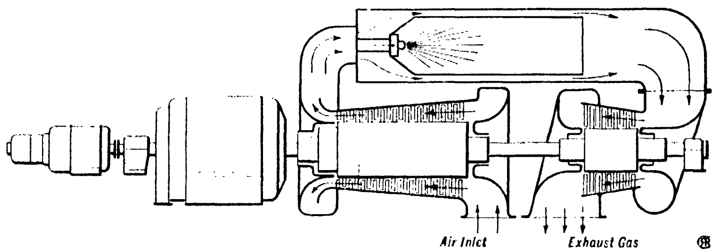

FIG. 3.—Arrangement of 4,000 kW Unit for Neuchâtel.

or emergency plant and also in aircraft. Fig. 3 shows the arrangement of such a plant for land service, and fig. 4 the application to jet propelled aircraft where the shaft furnishes no power.

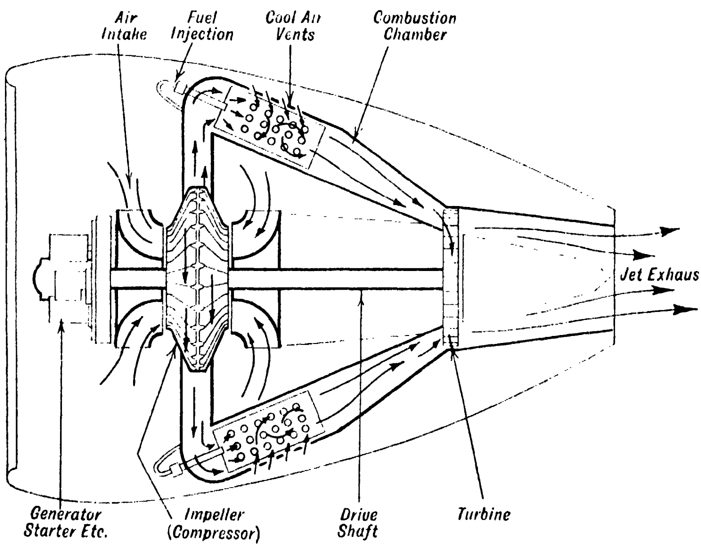

FIG. 4.—Simple Diagram of Jet Propulsion Unit.

Elaborations on the Plain Cycle.

Further developments and elaborations on the simple cycle are shown in fig. 5. The following fundamental means can be employed singly or in combination for obtaining improved efficiency and/or increased output per pound of air :—

(*a*) Reheating in the turbine (multi-stage burning).
(*b*) Intercooling in the compressor (or precooling before the compressor).
(*c*) Exhaust heat recuperation by a heat exchanger (also known as regeneration).

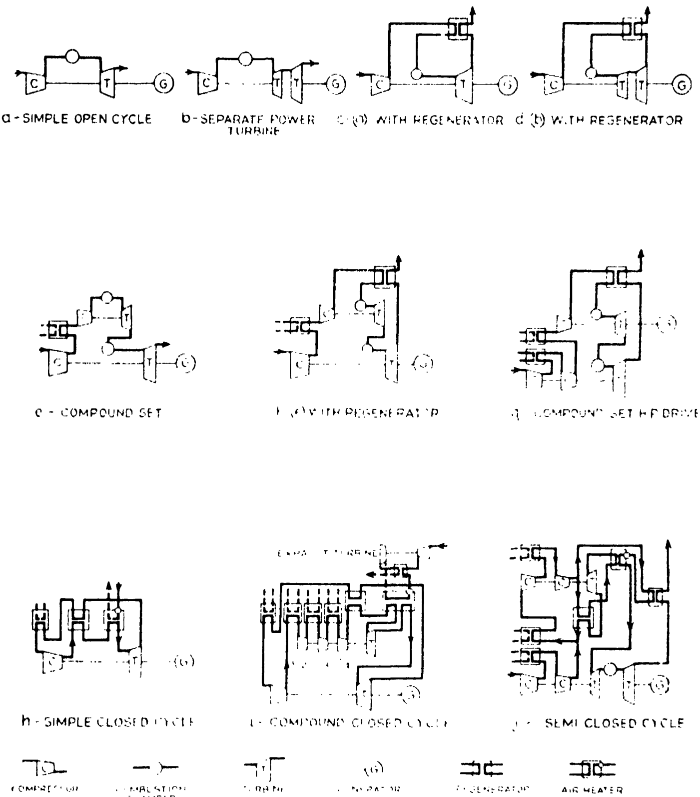

FIG. 5.—Cycles for Gas Turbines.

Various arrangements involving more than one shaft are adopted to avoid the risk of surging in the compressor, to overcome limitations on the quantity of fluid which can be handled on a single entry or exhaust annulus, to obtain part load characteristics suited to the drive and, in some cases, to avoid infringing patents.

It will be understood that the number of possible combinations of multi-shaft machines is large, and only the more important variants are shown. Turbines may be arranged in parallel as well as in series. The cycle may also be closed (fig. 5 (h) and (i)) or in an intermediate form semi-closed (fig. 5 (j)).

Reheat.

Reheat is readily applied in open circuit cycles by burning a second charge of fuel in a second combustion chamber after partial expansion in the turbine. This leads to a higher mean temperature without exceeding the maximum mentioned above and the turbine output is increased without increasing the amount of air or the heat rejected to the exhaust. The specific output and efficiency are thus increased and higher pressure ratios become advantageous.

Cooling the Compressor.

Similarly the mean temperature in the compressor is a guide to the work of compression. As the compression ratio is increased the saving by recooling the air back to its initial temperature after partial compression becomes sufficient to justify the cost of installing a cooler. The useful net output is thus increased resulting in improved efficiency and reduced capital cost per kilowatt of the turbine and compressor. Intercooling becomes important at the higher pressure ratios required when reheating is adopted in the turbine and the division into separate cylinders facilitates it.

Heat Recuperation.

The exhaust temperature in the simple cycle may be of the order of 600° F. while the temperature after compression is of the order of 350° F., therefore there is scope for transfer of heat from the exhaust to the air after compression. Regeneration in this way directly reduces the amount of fuel to be burnt. This has a marked effect on efficiency but the gains theoretically obtainable are reduced by pressure drops in the heat exchanger which must be overcome by the compressor, and by the temperature drop across the heater surface necessary to transfer the heat from the gas side to the air side. It will be clear that the scope for the use of heat exchanger is increased when the compressor is cooled, because the temperature at exit from the compressor is then lower. The most effective combination is reheating and intercooling with heat exchanger.

The thermal performance of a heat exchanger can be specified by its thermal ratio or 'efficiency' viz. :—

$$e = \frac{\text{mean temperature change } R_m}{\text{maximum temperature difference available } H.}$$

In the ideal case of a contra-flow exchanger of area A with equal quantities of fluid Q on each side and equal specific heats C_p we have

$$R + D = H. \quad D = \text{temperature difference.}$$

$$K = (\text{heat transfer coefficient}) \propto \frac{RC_pQ}{AD}$$

$$\therefore\ e = \frac{R}{H} = 1 - \frac{D}{H} = \frac{A}{A + \frac{C_pQ}{K}} = \frac{A}{A + B} \left(\text{writing } B = \frac{C_pQ}{K}\right).$$

The following table shows how A varies with e. The inordinate increase of A for each increment of e at higher values will be noted.

e	0·5	0·66	0·75	0·8	0·875	0·9	0·95	0·99
A/B	1	2	3	4	7	9	19	99

Status of Development.

There are upwards of 50 gas turbines built or at present in construction by some eighteen firms in Switzerland, the U.S.A. and Great Britain. This does not take account of the large number of smaller machines built from 1934 as auxiliaries for Velox boilers (about 90) and for Houdry oil cracking plants (about 33). The list on page 259 includes 25 units totalling 200,000 kilowatts ordered for electric power stations, of which particulars have been published. There are a few other units known to be in construction but not yet made public. In addition there are some 11 machines built or in construction for locomotives, and at least 5 for ships (possibly more). The remainder are mainly being built for internal experimentation and development. There are at least ten firms in Great Britain building such sets, apart from aircraft units.

The largest machine constructed to date is of 27,000 kW, and the best efficiency offered is 35 per cent. Nearly all builders are using the open cycle, the closed cycle being represented only by Escher Wyss and their licensees, and the semi-closed only by Sulzer Brothers, though patent literature shows interest by other concerns.

LIST OF GAS TURBINES ORDERED FOR ELECTRIC POWER STATIONS.

Date.	Location.	No.	Rating.	Maker.	Cycle (see Fig. 5).	Temp. °F.	Efficiency per Cent.	Fuel.
In service 1940	Neuchatel, Switzerland	1	4,000 kW	Brown Boveri	a	1,022	17·4 test	Oil
Tested 1946	Bucharest, Rumania	1	10,000 kW	Brown Boveri	e	1,100	23·3 test	Natural gas
Tested 1946	Chimbote, Peru	1	4,000 kW	Brown Boveri	a	1,022	19·5 test	Oil or gas
Delivered 1948	Lima, Peru	1	10,000 kW	Brown Boveri	g	1,100	28·3 guar.	Oil
Ordered 1945	Cucuta, Colombia	1	1,650 kW	Brown Boveri	c	1,100	25 guar.	Oil
Ordered 1945	Caracas, Venezuela	2	1,650 kW	Brown Boveri	c	1,100	21 guar.	Oil
Ordered 1945	Alexandria, Egypt	1	1,200 kW	Brown Boveri	c	1,100	22·9 guar.	Oil
Ordered 1945	Persia	2	4,000 kW	Brown Boveri	a	1,100	18 (at 95° F.)	Natural gas
In service December 1947	Beznau, Switzerland	1	13,000 kW	Brown Boveri	g	1,100	30·6 (at 41° F.)	Oil
Promised January 1949	Beznau, Switzerland	1	27,000 kW	Brown Boveri	g	1,100	31 (at 41° F.)	Oil
Promised August 1949	St. Denis, Paris	1	12,500 kW	Escher Wyss	i	1,250	34 guar.	Oil
Promised December 1950	Weinfelden, Switzerland	1	20,000 kW	Sulzer	j	1,200	35 approx. (at 41° F.)	Oil
Promised 1951	Stretford, Manchester	1	15,000 kW	Metro.-Vick.	f	1,200	30 approx.	Oil
Promised 1951	Dunston, Newcastle	1	15,000 kW	C. A. Parsons	—	1,200	27 approx.	Oil
Promised December 1950	Dundee, Scotland	1	12,500 kW	John Brown	i	1,250	34 guar.	Oil
Ordered 1948	Oklahoma, U.S.A.	1	3,500 kW	G.E.Co., U.S.A.	a	1,400	17 at 80° F.	Natural gas
Ordered 1948	Oklahoma, U.S.A.	2	5,000 kW	G.E.Co., U.S.A.	g	1,500	26·4	Natural gas
Ordered 1948	Central Maine, U.S.A.	1	3,500 kW	G.E.Co., U.S.A.	a	1,400	17 at 80° F.	Oil
Ordered 1948	Bangor, U.S.A.	1	5,000 kW	G.E.Co., U.S.A.	g	1,500	28	Oil
Ordered 1949	Metropolitan Water Board	1	2,500 kW	Brush	b	—	16·2	Oil
Ordered 1949	Metropolitan Water Board	1	2,500 kW	Metro.-Vick.	a	—	16·8	Oil
Ordered 1948	Metropolitan Water Board	1	1,875 kW	E.E. Co.	b	—	16	Oil

Efficiencies quoted on lower calorific value and on about 60° F. air or water temperature except where mentioned.

It appears that the limit of output for open cycle machines on a single exhaust is about 10,000 kW, unless the air temperature is particularly low. It also appears unlikely that a set larger than the present limit of 27,000 kW will be built in an open circuit gas turbine.

The following brief notes refer to most outstanding machines on point of size, efficiency or other aspect.

(a) *Stationary Plants.*

A 10,000 kW machine built by Brown Boveri for the Filaret Station, Bucharest, Rumania was demonstrated on test in 1946. It has two shafts using a pressure ratio of 11 : 1 with reheating but without regenerator according to the arrangement shown in fig. 5 (e). The set is intended to run on natural gas, hence high efficiency is not called for. The efficiency obtained was 23·3 per cent. with an inlet temperature of 1,063° F. at 12,000 kW. The time for starting up to putting on full load was seven minutes.

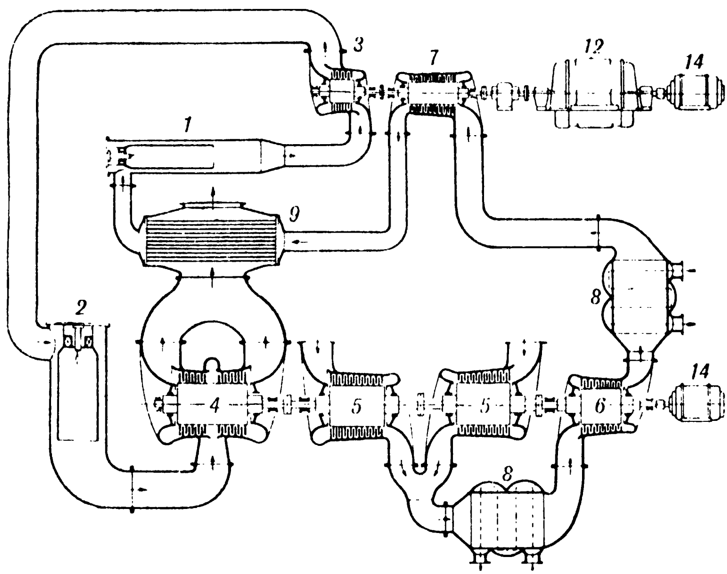

FIG. 6.—Schematic arrangement of the 27,000 kW unit for Beznau. (Numbers refer to Fig. 7.)

A somewhat similar Brown Boveri machine also of 10,000 kW was completed a few months later for Lima, Peru. In this case a higher efficiency was called for with oil firing. The cycle is that shown in fig. 5 (g), a regenerator being used. The alternator is driven from the h.p. shaft. The l.p. shaft thus serves as a supercharger and runs at variable speed according to load. The part load efficiency is thereby improved. The efficiency guaranteed was 28·3 per cent. with 86° F. air inlet and 1,100° F. maximum temperature. Pressure ratio is 9 : 1. The price was understood to be about £23 per kW.

A similar machine using the same frame size was installed in December 1947 at the Beznau Station in Switzerland. Rating on 41° F. air and water temperature and taking account of the overload capacity permitted of raising the output to 13,000 kW and the efficiency to 30·6 per cent. It was not tested in the works prior to despatch.

A second set of 27,000 kW is being erected in the same station. The cycle is the same, as are some of the components, duplicate l.p. machines being connected in parallel as shown in fuller detail in fig. 6. The efficiency guaranteed is 34 per cent. The Beznau Station, containing 40,000 kW, is the largest gas turbine station in the world. The generating plant cost approximately £17·5 per kW, and the whole station £29 per kW. A plan and elevation are shown in fig. 7.

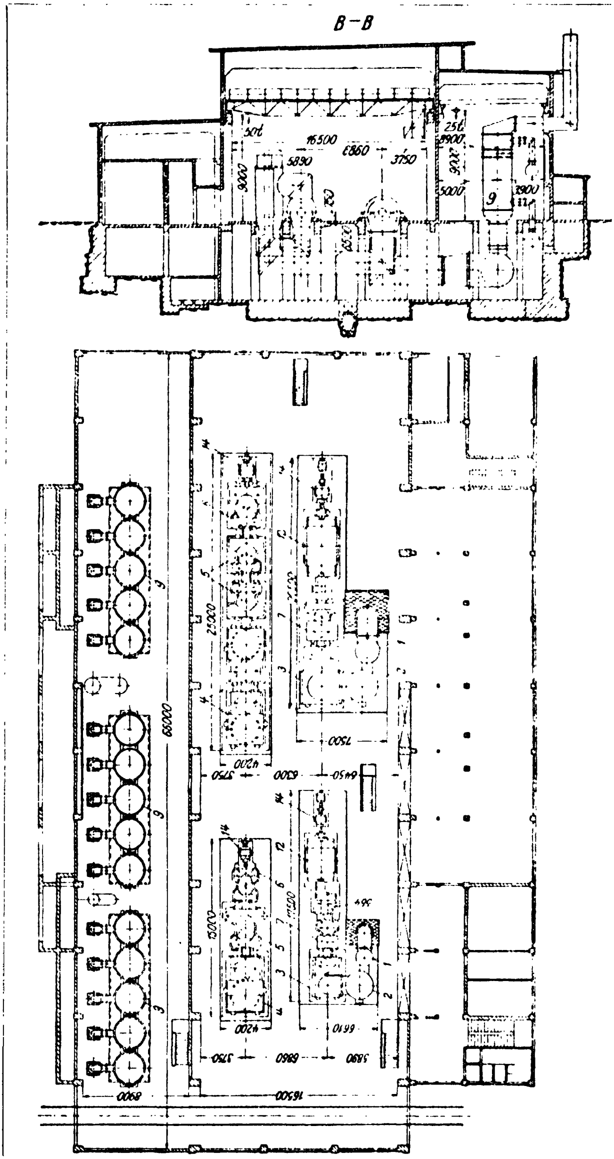

FIG. 7.—Beznau Power Station—Plan and Elevation (dimensions in millimetres).

(1) H.P. combustion chamber, (2) L.P. combustion chamber, (3) H.P. turbine, (4) L.P. turbine, (5) L.P. compressor, (6) I.P. compressor, (7) H.P. compressor, (8) Intercooler, (9) Regenerator, (12) Generator, (14) Starting motor.

Escher Wyss expect to have a 12,500 kW closed-circuit set in service at St. Denis Station, Paris, by about August 1949. The cycle, that shown in fig. 5 (i) and fig. 9 resembles very closely a steam cycle. Air is continuously recirculated, being first heated in an air heater equivalent to a boiler, expanded through the turbines with reheating, passed through a regenerator to a pre-cooler and then compressed in multi-stage compressors with intercooling and returned through the regenerator to the air heater. All heat rejected is carried away by cooling water, the pre-cooler and intercoolers being the analogue of a steam condenser. The main advantage over the steam cycle is in the use of a large regenerator and a small expansion ratio of about 10 : 1. There are two shafts, the h.p. turbine with the higher pressure compressors being free. The l.p. turbine drives the l.p. compressor and the alternator. The guaranteed efficiency at 1,250° F. with reheat and with 60° F. circulating water, is 34 per cent. The air heater is pressure-fired at about 3 atmospheres absolute by a combustion air blower driven by an exhaust gas turbine, which also drives a recirculating fan to attemperate the initial flame temperature. A feature of this cycle is the

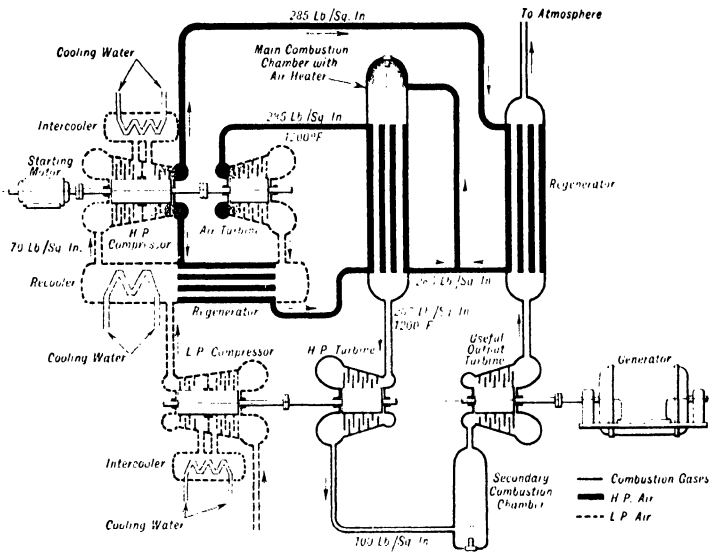

FIG. 8.—Circuit of 20,000 kW Sulzer Semi-closed Cycle Gas Turbine for Weinfelden.

variation of load by changing of the density of the medium. This results in a very flat efficiency characteristic. To raise load, air is let into the closed-circuit in conjunction with increase of fuel rate so as to maintain approximately constant inlet temperature. To reduce load air is expelled at the same time as the fuel is reduced and in addition the turbines may be momentarily by-passed.

Sulzer Brothers are building a 20,000 kW unit for Weinfelden Station, Switzerland, which is on the same company's network as Beznau. This is expected to be completed by the end of 1950. The circuit employed is a semi-closed cycle shown in fig. 5 (j). The efficiency expected is of the order of 35 per cent. based on an initial temperature of 1,200° F. and on cooling water and air at 41° F. The somewhat intricate circuit will be understood from fig. 8. There are three shafts which may be designated ; ' the air turbine,' ' the charging set,' and ' the work turbine.' The fluid fed in through the charging compressor passes out through the work turbine, but roughly an equal quantity of air is recirculated in the closed-circuit through compressor, regenerator, air heater and turbine back through regenerator and cooler. The pressure in the air heater is about 20 atmospheres on both sides of the tubes. One-third to a half of the heat in the fuel is transmitted through the tubes of the air heater into the air cycle, the remainder is employed in the charging turbine with supplementary reheating in combustion chamber before the work turbine. The recuperator permits of recovering a large fraction of the heat rejected by this turbine.

Two sets each of 15,000 kW have been ordered by the British Electricity Authority, one for Trafford Power Station, Manchester, from Metropolitan-Vickers Electrical Company, and the

other for Dunston Power Station, Newcastle, from C. A. Parsons & Company. These are expected to be completed in 1951. The cycle employed by Metropolitan-Vickers will be that shown in fig. 5 (f), employing an initial temperature of 1,200° F. with which it is expected to obtain an efficiency of about 30 per cent. The details of the Parsons machine have not yet been made public. Parsons have also in hand a 10,000 kW machine for the National Gas Turbine Establishment, Pyestock.

A 12,500 kW set is being built by John Brown of Clydebank under Escher Wyss licence for the Dundee Station of the North of Scotland Hydro-Electric Board. This is scheduled for completion late in 1950. It employs a closed cycle and is generally similar to the Paris unit described above. Fig. 9 shows the cycle in more detail. The efficiency quoted as 31·9 per cent. on the higher calorific value is equivalent to 34 per cent. on the lower, which is the basis on which most other gas turbines are rated.

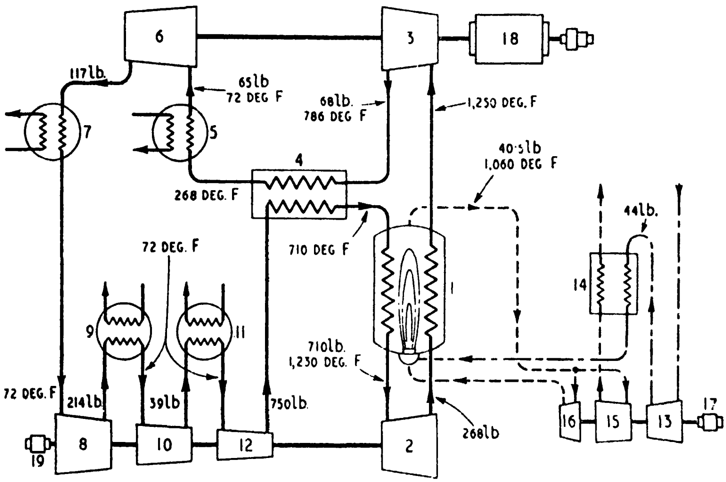

FIG. 9.—Circuit Diagram of Hot-Air Turbine (pressures shown in lb. per sq. in. absolute.)

(1) Air heater; (2) H.P. turbine; (3) L.P. turbine; (4) Heat exchanger; (5) Pre-cooler; (6) L.P. compressor; (7) First intercooler; (8) First I.P. compressor; (9) Second intercooler; (10) Second I.P. compressor; (11) Third intercooler; (12) H.P. compressor; (13) Combustion air compressor; (14) Combustion air pre-heater; (15) Exhaust gas turbine; (16) Recirculating gas fan; (17) Motor; (18) Main generator; (19) Starting motor or turbine.

Among smaller sets mention may be made of a 2,000 kW closed-circuit machine built by Escher Wyss, Zurich, in 1939 and tested in 1945. It is a two shaft unit without reheat and with an atmospherically aspirated air heater. The tested efficiency was 30·5 per cent. at full load with the high initial temperature of 1,300° F. and cold circulating water. It has now run about 3,500 hours.

The Oerlikon Company, Zurich, built a 1,000 kW set which has been running since December 1946, and is of interest as having a centrifugal compressor. The circuit is nearly as in fig. 5 (d). The exhaust gas is used to fire the works boilers. It has run some 4,000 hours and generated some 2,000,000 kWh, but no statement of the efficiency has been published.

Sulzer Brothers completed in 1948 a 7,000 h.p. unit employing their semi-closed cycle somewhat as above described which is to be tested in their works on a waterbrake.

In this country three industrial machines have been completed to date. One of these, a 500 h.p. unit, was begun by C. A. Parsons in 1939 and completed in 1945. It has been run for some 1,500 hours on a water-brake to provide experience with different blade materials and with different fuels. The efficiency is about 15 per cent. (as at generator terminals) based on 1,050° F. inlet. The circuit is as in fig. 5 (c). A somewhat similar machine built by John Brown to Pametrada designs has been run intermittently for about a year. Metro.-Vick. have recently completed a 2,500 kW machine for their own works supply. This is derived from aircraft practice, being somewhat similar to the unit in the gunboat mentioned below, but with the addition of a regenerator fig. 5 (d). The efficiency has not been disclosed.

Orders for three units of 1,875 and 2,500 kW for emergency standby purposes have just been placed with British firms by the Metropolitan Water Board at prices varying from £18 to £30 per kW.

In the U.S.A., four firms, the G.E. Company, Westinghouse, Allis Chalmers and the Elliott Company, have built and tested machines either as Government sponsored experiments or as speculations. A G.E. machine, which is derived from aircraft technique, was recently tested and at 3,500 kW gave an efficiency of 17 per cent. with an initial temperature of 1,470° F. The G.E. have several machines in hand including one of 5,000 h.p. for New Hampshire. In a 3,500 kW unit for the Huey Station in Oklahoma the exhaust gas at about 1,000° F. will be used for feed heating. An Elliott machine, employing Lysholm compressors, tested in 1946 gave an efficiency of 27 per cent. at 1,230° F. A Westinghouse 2,000 h.p. set completed in 1946 has run some 1,000 hours at 1,350° F. with an efficiency of 16·7 per cent.

(b) *Locomotives.*

Of the eleven locomotive-type gas turbines already built or being built eight are ordered for installation in actual locomotives and four are built or being built as speculations. All will use D.C. electric drive and all are for oil-firing, except two mentioned later destined to run on coal.

A 2,000 h.p. Brown Boveri gas turbine locomotive commissioned by the Swiss Railways in 1940 showed an efficiency at generator terminals of 17·7 per cent. based on a maximum temperature of 1,100° F. It has now run some hundred thousand kilometres on Swiss and French lines and has shown no serious difficulty with fouling of the compressor or in burning heavy fuel oil. When tested on the French Railways against a diesel locomotive hauling the same 600-ton train, the consumption worked out as three times that of the diesel.

A similar locomotive rated at 2,500 h.p. with an expected efficiency of about 19 per cent. is being supplied by Brown Boveri to the British Railways. Both these Brown Boveri locomotives employ a single shaft unit coupled through gears to the generator, the circuit being as fig. 5 (c), with a cross flow regenerator of less than 50 per cent. efficiency mainly to improve part load performance. A machine of the same rating being built by Metro.-Vick. for the former G.W.R. will employ a single shaft set without regenerator fig. 5 (a).

In the U.S.A. a G.E. Co. 4,500 h.p. unit installed in an ALCO locomotive recently began track tests on the Union Pacific line. The circuit is as fig. 5 (a).

The Elliott Company has two gas turbines in hand for locomotives, one an oil-fired unit of 3,000 h.p. for the Santa Fé railroad, and the other a coal-fired unit of 3,750 h.p. to be fitted in a Baldwin locomotive, as part of a coal-burning experiment sponsored by the Locomotive Development Committee of Bituminous Coal Research Inc. Both will use centrifugal compressors and an initial temperature of about 1,275° F. to obtain an expected efficiency of 24 per cent.

Allis Chalmers have completed a similar coal-fired unit of 3,750 h.p. at 1,300° F. to be fitted in an ALCO locomotive. The coal-firing equipment, combustion chamber and grit arrester are to be provided by the purchaser. Further information on this project is given under coal-firing.

The Northrop-Hendy Company also has in hand a 2,000 h.p. oil-fired unit for the Union Pacific Railway.

Among machines built for experiment should be mentioned the Brown Boveri 'comprex' set demonstrated in 1946. The addition of a 'comprex' raised the output of a 2,500 h.p. machine to 4,000 h.p. and the efficiency to 22·5 per cent. with small additional weight and space. The 'comprex' is a combined compressor and expander device consisting of a rotating wheel in the cells of which expansion and contraction take place by making use of compression waves. The maximum temperature has been raised to 1,400° F. since it is confined to the cell wheel and is only encountered intermittently.

(c) *Marine Units.*

No vessel has yet been built engined solely by a gas turbine. The first vessel to be propelled by a gas turbine was MGB 2009 which was run in trials in 1947, using a 2,500 h.p. gas turbine in place of one of its three 1,200 h.p. petrol engines. The design was derived from the Metro.-Vick. jet propulsion Beryl engine with the addition of a multi-stage low pressure turbine coupled through gears to the centre propeller fig. 5 (b). The efficiency obtained was 13·0 per cent. at full load of 2,550 h.p. and about 9 per cent. at half to two-thirds speed. The weight including gears, etc., was 3·5 tons.

The Elliott Company completed in 1940 an experimental unit for the U.S. Navy designed for installation in a Liberty ship ; this is mentioned above. So far as is known the machine has not yet been put into use.

The B.T.H. Co. have in hand a 1,200 h.p. two shaft machine for installation in the Anglo-Saxon Petroleum Company's tanker *Auris*. This will take the place of one of four Diesel electric sets. The h.p. turbine drives the compressor and rests on the l.p. turbine which drives the alternator. The maximum temperature is to be 1,200° F. and the efficiency expected over 25 per cent. A regenerator will be used, the circuit being as fig. 5 (d).

Other development machines include a 3,500 h.p. set by Pametrada for experiment, and a number of sets by different makers for naval purposes. A difficulty in marine applications of gas turbines is the necessity for astern going. This was avoided in the MGB by relying on the two flank petrol engines, and in both the Elliott machine and the *Auris* by the use of electric drive. The use of a reversible pitch propeller is generally looked to as the way out in case of direct drive.

(d) *Aircraft.*

Britain leads the world in aircraft gas turbines. Practically all first line high-speed fighters now employ jet propulsion engines which are allied to the gas turbines used in land practice. The jet engine produces no net power on the shaft, the whole surplus energy going into accelerating the exhaust gases. In aircraft service an immense premium is attached to saving in weight and cross sectional area, while a short life is acceptable. Efficiency is of importance primarily for reduction of fuel weight. Hence elaborations are at present not generally acceptable since their own weight exceeds that of the fuel saved in short flights. Aircraft machines contain the same items, viz. compressor, combustion chamber and turbine. Compressors may be centrifugal as in the Rolls Royce ' Derwent ' and ' Nene,' or the De Havilland ' Goblin ' or ' Ghost,' or axial as in the Metro.-Vick. ' Beryl ' and several foreign types. The axial machine has a better efficiency and a smaller diameter but is at present heavier. Combustion chambers are of metal and invariably multiple as opposed to the single large unit of land types. The turbine has usually a single row of blades, occasionally a double row. Temperatures are commonly in the region of 1,500 to 1,600° F., and life between 200 and 500 hours. The stressing of components is much higher than in land practice. The weight to power ratio is of the order of 0·31–0·46 lb. per lb. of thrust (1 lb. thrust at 375 m.p.h. = 1 h.p.). While the efficiency of such gas turbines is low, 13 per cent. or less, the efficiency of the jet as a means of propulsion is better than that of a propeller at high speed and improves as the flight speed approaches that of the jet. The maximum thrust obtainable from a single jet unit at 5,000 lb. is higher than in propeller types.

In civil and long range military aircraft there is a case for the gas turbine driving a propeller and providing some thrust from the exhaust. Several such units are available, *e.g.* the Armstrong Siddeley ' Python,' the Napier ' Naiad,' the Rolls Royce ' Dart,' and the Bristol ' Theseus.' Fuel consumption is better than in the jet types but still not so good as in reciprocating types, because intercooling and regeneration have not yet been successfully applied.

Commercial Running Experience.

In spite of the large number of land gas turbines actually completed, there is rather scanty running experience amounting, at most, to a few thousand hours in each of several, mainly small, plants. The number of hours run on test in the manufacturers' works amounts to a considerable total, but this is to be differentiated from normal commercial running. Brown Boveri as the most experienced builders can quote some 112,000 miles service running of the locomotive, and a total running into millions of hours with Houdry sets and Velox boiler auxiliaries together, but these operate mostly at lower temperatures than they are rated for. Similarly the locomotive runs much of its time at lower than the full temperature. The only higher temperature machines which have been run on site, are the Neuchatel set and Beznau No. 1, both of which have a total of 400 running hours and about 2,000 respectively.

Fuels.

All gas turbines to date consume oil or cleaned gas (see, however, coal-burning section). The use of gas if not already under pressure entails a separate compressor commonly centrifugal for the sake of regulability. Open cycle machines to date have generally been run on rather light oil, usually a blend of gas oil and heavier residual oil. Gas oil is a distillate and contains no ash. Heavy oils may contain ash to the extent of say 0·25 per cent. The ash may contain certain slag-forming substances which stick to the turbine blades in some designs, while with other designs no trouble has been experienced when using the same oil. The controlling variables have not yet been isolated ; it is possible that the design of the combustion chamber or of the blades may be significant, but pending further investigation several makers are prepared to use only distillate oil.

The closed cycle and the semi-closed expect to be able to use heavy oil, as the conditions are not substantially different from those in marine boilers. The slag is expected to be intercepted within the air heater so that it will not reach the following turbine. The surfaces within the closed circuit of course remain clean.

The price of oil in the United Kingdom varies somewhat with grade and with locality and quantity rebates. Average price are about £7 7*s.* 6*d.* per ton for heavy fuel and £9 10*s.* for gas oil. The price for ships bunkering at United Kingdom ports is £6 4*s.* 6*d.* per ton for heavy oil and £7 15*s.* for diesel oil. The higher calorific value may be taken as about 18,500 B.Th.U./lb., hence the inland price of oil is roughly 60 per cent. above that of coal on a heating basis. A similar ratio applies in parts of the U.S.A. (Price as at March 1949.)

Coal-burning Gas Turbines.

The burning of coal in a gas turbine can be tackled in at least four ways :—

(1) directly in an open circuit turbine as pulverised coal ;

(2) indirectly by gasifying in a producer with subsequent detarring and cooling of the gas ;

(3) indirectly by gasifying in a pressurised producer inserted between the compressor an combustion chamber ;

(4) in a closed-circuit gas turbine by any of the above methods.

Methods 1 and 3 were tried out in a small way by Brown Boveri some years ago and serious difficulties were encountered. Method 1 has been the subject of a very determined and costly full scale research over the last four years sponsored by the Locomotive Development Committee of Bituminous Coal Research Inc., but according to the latest reports no satisfactory means has yet been evolved of removing the ash particles before they enter the turbine. The notion that the ash would pass through the turbine without harm if sufficiently finely ground appears to be unfounded. Method 2 presents no obvious technical difficulties but is wasteful thermally because of the heat lost from the producer and as sensible heat in the gas. It also involves rather costly equipment. Method 3 was to be tried out in Germany but work on the project ceased with the end of the war, though one high pressure producer was built. It appears promising if a tar-free fuel can be used. The whole of the sensible heat would be retained in the cycle and the capital cost reduced by pressurising. Method 4 has not yet been tried but seems to offer fewer unfamiliar problems than some of the other alternatives.

Possibilities of Higher Temperatures.

Both the plain cycle and its variants show a marked improvement in efficiency and in specific output when the temperature at entry to the turbine is raised. Hence designers strive to employ the highest temperature allowable. The permissible temperature is limited mainly by the strength of the material of the first row of moving blades as determined by acceptable creep rate, erosion, or embrittlement, all of which are functions of operating time.

The maximum temperature for continuous operation has been put at 1,150° to 1,300° F. (both well in the red region), depending on the material and the opinion of the designer. For short life operation as in jet propelled aircraft, where the period of service can be restricted to say 300 hours, and more expensive material may be employed, very much higher temperatures, *e.g.* 1500° F. or above, may be tolerable.

The initial temperature permissible depends to some extent on the type of turbine. Most of the commercial sets so far installed are of the reaction type in which the gas enters the moving blades at practically its full initial temperature. In impulse turbines the temperature and pressure are first dropped in a set of stationary nozzles which, not being highly stressed, can withstand a higher temperature. The proposal has been made to employ 1,500° F. and to drop the temperature to a much lower value before entering the first wheel. However, the efficiency of a wheel utilising such a large drop tends to be low and it is not clear whether there will be any net advantage in the high temperature when used in this way.

Methods of Regulation.

Nearly all sets employ axial compressors and since these do not lend themselves to efficient regulation of the quantity of air delivered, except by varying the speed, all constant speed sets in which the compressor and turbine are coupled direct to the drive suffer from the disability that the quantity of air aspirated remains constant and the compressor work therefore changes very little with load. In the simple cycle the only practical means of varying the power delivered at constant speed is to vary the rate of fuel supply and thus change the initial temperature. The maximum efficiency is accordingly reached at full load when the temperature is the highest, while the efficiency falls off rapidly at lower loads. This does not apply to variable speed applications where low speed is associated with low load, *e.g.* in ship propulsion or to the drive of D.C. machines, nor does it apply in such marked degree to the more complicated cycles. If the compressor is dissociated from the constant speed drive, *e.g.* by coupling to a separate turbine on a free shaft, the load can be regulated mainly by varying the air quantity which results in a much better part load efficiency. In the latest Brown Boveri sets as shown in fig. 5 (g), the generator is coupled to the h.p. shaft. This allows the load to be varied by altering the speed of the l.p. shaft. In the Escher Wyss sets load is apparently varied by an altogether different method, but fundamentally the fuel rate remains the means of control. For rapidly throwing off load in the more complicated cycles the gases are by-passed round the turbines.

Starting.

Gas turbines are not self-starting; it is necessary to drive the compressor by external power in order to deliver sufficient air for lighting up the burners, after which the turbine begins to produce sufficient torque to bring the set up to full speed. The starting time in certain open circuit designs is between 5 and 10 minutes, but a much longer time may be required in other machines.

Gas Turbines as Auxiliary Machines.

The gas turbine and compressor find application in connection with certain chemical or combustion processes carried out under pressure. The compressor provides the combustion air required for the process and the turbine recuperates the energy in the products of combustion, furnishing the power to drive the compressor and sometimes additional external power. A step on the way to the emergence of the gas turbine as a prime mover was its successful use since 1936

in connection with the Houdry oil-cracking process. Some 33 sets have been built for this purpose by Brown Boveri and their licensees in the U.S.A. These are started on oil and were tested on oil in the works using temperatures of the order of 1,050° F., but in service surplus power is not the main consideration, and they are operated at lower temperatures, the fuel being carbon which is to be burnt off the catalyst.

A further application of gas turbines is in connection with the provision of wind for blast furnaces. In this case, instead of external power being generated, the excess energy is absorbed in providing compressed air for the furnaces, the compressor being tapped at a suitable point. Blast furnace gas is used as fuel. Two sets, each equivalent to 3,000 kW nett output, were supplied to the Hermann Goering Steelworks just before the war. One of them has now been brought to England. Two further sets for metallurgical works, one for Baracaldo in Spain, and the other for Luxembourg, are being built by Brown Boveri.

Future Prospects.

The difficulty in generalising on gas turbines is the wide variety of types available, each with its own characteristics and associated merits and defects. For instance, the efficiency may vary between 13 per cent. and 35 per cent. while the specific weight may range over a wider ratio. The present wide interest taken in the gas turbine is to a large extent the result of the publication of details of the intensive work carried out during and since the war on the development of aircraft types. The prospects of future development for commercial purposes and for the generation of electrical power should, however, be viewed with caution since it is likely to be found that good efficiencies are obtainable only in high quality, expensive and bulky plant and entail a very accurate knowledge of individual component characteristics. This combined with a knowledge of costs of production will tend to restrict future applications to those duties for which the gas turbine is well suited. These include aircraft use, metallurgical, peak load generation and possibly base load where oil is the only fuel and water is scarce (though this restricts the efficiency obtainable). There are also special cases where the high temperature by-product heat in the exhaust or the coolers makes the gas turbine attractive.

Whether the gas turbine can outclass the diesel in locomotives or operate successfully without electric drive remains undecided. Similarly, marine applications are waiting on land experience though navies are experimenting with sets up to 7,500 h.p. The prospect of the gas turbine competing with steam for base load power stations in industrial countries seems remote in view of the high price of oil, while even if the gas turbine could succeed in burning coal it is not certain that it would offer decisive all-round advantages. The present position must accordingly be regarded as still largely experimental.

SECTION XXIX

PART I

NAVAL ARCHITECTURE

(Revised by Norman L. Gemmell)

DIMENSIONS OF SHIPS.

Moulded Dimensions.

LENGTH L = 'Length between Perpendiculars' = Length on load water-line measured from the fore side of the stem ('F.P.,' or 'Fore Perpendicular') to the aft side of the stern post ('A.P.,' or 'After Perpendicular'), or fore side of rudder stock if there is no stern post.

BREADTH B = 'Moulded Breadth' = Breadth measured over the widest part of the frame at the middle of the length L.

DEPTH D = 'Moulded Depth' = Depth measured from top of keel to top of deck beam at side at the middle of the length L. To avoid error the name of the deck to which the depth is measured should be stated.

Registered Dimensions.

LENGTH = Length from fore part of stem head to aft side of stern post, or fore side of rudder stock if there is no stern post.

BREADTH = Breadth measured over the outside of the shell plating at the widest part.

DEPTH = 'Depth of Hold' = Depth measured from top of ceiling to top of deck beam at the centre line of the vessel at the middle of the length. This depth is measured to the 'tonnage deck,' which is the 'second deck from below.'

Overall Dimensions.

LENGTH = 'Length Overall' = Length measured from the foremost point of the stem or figure-head (but excluding bowsprit if any) to the aft side of the taffrail, or cruiser stern.

BREADTH = 'Breadth Extreme' measured over the outside of the shall plating or belting or paddle sponsons, if any.

DEPTH = Depth from underside of keel to top of deck amidships.

Drafts of a Ship.

The DRAFT d of a ship is the distance of the lowest point of the keel (or of the line of the keel produced) below the water line.

The MEAN DRAFT is half the sum of the drafts at the forward and after perpendiculars or at the stem and the stern post.

The MOULDED DRAFT δ is the distance of the top of the keel (or of the line of the top of keel produced) below the water line.

The LIGHT DRAFTS of a vessel are the drafts forward and aft when the vessel is floating complete, with water in boilers, condensers and/or water in engine cooling systems, but without crew, fuel, cargo, stores, water, or other loads.

The LOAD DRAFT of a vessel is the mean draft of the vessel when floating complete and ready for sea and with all fuel, cargo, passengers, crew, baggage, stores, spares, water, and other loads. The maximum load draft is determined by the freeboard tables of the Board of Trade; for passenger vessels the actual draft is limited to that determined by the spacing of the water-tight bulkheads, in accordance with the recommendations of the Convention for the Safety of Life at Sea. This draft is called 'The Bulkhead Draft.'

The FREEBOARD of a cargo vessel is the height of the top of the steel deck at side at the middle of the length above the water line. In a passenger vessel the freeboard is measured from a point three inches below the upper surface of the deck at side, at the middle of the water-line length, to the water line. The minimum freeboard allowable for any vessel entering or leaving a British port is fixed by law. It is assigned for each vessel by the Board of Trade or Classification Society, and must be marked upon each side of the vessel amidships by the 'Freeboard Disc' or 'Plimsoll Mark.'

The 'TRIM' or 'LEAD' of a vessel is the difference between the drafts forward and aft. It is said to be 'by the head' or 'by the stern' according as the draft forward or the draft aft is the greater. When the drafts forward and aft are equal, the vessel is said to be 'on even keel.' 'Change of Trim' is the arithmetical sum of the changes of draft forward and aft produced by the shifting of any weight.

Displacement.

The DISPLACEMENT of a vessel is the amount of water displaced by the underwater portions of her hull. It may be stated either by volume or by weight. The weight of the water displaced by a floating vessel is equal to the total weight of the vessel and her contents. If the vessel be floating in salt water, her displacement in tons Δ is equal to $\frac{1}{35}$ of her volume of displacement, V, in cubic feet. If in fresh water, $\Delta = \frac{V}{35 \cdot 9}$.

The TONS PER INCH of a vessel at any draft is the number of tons weight which must be placed on board in order to increase the mean draft one inch.

$$\text{Tons per inch, in salt water} = \frac{\text{area of water plane}}{420} = \frac{A}{420},$$

$$\text{Tons per inch, in fresh water} = \frac{A}{430 \cdot 8}.$$

where A is the area of the water plane in square feet.

Coefficients of Displacement.

The BLOCK COEFFICIENT, or *Coefficient of Fineness*, C_b, is the ratio of the immersed volume of displacement to the volume of the circumscribing parallelepipedon.

$$\text{Block coefficient} = C_b = \frac{V}{L\,B\,\delta} = \frac{35\,\Delta}{L\,B\,\delta} \text{ in salt water} = \frac{35 \cdot 9\,\Delta}{L\,B\,\delta} \text{ in fresh water,}$$

where V = Immersed volume of displacement in cubic feet,
Δ = Displacement in tons,
L = Length on load water-line, in feet,
B = Moulded breadth in feet,
δ = Moulded draft in feet.

Builders of cargo vessels usually estimate block coefficient with reference to length B.P., breadth over shell plating, and draft including flat plate keel.

The PRISMATIC COEFFICIENT, C_p, is the ratio of the immersed volume of displacement to the volume of the circumscribing cylinder having the same form of cross-section as the vessel below the water-line amidships.

$$\text{Prismatic coefficient} = C_p = \frac{V}{La} = \frac{35\,\Delta \text{ or } 35 \cdot 9\,\Delta}{La},$$

where a is the immersed area of the midship section to outside of frame in square feet.

The MIDSHIP SECTION COEFFICIENT, C_m, is the ratio of the area of the midship section up to the water-line to the area of the circumscribing rectangle.

$$\left.\begin{array}{r}\text{Midship section coefficient}\\ \text{or midship area coefficient}\end{array}\right\} = C_m = \frac{a}{B\,\delta}.$$

From the above values for the three coefficients it is easily seen that

$$C_p \times C_m = C_b.$$

Mr. W. H. Riddlesworth, M.Sc., gives the following approximate formulas connecting draft, displacement, and block coefficient:—

Let α **= water plane area coefficient =** $\frac{A}{LB}$

β **= block coefficient.**
δ **= moulded draft.**
Δ **= displacement in tons.**

Then, approximately,

(1) The water plane area coefficient is equal to one-third plus two-thirds of the block coefficient,
i.e. $$\alpha = \tfrac{1}{3} + \tfrac{2}{3}\beta$$

(2) The change (c) in block coefficient per foot change in draft is equal to the complement of the block coefficient divided by three times the draft,

i.e. $$c = \frac{1-\beta}{3\delta}.$$

(3) The complement of the block coefficient varies inversely as the cube root of the draft,
i.e. $$1-\beta = \text{constant} \div \sqrt[3]{\delta},$$

the constant being determined for each ship from any one known draft δ_0 and the corresponding block coefficient β_0; constant = $\sqrt[3]{\delta_0}\,(1-\beta_0)$.

The above three relations have been found to be both useful and reliable in practical work.

Curves of Displacement, etc.

As the draft of a vessel changes, the displacement, area of water plane, coefficients, etc., also vary, and it is customary to record these changes by means of curves whose vertical abscissæ represent draft, while the horizontal ordinates represent areas, displacements, coefficients, etc.

The ordinate of the curve of displacement at any draft is proportional to the area of the curve of water plane areas up to that draft.

Centre of Buoyancy.

The CENTRE OF BUOYANCY, B, at any draft, is the centre of gravity of the volume of displacement at that draft. The vertical position of the centre of buoyancy is the same as that of the centre of gravity of the curve of water plane areas, and its longitudinal position is the same as that of the centre of gravity of the prismatic curve. (See next page.)

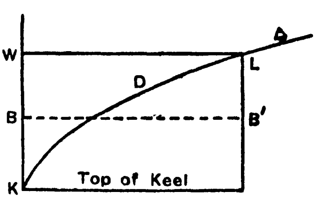

FIG. 1.

To find the height, K B, of the centre of buoyancy above the top of keel, draw the line BB′, across the displacement curve so that the area of the rectangle WB′ is equal to the area W L D K above the displacement curve.

MORRISH'S RULE.

Very approximately $KB = \frac{5}{6}\delta - \frac{V}{3A}$;

where K B = height of centre of buoyancy above top of keel, in feet
δ = moulded draft, in feet;
V = displacement, in cubic feet;
A = area of the water plane, in square feet.

$\frac{V}{A}$ is called 'Rankine's Mean Draft.'

$\frac{KB}{\delta}$ **varies from 0·53 in full form ships to 0·57 in fine forms.**

Wetted Surface.

The WETTED SURFACE or IMMERSED SURFACE of a vessel is the total area of the surface of the shell plating, keel, bilge keels and rudder in contact with the water in which the vessel is afloat.

Approximately,

$$\left.\begin{array}{ll} S = L(1{\cdot}7\,\delta + C_b B) & \text{(Mumford)} \\ S = L(1{\cdot}5\,\delta + 1{\cdot}075\,C_b B) & \text{(Gemmell)} \\ S = 3{\cdot}4\,V^{\frac{2}{3}} + 0{\cdot}5\,LV^{\frac{1}{3}} & \text{(Froude)} \\ S = 15{\cdot}4\sqrt{L\Delta} & \text{(Taylor)} \end{array}\right\} + \text{surfaces of keel, bilge keels, and rudder.}$$

where L = length between perpendiculars, in feet;
δ = moulded draft, in feet;
C_b = block coefficient;
B = moulded breadth, in feet;
Δ = displacement, in tons; V = displacement in cubic feet
S = wetted surface, in square feet.

The second of the foregoing formulæ should be used for vessels of large $\frac{B}{\delta}$ values.

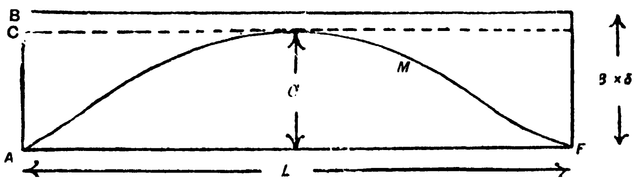

FIG. 2.

The PRISMATIC CURVE or CURVE OF AREAS for any draft is a curve whose horizontal base represents to scale the length of the vessel on load water-line, and whose ordinate at any point is proportional to the immersed area of the corresponding transverse section of the vessel. This curve shows the longitudinal distribution of the displacement, which has an important bearing upon the resistance.

Let A M F (fig. 2) be a prismatic curve, inscribed within a rectangle C F of height representing the area of the midship section, and surrounded by another rectangle B F of height representing the area of the rectangle circumscribing the midship section. Then

Area of prismatic curve is proportional to displacement.

$$\frac{\text{Area of prismatic curve}}{\text{Area of rectangle C F}} = \frac{V}{L \times a} = \text{Prismatic coefficient.}$$

$$\frac{\text{Area of prismatic curve}}{\text{Area of rectangle B F}} = \frac{V}{L \times B \times \delta} = \text{Block coefficient.}$$

$$\frac{\text{Height of rectangle C F}}{\text{Height of rectangle B F}} = \frac{a}{B \times \delta} = \text{Midship section coefficient.}$$

Centre of Flotation.

The CENTRE OF FLOTATION is the centre of gravity of the water plane. The two waterlines defining any small change of trim or heel intersect at the centre of flotation.

Transverse Metacentre.

If a vessel be slightly inclined to one side the centre of buoyancy, B, will move slightly from the middle line towards that side, say to B′, and the vertical line through B′ representing the upward pressure of the water will cut the inclined middle line at the point M called the 'Transverse metacentre.'

$$BM = \frac{I}{V}$$

where,

BM is the height of the transverse metacentre above the centre of buoyancy,
I is the transverse moment of inertia of the water-plane about its middle line,
and V is the volume of displacement.

BM is approximately equal to ·075 to ·085 × breadth^2 ÷ draft, at load draft.

The METACENTRIC HEIGHT, GM or m, in any condition of loading is the vertical distance between the transverse metacentre, M, and the centre of gravity, G, of the whole vessel and her contents. If, in the upright condition, G lies above M the vessel is unstable and will not remain

upright; if G lies below M, the vessel is stable and will return to the upright position if slightly inclined and set free. GM is a measure of the vessel's 'Initial Stability.'

The value of GM can be obtained either by separate calculation of the heights of G and M or by an inclining experiment.

Inclining Experiment.

In carrying out an 'Inclining Experiment' on a vessel, to determine the height, KG, of the centre of gravity, the following procedure should be observed :—

Have the vessel free from wind, tide, current, transverse mooring ropes, gangways, and particularly from loose water or other weights liable to move when the vessel is inclined. Have no men on board except those engaged on the experiment. Read the drafts carefully at each end from a small boat. Move any known weight w (enough to produce an inclination of about 2°) transversely across the deck through a total distance, a, and observe the corresponding deflection d, of a simple pendulum of length l, suspended anywhere on board. Several shifts of the weights are usually made to each side of the ship and the mean value of d taken. From the draft readings and the curves of displacement and transverse metacentres we can obtain the value of Δ, and of KM.

Then GM as inclined $= \frac{w\,a\,l}{\Delta\,d}$, w and Δ being in tons, GM and a in feet, and l and d in inches

and KG as inclined = KM − GM.

These results apply only to the vessel in the inclining condition. To obtain the metacentric height for any other condition it is necessary to make suitable corrections for the different amounts and positions of the various items of loading and for the new values of Δ and KM.

It is usual to estimate the value of GM for the following conditions :—

Light Condition.—Ship and machinery complete, boilers and condensers and/or engine cooling systems full, but no fuel, cargo, passengers, crew, baggage, stores, spares, fresh or salt water, or reserve feed-water on board.

Docking Condition.

Load Conditions.—Fully loaded condition; ship and machinery complete, boilers and condensers and/or engine cooling systems full, and with all fuel, passengers, crew, baggage, stores, spares, fresh and salt water, reserve feed-water, and holds filled with homogeneous cargo of such density as to bring the vessel to her load draft.

Spent Condition.—Same as full load condition, but with all fuel, water, and stores consumed.

Ballasted Condition.—Same as spent condition, but with water-ballast tanks filled.

Any other special conditions likely to arise in practice.

Rolling Period of a Vessel.

In Smooth Water.

K = Radius of gyration of the vessel and all weights on board, about a longitudinal axis passing through her centre of gravity.

m = Metacentric height;

2 T = Time of double roll, say from port to starboard and back again, in seconds;

g = Force of gravity = 32·2.

then

$$T = \pi\sqrt{\frac{K^2}{g\,m}} = \cdot554\,\frac{K}{\sqrt{m}},$$ neglecting water and air resistances.

The period 2T of a double roll varies from about 3 to 30 seconds; in large Atlantic liners it is about 20 seconds.

Stability.

The INITIAL STABILITY of a vessel is the measure of the tendency of the vessel to return to the upright if she is forcibly inclined to a small angle, θ, of not more than about 10°.

Initial Stability or Righting Moment at the inclination $\theta = RM_\theta = \Delta\, m\, \theta$ foot-tons;

where,

Δ = displacement in tons;

m = metacentric height in feet;

θ = angle of heel in circular measure
= inclination in degrees ÷ 57·3.

CURVE OF STABILITY.—When a vessel is inclined to any angle θ (fig. 3), the centre of buoyancy moves to one side (B to B′). The upward force of buoyancy, Δ, now acts through B′, while the weight acts downwards through G, the centre of gravity. These two forces form the righting couple, whose arm is GZ (the righting arm) and whose moment is W.GZ

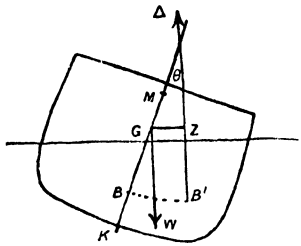

FIG. 3.

(the righting moment). When θ is small, B′Z passes through M, as already stated, and $GZ = m\,\theta$; at larger angles GZ must be separately calculated, and it is customary to obtain its value at each 10° of inclination and to connect the series of righting arms by a curve which is called the curve of stability (fig. 4).

OR is called the 'Range of Stability,' H the 'Maximum Righting Arm' occurring at some

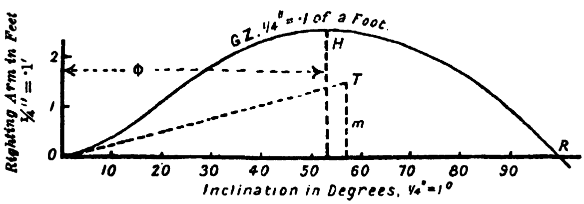

FIG. 4.

angle ϕ, while the initial slope of the curve is measured by the metacentric height, m, set up at 57·3° ($\theta = 1$), as shown in the figure, where OT is tangent to the curve at the origin O. (The scales marked are those to which the curves are usually drawn, but of course do not apply to the reduced figure.) The area of the curve of stability up to any angle is proportional to the work which must be done (by wind or other external forces) in order to incline the vessel to that angle. The work so done is called 'Dynamical Stability.'

Longitudinal Metacentre.

If a vessel be slightly inclined about a transverse horizontal axis, the centre of buoyancy will move longitudinally, and the point in which the vertical line through the new centre of buoyancy cuts that through the centre of buoyancy corresponding to even keel is called the 'longitudinal metacentre.'

The height of the longitudinal metacentre above the centre of buoyancy = LBM = $\frac{I}{V}$, where I is the moment of inertia of the waterplane about a transverse axis through its centre of gravity, and V is the volume of displacement.

The LONGITUDINAL METACENTRIC HEIGHT, LGM, is the height of the longitudinal metacentre above the centre of gravity = LBM − BG = M.

The longitudinal GM is used in calculating changes of trim. If any weight, w, be moved longitudinally through a distance, a, the 'moment to change trim' is wa.

The 'moment to change trim one inch' or 'inch trim moment' = ″M = $\frac{\Delta M}{12L} \doteqdot^{*} \frac{I}{420L}$

* $\doteqdot$ is the symbol for 'approximately equal.'

Approximately, $''M = \frac{30\,t^2}{B}$

where, $''M$ = inch trim moment, in foot tons.
Δ = displacement, in tons.
L = length between draft marks, in feet.
t = tons per inch.
B = moulded breadth, in feet.
I = longitudinal moment of inertia of water plane.

The *change of trim* in inches due to any moment $w\,a$ is $\frac{w\,a}{''M}$. Of this total change of trim half is usually added to the draft at the end towards which the weight w was moved, and half deducted from the draft at the other end.

If instead of merely moving a weight already on board, we desire to find the alteration of drafts due to placing a new weight on board, first imagine the weight to be placed at the centre of flotation F. This will increase the drafts both forward and aft equally by an amount $\frac{w}{t}$. Then imagine the weight moved longitudinally to its assigned position and calculate the change of trim. Then combine these changes of drafts with the additional immersions $\frac{w}{t}$ and so find the total changes of draft forward and aft.

Curves connecting the mean draft with the position of the centre of flotation, the tons per inch, and the inch trim moment should be prepared to facilitate such calculations.

For large additions of weight the above method is not accurate, and it is necessary to prepare a complete list of all the items making up the displacement, together with their moments forward or aft of midships. Then

$$\frac{\text{Total moment}}{\text{Total weight}} = G\otimes \text{ or } \otimes G = \text{distance of centre of gravity aft or forward of midships.}$$

From a curve connecting draft with the distance of the centre of buoyancy for even keel from midships, we can find the value of $B\otimes$ or $\otimes B$, and hence the value of GB or BG, that is the longitudinal distance of the centre of gravity aft of or forward of the centre of buoyancy. The moment to change trim is then $\Delta \times GB$, and the change of trim $\frac{\Delta . GB}{''M}$.

Weights.

The total weight or displacement of a merchant vessel may be subdivided as follows :—

DISPLACEMENT
- Light Weight
  - Hull
    - Steel
    - Wood and fittings
  - Machinery
    - Engines
    - Boilers
- Deadweight

The *Weight of Steel* includes :—

Steel and iron plates and bars of all kinds.
Structural forgings and castings, whether of steel or of bronze.
Pillars.
Steel masts.

The *Weight of Wood and Fittings* includes :—

Carpenter work.
Joiner work.
Plumber work.
Wood masts and spars.
Upholstery.
Boats.
Smithwork.
Deck machinery and piping.
Electric lighting installation.
Refrigerating machinery.
Heating installation.
Ventilation.
Galley outfit.
Paint.
Cement.
Insulation.
Rigging and sails.
Canvas covers and awnings.
Sheet iron work.
Fixed ballast.
Deck Coverings. Etc.

The *Weight of Engines* includes :—

Main propelling engines.
Shafting and propellers.
Condensers and circulating pumps.
Air-pumps and bilge-pumps.
electric generators.
Sanitary and fresh-water pumps.
Floors, ladders, and gratings in engine spaces.
Feed water.
Oil in forced lubrication system and drain tank.
Piping in engine-room and tunnel.
Water in condensers and piping.
Tools, etc.
Blowers, silencers.
Air bottles.
Water in engine cooling systems.

The *Weight of Boilers* includes :—

Main boilers and donkey boiler.
Uptakes and funnels.
Fans and fan engines.
Piping in boiler rooms.
Feed-pumps.
Fuel pumps.
Hot water in boilers.
Floor-plates, ladders, and gratings in boiler-rooms.
Tools.
Etc.

Deadweight includes :—

Spare gear.
Crew and effects.
Passengers and baggage.
Coal in bunkers and on firebars.
Fresh water for ship's use.
Salt water for ship's use.
Reserve feed water.
Water ballast.
Bilge water.
Cooling water.
Mails and cargo.
Oil fuel in tanks and pipes.
Stores and provisions.
Bedding and napery.
Cutlery and crockery.
Glass and silverware.
Weights added by the owner.
Etc.

Hull weight may be estimated either in detail or as a whole. Detail calculation requires that complete plans of the vessel are available, together with reference lists giving weight-rates or actual weights of all varieties of fittings. An accurate record of the finished total weights of the various items of the outfit of previous completed vessels is of great value in this connection.

For preliminary work, where a rapid estimate of the weights is required, the method of coefficients is largely relied on. In this method the whole weight of the hull, or of certain sectional portions thereof, is compared with some arbitrary parameter or parameters of simple form, depending upon the principal dimensions of the vessel or of her sectional parts. For each vessel completed an accurate record of these weights is filed, and the values of the 'Coefficients of Weight' $\left(=\frac{\text{weight}}{\text{parameter}}\right)$ worked out. Then for any proposed new vessel the weight of the hull, or of any of its parts, is found approximately by multiplying the proper parameter by a suitable coefficient chosen from among those of similar finished vessels.

The most commonly used parameter is the *Cubic Number*, which is the product of the Length, Breadth, and Depth, divided by 100.

Cubic number $= N = L\,B\,D \div 100.$

where L = Length between perpendiculars, in feet,

B = Breadth moulded, in feet,

D = Depth moulded, in feet, taken to the highest deck to which the shell plating extends continuously or almost continuously throughout the whole length of the vessel;

then,

$$\text{Weight of Hull, } H = N \times \text{Coefficient of Weight of Hull}$$
$$= N \times C_h$$

Similarly,

$$\text{Weight of Steel, } S = N \times C_s$$

$$\text{Weight of Wood and Fittings, } W = N \times C_w.$$

The weights of deck machinery, refrigerating machinery, insulation, etc., may either be included in the wood and fittings coefficient or separately estimated.

The following table gives average values of these coefficients :—

Type of Vessel.	C_s	C_w.	C_h.
Torpedo Boat Destroyer	·24	·10	·34
Cruiser	·27	·10	·37
Battleship	·33	·12	·45
River Paddle Steamer	·19	·12	·31
Channel Steamer	·20	·16	·43
Coasting Steamer	·32	·20	·52
Cargo Tramp	·35	·10	·45
Intermediate Liner	·42	·17	·59
Fast Mail Liner	·38	·19	·57
Oil Tanker	·38	·09	·47

Other parameters sometimes used for estimating the weight of wood and fittings are

$$(L \times B) \text{ and } L\,(B + D)$$

Weight of Machinery.

In making preliminary estimates, the weight of machinery can be taken as proportional to the horse-power, the number of horse-power per ton of total machinery weight being recorded for all vessels completed and tried. A more accurate method is to record separately the weight of engines and the weight of boilers per horse-power, and to employ these rates when estimating the weights of proposed machinery of similar type. The weight of reciprocating engines may be taken as proportional to the product of the square of the diameter and the square root of the stroke of the high-pressure cylinder. For cylindrical boilers a suitable weight parameter is the product of boiler volume and square root of working pressure. For the greatest accuracy the weights of both engines and boilers must be made up in detail from the drawings and the detailed weight records of previous jobs. The machinery weight for Diesel-engined vessels varies considerably according to the type of engines installed. Generally the weight of the engine(s) proposed can be obtained from the makers. The complete weight of an installation of Diesel machinery is about $1\frac{1}{4}$ to $1\frac{1}{2}$ times the weight of the main propelling Diesel motors.

Deadweight.

The total deadweight may either be specified by the owner or must be made up in detail from the particulars of the service to be performed.

Spare Gear.—Make up the weight in detail from the specified list of spares or allow a total approximate amount by reference to the actual weights carried by similar steamers. The amount may vary from about two tons in river paddle steamers and fast Channel steamers to about 120 tons in an Atlantic liner.

Crew and Effects.—Allow about one ton per ten men.

Passengers.—Allow one ton for every fifteen persons in ordinary cases and for every twenty persons in excursion crowds including women and children.

Baggage.—For the hand baggage of excursion passengers allow about one ton for every 250 persons. For long voyages allow about three tons for every ten persons.

Fuel in Bunkers = horse-power at sea, including that of auxiliaries × pounds of fuel consumed per horse-power per hour ÷ 2240 × distance between fuelling stations farthest apart ÷ service speed, + fuel for galleys etc. + allowance for use in port + a margin of 10 to 20 per cent. for emergencies.

Coal on Bars.—Allow about 35 lbs. per square foot of grate area.

Fresh Water.—Allow about 3 tons per day for every 10 cabin or tourist passengers and about one ton per day for every 10 third-class or steerage passengers and crew.

Salt Water.—For sanitary purposes a tank containing from ½ ton to 5 tons according to the extent of the sanitary accommodation.

Reserve Feed Water.—Allow about 4 tons per 1,000 H.P. per 24 hours for short voyages and about half as much in vessels where distilling apparatus is carried.

Provisions.—Allow about one ton per day for every 75 cabin and tourist passengers and about one ton per day for every 250 third-class or steerage passengers and crew.

Water Ballast.—As may be required for purposes of immersion, stability or trim during the voyage. Say one-half of weight of consumables.

Bilge Water.—Is more or less inevitable, but should not amount to much if proper care in pumping is continually taken. Allow about one-fifth of the vessel's 'tons per inch.'

Mails, cargo, and stores.—As required by owners.

Bedding and napery, *Cutlery and crockery*, *Glass and silverware* } Together about one ton for every 15 persons on board.

Resistance of Ships.

The total resistance to the ahead motion of a ship is made up of four parts :—

1. 'Skin-friction resistance,' or 'skin resistance.'
2. 'Wave-making resistance,' or 'wave resistance.'
3. 'Eddy-making resistance,' or 'eddy resistance.'
4. Air resistance.

2 and 3 are usually considered together under the name 'residuary resistance,' or 'wave resistance' merely, since eddy resistance should be very small. An allowance of 10 to 15 per cent. is usually added to the resistance of the 'naked' hull to account for the resistances of bossings, bilge-keels, rudder and other appendages, and air resistance.

HORSE-POWER.

The horse-power required to overcome any of these resistances is proportional to the resistance multiplied by the speed, and is called the 'effective horse-power.' It is from about ·45 to ·65 of the corresponding indicated or shaft horse-power developed within the vessel, the remainder of the power developed being absorbed by engine and shaft friction and losses in the propeller. The ratio of effective horse-power to indicated or shaft horse-power is called the 'propulsive efficiency,' or 'propulsive coefficient.'

$$e = \frac{\text{E.H.P.}}{\text{I.H.P.}} \text{ or } \frac{\text{E.H.P.}}{\text{S.H.P.}}$$
$$= \text{from ·45 to ·60.}$$

Skin Effective Horse-Power.

Skin E.H.P. is directly calculable :—

$$\text{Skin E.H.P.} = \text{E}_s = \frac{\text{S}}{100} \times \text{F}_{10} \times \left(\frac{\text{K}}{10}\right)^{2·83}.$$

where,

S = wetted surface in square feet.
F_{10} = Skin E.H.P. per 100 square feet at 10 knots.
K = speed in knots.

The following table gives the values of F_{10} and of $\left(\frac{\text{K}}{10}\right)^{2·83}$ for various lengths and speeds :—

L.	F_{10}.	L.	F_{10}.	K.	$\left(\frac{\text{K}}{10}\right)^{2·83}$	K.	$\left(\frac{\text{K}}{10}\right)^{2·83}$
50	1·999	450	1·832	10	1·00	18	5·28
100	1·918	500	1·826	11	1·31	19	6·15
150	1·888	600	1·816	12	1·68	20	7·11
200	1·873	700	1·807	13	2·10	25	13·37
250	1·863	800	1·798	14	2·59	30	22·40
300	1·854	900	1·790	15	3·15	35	34·65
350	1·846	1000	1·782	16	3·78	40	50·56
400	1·839			17	4·49		

From these figures curves may be drawn upon squared paper from which intermediate readings can be obtained.

Wave Effective Horse-Power.

The wave effective horse-power is not directly calculable, although several empirical formulæ and curves of coefficients have been published.

Taylor gives :—

$$\text{Wave E.H.P.} = \text{E}_w = \text{B}_e \frac{\Delta^{\frac{2}{3}}}{\text{L}} \times ·0030707\ \text{K}^5$$

Where B_e = from ·35 to ·55, according to the degree of fullness of the vessel and her ratio of length to breadth.

The most accurate method of estimating E_w is by using the results of model experiments or of actually tried vessels, and Froude's 'Law of Comparison.' The Law of Comparison may be stated thus :—If two vessels of exactly similar form, but of different size, are run at speeds proportional to the square roots of their lengths, then their wave effective horse-powers will be proportional to the products of their displacements by their speeds. If, then, we are designing a vessel n times as long as a model or similar smaller ship whose speeds and corresponding wave E.H.Ps. we know, the following ratios which various elements of the design bear to corresponding elements of the prototype may be used :—

Linear dimensions	n	Speeds	$\sqrt{n}$
Surfaces	n^2	Wave resistances	n^3
Displacements	n^3	Wave E.H.Ps.	$n^3\sqrt{n} = n^{3·5}$

Speeds related as above are called 'Corresponding Speeds,' and the ratio $\frac{\text{K}}{\sqrt{\text{L}}}$ of speed to square-root of length is called the 'Speed-Length Ratio.'

Model experiments give us the total E.H.P. at any speed. From this the wave E.H.P. can be obtained by separately calculating the skin E.H.P., as above described, and deducting it from the total. The wave E.H.P. for the full-size ship will be $n^{3\frac{1}{2}}$ times that of the model, and the skin E.H.P. for the full-size ship can be separately calculated. The sum of these two results gives the

total E.H.P. for the full-size ship. It is then finally necessary to assume a suitable value for e, the propulsive coefficient, and calculate the I.H.P. or S.H.P. by dividing the total E.H.P. by e. If we are designing from the trial results of a similar completed vessel, the procedure is slightly different :—

I.H.P. or S.H.P. of Type Ship $\times e$	=	E.H.P. of Type Ship	at K knots.
$\frac{S}{100} \times F_{10} \times \left(\frac{K}{10}\right)^{2 \cdot 83}$	=	Skin E.H.P. of Type Ship	
Difference	=	Wave E.H.P. of Type Ship	
Multiply by		$n^{3\frac{1}{2}}$	
and so obtain		Wave E.H.P. for Design	at $\sqrt{n}$ K knots.
$\frac{S'}{100} \times F'_{10} \times \left(\frac{K'}{10}\right)^{2 \cdot 83}$	=	Skin E.H.P. for Design	
Sum	=	Total E.H.P. for Design	
Divide by		e	
To obtain		I.H.P. or S.H.P. for Design	

where,
S = wetted surface of type ship, in square feet,
$S' = n^2 S$ = „ design „
K = speed of type ship, in knots,
$K' = \sqrt{n}\,K$ = corresponding speed of design, in knots,
F_{10} = skin E.H.P. per 100 square feet at 10 knots for type ship,
F'_{10} = „ „ „ for design.

D. W. Taylor's book, 'The Speed and Power of Ships,' which contains a series of curves based on model experiments and covering a large range of proportions of dimensions and speeds, will be found to give reasonably accurate estimates of effective horse-power.

For fast, fine vessels, the paper 'On some Results of Model Experiments,' by R. E. Froude, published in the 'Transactions of the Institution of Naval Architects for 1904,' may be advantageously consulted. Many other experimental results have now been published in Great Britain, America and other countries.

Admiralty Coefficients.

The 'Admiralty Coefficient of Performance' $= \dfrac{\Delta^{\frac{2}{3}} K^3}{P} = C$

where,
Δ = displacement, in tons,
K = speed, in knots,
P = I.H.P. or S.H.P.

Conversely $P = \dfrac{\Delta^{\frac{2}{3}} K^3}{C}$, so that if C is known or can be correctly assumed, P can readily be calculated. In similar ships at 'corresponding speeds $\Delta^{\frac{2}{3}} K^3$ varies as $(n^3)^{\frac{2}{3}} (\sqrt{n})^3$, that is, as $n^{3\frac{1}{2}}$. Hence, if P were also to vary as $n^{3\frac{1}{2}}$, the values of C would remain the same. And also, if for any given vessel P varied as K^3, C would be the same for all speeds. For these reasons C is sometimes called the 'Admiralty Constant,' but as the above relations are theoretical assumptions only, and C is found to vary from speed to speed and from ship to ship, it is better to use the term 'Admiralty Coefficient.'

Although wave-making power follows the law of comparison, and therefore varies as $n^{3\frac{1}{2}}$ skin-friction power does not obey the same law and only increases at the lesser rate

$$n^2 \frac{F'}{F} (\sqrt{n})^{2 \cdot 83} = \frac{F'}{F}\, n^{3 \cdot 415}.$$

And hence larger ships have relatively less power and larger values of C than smaller vessels. In the case of large vessels, also, a lesser proportion of power is lost in overcoming internal friction and eddy-making, and a further increase of C is the result.

In spite of its known defects, the 'Admiralty Coefficient' is largely used for estimating horsepower, the assumed value being based upon that for a similar, or nearly similar, completed vessel at 'corresponding' speed, and suitable allowances made for variations in size and proportions.

If the prismatic coefficient of the type ship differs from that of the proposed vessel, we may still find suitable values for O by modifying the 'corresponding speed' of the type ship, thus:—

$$K = K'\sqrt{\frac{L}{L'} \cdot \frac{1 - O_P}{1 - O'_P}}$$

where K, L, and O_P are the corresponding speed, length between perpendiculars, and prismatic coefficient respectively for the type ship, and K', L', and O'_P the desired speed, length, and prismatic coefficient for the proposed vessel.

Admiralty Coefficient applied to Fuel Consumption.

A variation of the Admiralty Coefficient much used by superintendent engineers, when comparing performances at sea, consists in substituting the daily fuel consumption in tons for horse-power in the formula $O = \frac{\Delta^{\frac{2}{3}} K^3}{P}$. We thus get:—

$$\text{Fuel Coefficient of Performance} = \frac{\Delta^{\frac{2}{3}} K^3}{T}$$

Where Δ = mean service displacement in tons,
K = mean service speed in knots,
T = daily fuel consumption in tons.

Rudders.

The area of a vessel's rudder is determined by dividing the product of her length and load draft by about 30 to 40 in the case of warships, 60 to 70 for fast liners, 90 to 100 for slow cargo tramps. The most efficient angle is about 35° from the middle line, at which angle the total pressure upon the rudder in tons is about $\frac{AK^2}{700}$ for single screw ships, $\frac{AK^2}{1000}$ for twin screws, where A is the rudder area in square feet and K the ship's speed in knots. The centre of pressure at 35° is found by assuming that the pressure on each elementary horizontal strip is applied at a point four-tenths of the breadth of the strip from its leading edge, summing the moments for each strip, and dividing by the total area.

Let h be the distance of the centre of pressure from the axis in inches, and P the total pressure upon the rudder in tons. Then T, the twisting moment in inch-tons, = Ph, and

$$D = \text{diameter of stock, in inches} = \sqrt[3]{\left(\frac{16\,T}{\pi F}\right)}$$

where F = maximum allowable shearing stress in material in tons per square inch.

$$\text{If } F = 5{\cdot}1,\ D = \sqrt[3]{T}$$

In practice the diameters of the rudder stocks of all classified vessels are determined by the rules of the Classification Societies.

Estimate Sheet.

When making preliminary estimates of dimensions, weights, power, etc., the following form will be found convenient:—

Number of Inquiry. Type of Vessel. Owners. Date.

Conditions.

Length × Breadth.

Type. Length × Breadth × Depth. Cubic Number.

S Steel Weight. Steel Coefficient.
W Wood and Outfit Weight. W. & O. Coefficient.
M Machinery Weight. H.P. per Ton.
D Deadweight.

$$\frac{\text{Displacement}^{\frac{2}{3}}\ \text{Speed}^3}{\text{Admiralty Coefficient}} = \text{Horse Power.} \qquad \frac{\text{Length} \times \text{Breadth} \times \text{Draft full Keel}}{35} = \text{Block Number}$$

Block Coefficient

Displacement

For example, in figures:—

Inquiry No. 42. Cargo and Passenger Steamer. Messrs. Brown and Black. **3.3.47.**

To carry 6000 tons and steam 13¼ knots on 24 ft. draft. Class, 100 A1 at Lloyd's. Sixty first-class. 100 third-class.

	19200			
T.S.S.	400 × 48 × 30		5760	
S.	2200	·382		
W.	850	·147		
M.	750	4·54		24′ 0′
D.	6000			2″ keel

$$\frac{9800^{\frac{2}{3}}\ 13\tfrac{1}{4}^{3}}{313} = 3400 \text{ I.H.P.} \qquad \frac{400 \times 48 \times 23'\ 10''}{35} = 13080$$

$$\begin{array}{r} 13080 \\ \cdot 75 \\ \hline 9800 \end{array}$$

These figures are arrived at by a process of trial and error-correction until a satisfactory balance is reached between weights and displacement, block coefficient and speed length ratio, horse-power and weight of machinery. The block coefficient should not exceed 1·06 minus half the speed-length ratio. (Speed in knots divided by square root of length in feet.)

Elements of Propulsion.

If a vessel (without propeller) moving at a speed of V feet per minute experiences a total resistance of R pounds, a force R must be applied continuously by means of a thrust or tow-rope pull in order to overcome the resistance and maintain the speed. The power required is RV foot-pounds per minute and is called the Tow Rope Power or Effective Power.

$$\text{Effective Horse Power, E.H.P.} = \text{R.V.} \div 33000 = \cdot 00\dot{3}0\dot{7}\ \text{RK}.$$

If the thrust is delivered by a screw propeller working behind the ship, it is found that the action of the propeller increases the resistance. This increase is called the 'Augment of Resistance.' T, the total thrust of the propeller, must therefore be equal to R + Augment = R + A, and T − A = R. The augment of resistance can therefore be regarded as a deduction from the thrust: it is alternatively called the 'Thrust Deduction' and is written A = *t*T, where *t* is the 'Thrust Deduction Fraction.'

$$T - tT = T(1 - t) = R$$

$(1 - t)$ is called the Thrust Detection Factor.

If a vessel is being towed at a speed of K knots, the skin friction sets the adjacent water in motion, and at the stern there will be found a 'wake' current moving in the same direction as the ship at some speed W knots. The stern, and with it the propeller, will therefore be moving at a speed K − W relatively to the wake water, and this speed is called 'the Speed of Advance.' Froude compares wake speed with speed of advance, and writes $W = \omega(K - W) = \omega K'$.

Wake fraction	$\omega = \dfrac{W}{K - W} = \dfrac{W}{K'}$
Wake factor	$1 + \omega = \dfrac{K}{K - W} = \dfrac{K}{K'}$
Wake per cent.	100ω.

Taylor compares wake speed with ship speed, and writes—

$$W = \omega K$$

Wake fraction	$\omega = \dfrac{W}{K}$
Wake factor . . .	$1 - \omega = \dfrac{K - W}{K} = \dfrac{K'}{K}$
Wake per cent.	100ω.

If a propeller having a pitch P and making N revolutions per minute is working behind a ship and producing a thrust T with a torque Q in the shafting just forward of the propeller, the ship's speed being K and the speed of advance of the propeller K′ = K − W, the work obtained will be RK (E.H.P.) and the work expended 2πNQ, which we can call the 'Received Horse Power Behind' R.H.P.$_b$. The efficiency η is therefore $\dfrac{\text{E.H.P.}}{\text{R.H.P.}_b} = \dfrac{\text{RK}}{\text{R.H.P.}_b} = \dfrac{T(1 - t) \times K'(1 + \omega)}{\text{R.H.P.}_b}$.

TK′ is called the 'Thrust Horse Power' (T.H.P.) and the product $(1 - t)(1 + \omega)$ the 'Hull Efficiency,' being the product of one factor $(1 - t)$ representing the effect of the propeller on the hull and another $(1 + \omega)$ representing the effect of the hull on the propeller. If we write—

$$\text{Hull Efficiency} = h = (1 - t)(1 + \omega)$$

we have

$$\text{Screw Efficiency Behind} = \eta = \frac{\text{T.H.P.}}{\text{R.H.P.}_b} h.$$

Now if the same propeller be mounted on a shaft alone, without ship or model, and run in open water at the same revolutions N, and its speed of advance adjusted until it gives the same thrust

T, we can fairly assume that the speed of advance so found must be the same as the speed of advance when in place behind the ship. We are thus able to determine the wake speed. The torque is not necessarily the same as when behind the ship, though it is usually not very different, so we call the power in the shaft 'Received Horse Power in the Open,' R.H.P.$_o$, and the 'Efficiency in the Open,' $\odot$, is $\dfrac{TK'}{\text{R.H.P.}_o} = \dfrac{\text{T.H.P.}}{\text{R.H.P.}_o}$.

The ratio $\dfrac{\text{R.H.P.}_o}{\text{R.H.P.}_b}$ is called the 'Relative Rotative Efficiency,' r.

Finally, therefore, we can write—

$$\eta = \frac{\text{T.H.P.}}{\text{R.H.P.}_b}h = \frac{\text{T.H.P.}}{\text{R.H.P.}_o} \times \frac{\text{R.H.P.}_o}{\text{R.H.P.}_b}h = \odot rh,$$

or screw efficiency behind = screw efficiency in open × relative rotative efficiency × hull efficiency.

S.H.P., the 'Shaft Horse Power' (or B.H.P., the 'Brake Horse Power'), is the power in the shafting just abaft the engine. The shaft line efficiency l is the ratio $\dfrac{\text{R.H.P.}_b}{\text{S.H.P.}}$. The mechanical efficiency of the engine m is the ratio of S.H.P. to the indicated horse power (I.H.P.).

$$\therefore\ \text{S.H.P.} = m \times \text{I.H.P.}$$

$$\text{R.H.P.}_b = l \times \text{S.H.P.} = l.m.\text{I.H.P.}$$

$l \times m$ is the 'Transmission Efficiency,' $f = \dfrac{\text{R.H.P.}_b}{\text{I.H.P.}}$

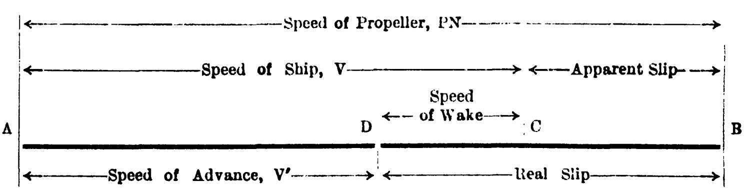
The overall propulsive efficiency or propulsive coefficient, ϵ,

$$= \frac{\text{E.H.P.}}{\text{I.H.P.}} = \frac{\text{E.H.P.}}{\text{R.H.P.}_b} \times \frac{\text{R.H.P.}_b}{\text{I.H.P.}} = \eta f = \odot rhf.$$

η is sometimes called the 'Quasi-Propulsive Coefficient.'

A propeller having a pitch P and making N revolutions per minute would advance a distance PN if there were no slip. On account of slip, however, it actually advances a lesser distance V' called the 'speed of advance.' The difference is called slip, so that slip = PN − V', and the 'slip ratio' $s = \dfrac{PN - V'}{PN} = 1 - \dfrac{V'}{PN}$. If the thrust is T and the torque Q, the efficiency $= \dfrac{TV'}{2\pi NQ} = \dfrac{TP(1-s)}{2\pi Q}$.

When the propeller is attached to a ship its apparent speed of advance is the ship's speed K knots or V feet per minute, where V = 101⅓K. The apparent slip is PN − V. On account of the presence of the wake stream, however, the true speed of advance of the propeller through the water surrounding it is K − W(= K') knots or V' (= 101⅓K') feet per minute, and the real slip is PN − V'. Let AB represent to scale the 'Speed of the Propeller':



AC the speed of the ship V, and CD the speed of the wake.

$$\text{Then apparent slip ratio} = \frac{CB}{AB}$$

$$\text{Real slip ratio} = \frac{DB}{AB}$$

$$\text{Froude's wake fraction} = \frac{DC}{AD}$$

$$\text{Taylor's wake fraction} = \frac{DC}{AC}$$

Law of Comparison for Model Propeller Experiments.

If a model propeller $\frac{1}{n}$th of the size of the ship's propeller is run at $\sqrt{n}$ times the revolutions and its speed of advance adjusted so that both screws are working with the same slip ratio, the thrust of the ship's propellers will be n^3 times that of the model, the torque n^4 times, the powers $n^{3\frac{1}{2}}$ times, and the efficiencies equal.

	Model Propeller		*Ship's Propeller*
Diameter	d		$D = nd$
Pitch	p		$P = np$
Revolutions	r		$R = n^{-\frac{1}{2}} r$
Speed of Advance	v'		$V' = n^{\frac{1}{2}} v'$
Slip Ratio, s	$1 - \frac{v'}{pr}$	=	$1 - \frac{V'}{PR}$
Thrust	t		$T = n^3 t$
Torque	q		$Q = n^4 q$
THP = U	$\frac{tv'}{33000}$		$\frac{TV'}{33000} = n^{3\frac{1}{2}} \frac{tv'}{33000}$
RHP = P	$\frac{2\pi rq}{33000}$		$\frac{2\pi RQ}{33000} = n^{3\frac{1}{2}} \frac{2\pi rq}{33000}$
Efficiency	$\frac{tv'}{2\pi rq}$	=	$\frac{TV'}{2\pi RQ}$
ρ_U (Rho-U)	$\frac{ru^{\frac{1}{2}}}{v'^{2\frac{1}{2}}}$	=	$\frac{RU^{\frac{1}{2}}}{V'^{2\frac{1}{2}}}$
ρ_P (Rho-P)	$\frac{rp^{\frac{1}{2}}}{v'^{2\frac{1}{2}}}$	=	$\frac{RP^{\frac{1}{2}}}{V'^{2\frac{1}{2}}}$
δ (Delta)	$\frac{dr}{v'}$	=	$\frac{DR}{V'}$

The last three functions are the same for all similar propellers working at the same slip ratio; ρ_U and ρ_P depend on revolutions, power and speed, which are given quantities in the initial stage of propeller design. The results of systematic propeller experiments are usually plotted on some function of Rho as base, since this is independent of diameter. For each of a series of pitch ratios, a curve of efficiency and a curve of some function (such as δ) involving the diameter are plotted, from which the most suitable diameter and pitch ratio can be found for the given power, revolutions, and speed of advance. Taylor has published four ' Rho-delta ' diagrams obtained by combining and averaging his own propeller experiments with those of Froude, Durand, and Schaffran. These were reproduced in *The Shipbuilder*, January 1925.

SECTION XXIX

PART II

MARINE ENGINES (STEAM)

(Revised by A. W. Davis, B.Sc.)

BASES OF ENGINE AND BOILER DESIGN.

Reciprocating Engines—Cylinder Ratios.

On account of its relatively low efficiency the reciprocating steam engine is seldom employed to-day except in certain cargo vessels and ships built for special purposes in which simplicity is of paramount importance. Triple expansion engines are the most popular for these services and the quadruple expansion engine, originally developed for large powers with minimum inefficiency, is now almost obsolete. The following table of cylinder area ratios is in accordance with modern practice for various types of marine engines:—

TABLE SHOWING CYLINDER AREA RATIOS.

Type of Engine.	Boiler Pressure. Lbs. per Sq. In.	Ratio of Cylinder Areas.			
		L.P. / H.P.	2nd M.P. / H.P.	1st M.P. / H.P.	H.P.
Quadruple expansion	200 to 250	8 9·5	4·0 4·5	2·0 2·1	1 1
			M.P. / H.P.		
Triple expansion	160 to 220	6·5 to 8·5	2·5 to 2·9		1
Compound engines, screw	100 to 140	4 to 5	—		1
,, ,, paddle	90 to 130	3·5	—		1

Mean Pressures and Expansion of Steam.

The total power developed in an engine may be varied by altering the point at which steam is cut off in the H.P. cylinder, and generally provision is made to enable the cut-off in each cylinder to be independently adjusted if necessary to equalise the powers developed in each cylinder. For the maximum designed power the cut-off in the H.P. cylinder takes place at from ·65 to ·75 of the stroke, and the total number of expansions of the steam is

$$= \frac{\text{Volume of L.P. cylinder}}{\text{Volume of H.P. cylinder at point of cut-off}};$$

$$\frac{\text{Ratio of } \dfrac{\text{L.P. cylinder area}}{\text{H.P. cylinder area}}}{\text{Cut-off in H.P. cylinder (expressed in fraction of stroke)}}$$

The total expansion of the steam is usually considered with clearance neglected and neglecting also the fact that release takes place before the end of the stroke. In estimating the mean pressure obtainable in any multiple-stage expansion engine it is referred to the L.P. cylinder, the mean pressure thus obtained being that necessary if the whole of the power were developed in the

L.P. cylinder. The actual referred mean pressure is, therefore, in the case of a triple expansion engine equal to

$$\text{Mean pressure in L.P. cylinder} + \frac{\text{Mean pressure in M.P. cylinder}}{\text{Ratio of L.P. to M.P. cylinder area}} + \frac{\text{Mean pressure in H.P. cylinder}}{\text{Ratio of L.P. to H.P. cylinder area}}.$$

The theoretical referred mean pressure may be calculated, assuming that the steam is moderately moist, the curve of expansion being a hyperbola. It depends upon the designed number of expansions and the absolute admission pressure of the steam.

Let Pa = absolute initial pressure,

Pm = absolute theoretical referred mean pressure,

r = total number of expansions,

$\frac{1}{r}$ = cut-off, or reciprocal of r,

then

$$Pm = Pa\,\frac{1 + \text{hyp. log. } r}{r}.$$

PRESSURE OF STEAM IN CYLINDERS OF COMPOUND AND TRIPLE-EXPANSION ENGINES.

The values of $\frac{1 + \text{Hyp. Log. } r}{r}$ for Various Expansions are given on page 73.

The initial pressure, Pa, should be taken 5 to 10 lbs. below the absolute boiler pressure to allow for the drop between boilers and engines, and the back pressure, which must be deducted from Pm as found above, should be taken at not less than 4 lbs. per square inch absolute.

Diagram Factor.

Owing to the losses which occur while the steam is expanding in the various cylinders the actual referred mean pressure obtained from indicator diagrams is less than the theoretical referred mean pressure, and consequently the latter must be multiplied by a diagram factor which takes into account the losses due to clearance, condensation, radiation, friction of ports, compression, drop in pressure between the cylinders, and other losses. The value of this factor is obtained by experience, and, when possible, should be derived from engines similar to the one projected, and working under similar conditions. The values for various types of engines are approximately:—

Quadruple-expansion engines	·63 to ·68
Triple-expansion engines	·6 to ·65
Compound engines	·63 to ·70

When cylinders are jacketed the diagram factors may be increased by about 5 per cent.

The power is usually divided equally among the cylinders of an ordinary compound, triple, or quadruple-expansion engine, and if N is the number of cylinders and P the referred mean pressure (*i.e.* theoretical mean pressure × diagram factor) the mean pressure in the various cylinders of a triple-expansion engine, for example, will be:—

$$\text{L.P. cylinder mean pressure} = \frac{P}{N}$$

$$\text{M.P. ,, ,, ,,} = \frac{P}{N} \times \frac{\text{L.P. cylinder area}}{\text{M.P. cylinder area}}$$

$$\text{H.P. ,, ,, ,,} = \frac{P}{N} \times \frac{\text{L.P. cylinder area}}{\text{H.P. cylinder area}}$$

In the case of four-crank triple-expansion engines the power developed in each L.P. cylinder is usually five-eighths that of the H.P. or M.P. cylinder.

Piston Speed.

The mean piston speed is usually reckoned in feet per minute and is equal to stroke in feet × 2 × revolutions per minute.

The power which may be obtained from a given weight of engine varies almost directly with the piston speed ; the wear and tear of the engine, however, is increased with the higher speeds on account of the increased inertia stresses involved.

Piston speed may be increased either by increasing the stroke and keeping the revolutions constant or by increasing the revolutions, keeping the stroke constant.

By adopting the former method the cost, dimensions, and weight of the engines are increased, whilst by adopting the latter method there is practically no increase in any of the items mentioned. It is evident, therefore, that in cases where weight and space are limited high piston speed must be obtained by high revolutions; these have a limit, however, on account of the stresses due to the inertia of the reciprocating parts.

The piston speed and revolutions of engines fitted in various types of vessels are as shown in the following table :—

Table showing Piston Speed and Revolutions of Reciprocating Machinery for Various Types of Steamships.

Description.	Number of Cranks.	Piston Speed in Feet per Minute.	Revolutions per Minute.
Cargo vessels	4	650 to 800	70 to 100
	3	550 „ 650	60 „ 100
Paddle steamers	3	550 „ 650	45 „ 55

(Also see remarks about propeller revolutions for geared turbines.)

Calculation of Cylinder Diameters.

In determining the diameter of cylinders required for an engine of a given I.H.P., the type of vessel for which the engine has to be designed to a certain extent determines the piston speed and cylinder ratios, due consideration being given to the boiler pressure, the number of expansions being increased as higher boiler pressures are adopted.

Having decided the piston speed and the mean pressure referred to L.P. cylinder as already described, the area of the L.P. cylinder may be calculated, and from the cylinder ratios decided upon the areas of the remaining cylinders are determined.

Let piston speed = S feet per minute;

referred mean pressure = P lbs. per square inch,

then,

$$\text{Indicated H.P.} = \frac{\text{Area of L.P. cylinder} \times P \times S}{33{,}000}$$

or

$$\text{Area of L.P. cylinder} = \frac{\text{I.H.P.} \times 33{,}000}{P \times S};$$

$$\text{Area of M.P. cylinder} = \text{Area of L.P. cylinder} \times \text{Ratio of } \frac{\text{M.P. cylinder area}}{\text{L.P. cylinder area}};$$

$$\text{Area of H.P. cylinder} = \text{Area of M.P. cylinder} \times \text{Ratio of } \frac{\text{H.P. cylinder area}}{\text{M.P. cylinder area}}.$$

Combined Turbo-Reciprocating Machinery.

The reciprocating engine is not suitable for obtaining work from very low pressure steam owing to practical difficulties such as the large cylinder diameters and port areas which the greater volume of steam would require. A turbine can make use of this low pressure work and much has been done in an effort to obtain a satisfactory combination of the systems whereby a low pressure turbine utilises the exhaust from the reciprocating engine.

Early experiments in which the turbine was direct coupled to a third propeller shaft only met with partial success on account of the low efficiency of a fast running propeller. It was fitted in several large liners but is now entirely displaced by the simpler and more efficient geared turbine installation.

Various systems have since appeared in which the turbine has been coupled to the reciprocating engine shafting. The principal difficulty of such an arrangement lies in reconciling the irregular angular velocity of the reciprocating engine with the steady velocity of the turbine and when the coupling is made through gearing a flexible member must be introduced. In the Bauer Wach system which has double reductional mechanical gearing, the flexibility is provided by a hydraulic clutch which also acts as a ready means of disconnecting the turbine for astern running. Where electric transmission is employed the exhaust turbine drives a generator, and a motor is directly coupled to the propeller shafting, thus dispensing with any gearing.

Another system embodies the Gotaverken exhaust steam, turbo compressor, fitted in conjunction with a reciprocating engine, and it has proved highly successful. In principle, exhaust steam from the L.P. cylinder drives a turbine which is coupled to a multi-stage rotary compressor. The exhaust from the H.P. cylinder is led to the compressor and is raised in pressure before entering the M.P. receiver.

The advantage of these arrangements lies in the facility with which an exhaust turbine can be installed in combination with the reciprocating machinery of existing vessels. Usually when a conversion of this nature takes place, other improvements are also incorporated with the reciprocating engine and boilers and a reduction in fuel consumption of about 20 per cent. is obtained.

TURBINES.*

The steam turbine is the mode of propulsion adopted for the largest passenger vessels and for all high-powered naval craft. It is also widely employed for intermediate and cross channel passenger vessels and for cargo liners. In the earlier stages of its adoption, when the turbine was directly coupled to the propeller shafting, the high revolutions necessary to obtain suitable blade speeds for low steam consumption without abnormally increasing the size and weight of the turbines entailed small propellers which were inefficient except for fast vessels, and even in these the turbines were run at an uneconomically low speed in order to improve the propellers.

The introduction of gearing between the turbines and propellers permitted the turbine and **propeller designers to select the revolutions most suitable for their individual purposes so as to obtain the maximum efficiency of turbine and propeller respectively. The revolutions of the most efficient propeller for a vessel depend on horse-power, speed and form of vessel, and should be worked out in conjunction with experimental results such as those published by Taylor and Froude, but the following method gives very satisfactory results for turbines, gearing and propellers:—**

If

R = revolutions of propeller per minute;
SHP = shaft horse-power of each shaft;
V = speed of vessel in knots on trial;

then,

$$R = C\sqrt{\frac{V^4}{SHP}}.$$

Geared Turbines.

For many years the single reduction geared turbine unit was most generally adopted for both merchant and naval practice. In merchant practice it was usual to fit two turbines in conjunction with each propeller shaft for cross channel vessels where the propeller shaft revolutions were naturally fairly high but for ocean-going vessels it was more customary to employ three turbines per shaft, the steam passing in series from one to the other. To-day the double reduction gear has evolved into a unit of high reliability and for ocean-going vessels with relatively low propeller shaft revolutions it is common to employ such units in co-operation with two turbines per shaft working in series. A similar trend is to be found in naval construction.

For many years two principal types of turbines held the field, namely, the Parsons reaction turbine and the Brown Curtis impulse turbine. It is now quite general for high-pressure turbines to be of the impulse type and low pressure of the reaction type. Designs are prepared and developed and researches are progressed by the marine engineering industries' Research Association —Pametrada (Parsons and Marine Engineering Turbine Research and Development Association).

The tendency to increase boiler steam pressures and temperatures still persists, leading to economy which makes turbine machinery a successful rival to oil engines between powers of 3,000 s.h.p. per shaft and 10,000 s.h.p. per shaft, above which limit the turbine alone holds the field.

Turbine casings are of cast steel or fabricated construction where subjected to steam temperatures above 450° F., while for lower temperatures cast iron is usually employed. Blading material is usually of stainless iron or Monel metal, the latter often being regarded as more suitable for low temperature turbines.

Reduction Gear for Propulsion.

The single reduction type of gear consists of a large gearwheel having double helical teeth coupled to the propeller shaft and driven by two or more pinions coupled to the turbine through sliding couplings comprising toothed and sleeved members so arranged as to take up axial movement during the expansion of the turbine rotor under steam.

In the case of double reduction gears, a high-speed or primary train forms an addition to the unit described in conjunction with each of the turbine shafts.

TURBINE GEARING.

Single Reduction.

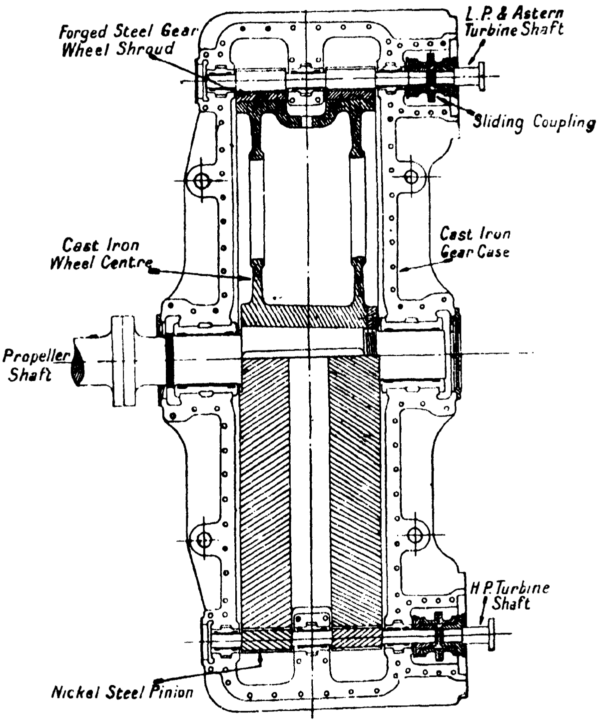

FIG. 1.—Plan with Top Casing removed.

The gearing is completely enclosed in a cast iron or fabricated steel casing with which the thrust block is sometimes arranged in integral construction.

Sprayers are provided to enable oil from the forced lubrication system to be directed on to the teeth adjacent to the zones of contact.

Pinions are normally made of 3 per cent. nickel steel, normalised, oil-hardened and tempered, having a tensile strength of about 45 tons per sq. in. and 25 per cent. elongation.

Gear wheel rims are of 0·3 per cent. carbon steel, normalised and having a tensile strength of about 35 tons per sq. in., with 26 per cent. elongation.

Extreme accuracy in cutting the gear teeth is essential and the hobbing machines employed for the work are the result of extensive and costly research both in design and construction, guidance on this subject being available in the form of a British Standard Specification.

The highest quality of gears are finished by a post hobbing process involving either lapping of the teeth with abrasive or the newly perfected system of selective shaving whereby, in the case of an accurately hobbed gear, the surfaces in contact on even a broad faced gear may be increased to as much as 90 per cent. of the total available tooth service.

The permissible pressure per inch width of gear face is a function of the diameter of the pinion and for normal ratios of face width to pinion diameter may be defined by the expression

$$150 D_e^{\frac{2}{3}} \text{ where } D_e = \text{pinion P.C.D.} \left(\frac{R}{R+1}\right)$$

where R in turn equals the gear ratio. The pitch of the teeth employed is a function of the pressure per inch width and may be given approximately as—

$$\frac{\text{Pressure in lbs. per inch width of tooth}}{2{,}000} \text{ inches.}$$

The normal depth of tooth employed varies between 20 per cent. and 45 per cent. in excess of the British Standard Form of involute rack for spur gears and the helical angle employed varies between 15° and 30°.

Electric Transmission of Power for Propelling Machinery.

The application of electricity for transmitting power between the prime mover and the propeller may be divided into two classes—viz. Turbo-electric and oil-electric.

TURBO-ELECTRIC DRIVE

The electrical equipment required is an alternating current generator suitable for direct coupling to a high-speed turbine, a motor of suitable speed for direct coupling to the propeller shaft, a direct current exciter or an auxiliary generator, from which direct current can be obtained, and suitable control gear. The whole can be regarded as a reduction gear having a ratio of reduction determined by the relative number of poles on the motor and generator. Thus with a two-pole generator and a sixty-pole motor the ratio of reduction would be 30 to 1, and, as with mechanical gearing, any variation in speed is obtained by varying the speed of the prime mover.

Two types of alternating current motors have been used for driving propellers :—

(a) Induction machines, both slip-ring and squirrel-cage types.
(b) Self-starting synchronous motors.

All things considered, the self-starting synchronous motor is the most suitable for this class of work on account of the large air gap, simplicity of construction, accessibility of windings, high power factor, and efficiency. When starting from rest the synchronous motor functions as a squirrel-cage motor with its field unexcited.

On account of its greater flexibility direct current is preferable for vessels up to about 3,000 s.h.p. on one shaft; beyond this power, owing to the limitations of voltage, the cables become excessively large.

The astern turbine is eliminated entirely in an electrically-driven vessel, power astern being available without reversing the direction of rotation of the turbine.

Manœuvring is very efficient with this type of power transmission, so that perfect speed control in heavy seas is maintained without danger of racing.

DIESEL ELECTRIC DRIVE.

Many types of small coasting vessels and vessels for harbour duties are particularly suited to propulsion by high-speed diesel engines operating through electric reduction drives.

BOILERS.

General Proportions.

Cylindrical Boilers.

Present-day economic conditions have led to the widespread use of oil fuel on shipboard instead of coal where the fuel is to be burned in cylindrical or watertube boilers. In designing cylindrical boilers for sea-going vessels it is, however, still customary to proportion them for coal-burning so that they may be converted at a later date if economic conditions change.

The weight of coal that can be burnt in the furnaces of a marine boiler depends on several factors.

In cylindrical boilers with natural draught some experiments were carried out with varying length of fire bar, and the results showed that the quantity of coal was practically the same with short and long bars and evidently depended more on the cross sectional area of the furnace than the length of grate. The height of the funnel is a controlling factor, and a useful rule for this type of boiler is as follows :—

$$\text{lbs. coal per hour per furnace} = D_m^2 \times \sqrt{F} \times C$$

where D_m = Mean diameter of furnace in feet;
F = Height of funnel in feet above firegrate;
C = Coefficient = 4 Welsh coal on short trial
3·5 „ „ long „
3 „ „ service.

The above values of C are a reasonable average, but may be increased or decreased, depending on the efficiency of the boiler. An extra large ratio of heating surface will take more heat out of the gases, thus decreasing their temperature and reducing the suction which causes the draught and consequently the rate of combustion.

With forced draught the quantity of coal that can be burnt in a cylindrical boiler varies more directly with the area of the grate bars and also depends on the available air pressure.

The air pressure in the ashpit measured in inches of water for various rates of combustion may be taken as follows :—

	Lbs. of Coal per Sq. Ft. of Grate Area per Hour.			
	20	25	30	35
Closed stokehold or closed ashpit with retarders but no air heaters	$\frac{5}{8}$ in.	$\frac{11}{16}$ in.	1 in.	$1\frac{3}{8}$ in.
Closed ashpit with retarders and air heaters	$\frac{1}{2}$ in.	$\frac{3}{4}$ in.	$1\frac{1}{4}$ in.	$1\frac{3}{4}$ in.

These pressures are also approximate as they are affected by the assistance received from the funnel. Due allowance must be made at the fans for the additional resistance of air trunks and the air side of the heaters.

With oil fuel the consumption in lbs. per furnace per hour varies approximately as D_m^2, and usually averages about $25D_m^2$ for Howden draught, but 30 per cent. more has been burnt successfully.

With regard to the heating surface the rate of evaporation in a boiler is the principal factor in determining the efficiency of this plant, but this also is subject to other factors, such as cleanliness, etc.

The rates of evaporation per square foot from and at 212° F. in ordinary practice for long trials are as follows :—

	Evaporation.	Boiler Efficiency.
Natural draught—		
Funnel height 50 feet . . .	5·0	73 per cent.
Howden draught—		
Ocean liners	6·5	80 „
Channel steamers	9·0	75 „
Closed stokehold—		
Channel steamers	9·0	70 „ with retarders
		65 „ without retarders

These rates of evaporation decrease on continuous service with coal owing to the surfaces getting dirty, cleaning fires, etc., and the efficiencies are about 5 per cent. lower. With oil fuel they can be maintained, especially if blowers are fitted for sweeping the tubes.

Cylindrical boilers of the return tube type as shown in figs. 2 and 3 (p. 295) are made single ended or double ended, and in the latter case the combustion chambers of furnaces axially in line with each other, are sometimes fitted with a common combustion chamber. This arrangement reduces the length and weight of the boiler but should not be used when burning coal with Howden or closed ashpit draught unless a high brick wall is provided between the furnaces to prevent flame being blown out of an open furnace door by the pressure in the opposite furnace.

The size and number of furnaces to burn the required quantity of coal and the area of heating surface to give the desired efficiency may be computed from the figures given above.

Furnaces and Firebars.

If forced draught is employed it is not desirable to have firebars longer than 6 ft. on account of the tendency for large quantities of air to pass through the firebars if the fire should burn into holes. With Howden's system 5 ft. 6 ins. is the length of firebar generally adopted. In naval practice with water-tube boilers working at full power under a moderate forced draught of 0·5 in. to 0·75 in. of air pressure, grate bars having a maximum length of 7 ft. are frequently employed; this, however, requires skilful firing, and extreme care to ensure the boiler efficiency being maintained at a maximum. For natural draught the length of grate bar should not exceed 6 ft. 6 ins., but increased boiler efficiency will be attained by using shorter bars, on account of the greater control over the fires. The diameter of furnaces for cylindrical boilers (figs. 7 and 8) should not be less than 32 ins., nor greater than 48 ins., and the number of furnaces which can be fitted in boilers of the following dimensions is:—

Boilers up to 9 ft. 0 ins. diameter	1 furnace	Boilers up to 15 ft. 6 ins. diameter	3 furnaces
,, ,, ,, 13 ft. 0 ins. ,,	2 furnaces	exceeding 15 ft. 6 ins. ,,	4 furnaces

The grate area of a cylindrical boiler is equal to:—Length of firebars × mean diameter of furnace × number of furnaces.

Length of Cylindrical Boilers.

The length of a cylindrical boiler is determined by the length of combustion chamber tubes or the furnace which is practically the same length as the tubes, the length of the combustion chamber and the water spaces at their backs. The combustion chamber measured horizontally should be as long as possible, and usually is about 30 ins. in single-ended boilers and from 50 to 57 ins. in double-ended boilers. The water space between the back of the combustion chamber and the back end-plate of the boiler should be from 5 to 7 ins. at the bottom and wider at the top, the taper being about ½ in. per foot on the combustion chamber back.

Heating Surface.

The heating surface of cylindrical boilers consists of the external surface of the tubes, the length being measured between the tube plates, the surface of the furnaces above the firebar level, and the surface of the combustion chambers. The surface of the front tube plate on the boiler end, although in contact with the hot gases, is not usually reckoned as effective heating surface, and should not be included in the total heating surface of the boiler. In boilers using oil fuel the total surfaces of the furnaces and combustion chambers is included. The heating surface of a water-tube boiler is the total external surface of the tubes in contact with the fire and hot gases.

Diameter of Tubes for Cylindrical Boilers.

In forced-draught boilers the combustion chamber tubes are generally 2½ or 2¾ ins. diameter, and in natural-draught boilers the diameter is 3 ins. to 3¼ ins., the increased sectional area being necessary to reduce the resistance to flow of the products of combustion.

Thickness of Cylindrical Boiler Shells.

The shell plates of cylindrical boilers must be of the following thickness to satisfy the requirements of the revised rules of the Board of Trade, Lloyd's, British Corporation, and Bureau Veritas.

CYLINDRICAL MARINE BOILER.

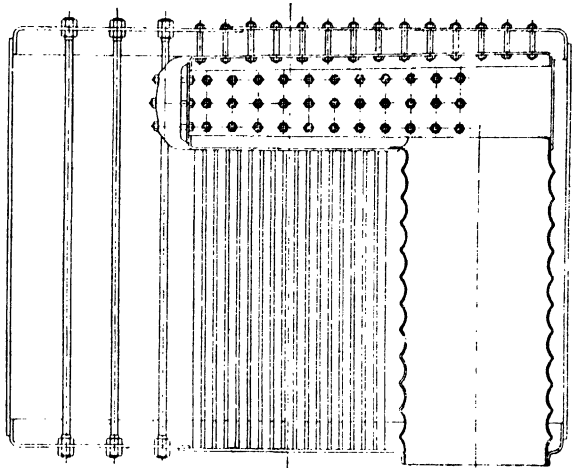

FIG. 3.

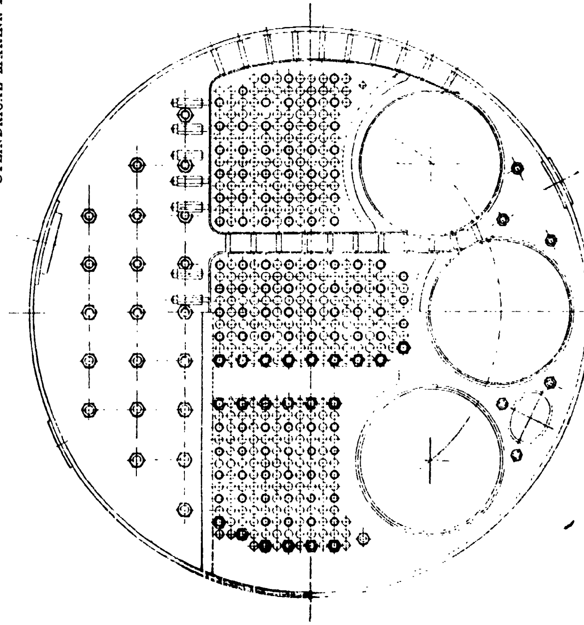

FIG. 2.

The thicknesses shown assume the steel to have a minimum ultimate tensile strength of 28 tons per sq. in., and the longitudinal joint to have double butt straps with an efficiency of riveting equal to 84 per cent.

Superheaters for Cylindrical Boilers.

The types of superheaters manufactured for cylindrical return-tube boilers consist in principle of a series of loops or elements of solid cold-drawn steel tubing inserted in the smoke tubes of the

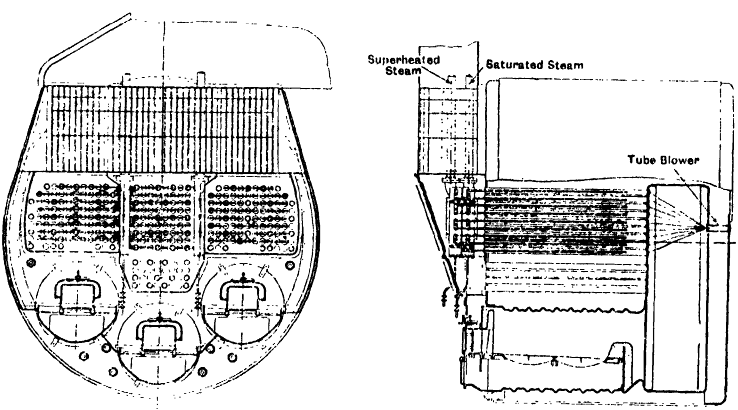

FIG. 4.—**Three-Furnace Boiler, Forced Draught, with Smoke-tube Superheater.**

cylindrical boiler and connected to suitable headers or collectors placed vertically in front of the boiler between the nests of smoke tubes. The saturated steam from the boiler stop valve enters the saturated steam header, the steam circulates through the elements and returns superheated to the superheated steam collector, and thence to the prime mover. The elements are, therefore, in the direct path of the gases flowing from combustion chamber of boiler to smoke-box. (See fig. 4.)

Draught.

The two systems of forced draught most commonly adopted are closed stokeholds and the Howden system with closed ashpits. In the former an air pressure is maintained in the boiler rooms by forcing in air with fans, all openings in the boiler room are closed down with doors, and air locks fitted for access purposes. With a Howden system the boiler room is open,

no air locks being required, and the air is forced by fans over the surface of a nest of tubes, or other form of air preheater situated in the uptakes, through which the products of combustion pass on the way to the funnel. The air is raised to a temperature of about 250° F., or over, by the air heater, and passes through passages on either side of the uptake into a reservoir surrounding the furnace fronts, from which reservoir the air is admitted to the furnaces by valves in the furnace fronts, at the sides and the top, to the ashpit and above the fire respectively. Valves are fitted to control the admission of air above and below the fires: these must be shut before opening the furnace door to fire the boiler, otherwise the flame would be blown out into the stokehold. The proper use of the top valve prevents excessive smoke without reducing the boiler efficiency or the amount of evaporation per lb. of coal. Special strips of twisted steel ribbon called 'retarders' are placed in each boiler tube, causing the hot gases traversing the tubes to take a spiral course and be retained longer in close contact with the tubes than they otherwise would.

The latest type of furnace fronts has the side valves controlled by one handle, and is also fitted with a safety guard, so that the furnace doors can only be opened when the air valves are shut, thereby preventing the possibility of any flame coming back through furnace door when it is opened.

Fronts have also been developed for firing powdered coal, in conjunction with various patentees of powdered fuel firing systems.

On account of the abstraction by the air of what would otherwise be waste heat passing up the funnel a considerable measure of increased boiler efficiency is attained compared with the closed stokehold system, and the uniform condition of furnace temperatures which Howden's system ensures tends to reduce the wear and tear of the boiler.

A more uniform efficiency of furnace can be maintained with forced draught and it may be readily controlled to suit any desired rate of combustion, being quite independent in this respect of prevailing atmospheric conditions.

The original air preheater was of the tubular type, but heaters are now made with surfaces of steel plates arranged to control the flow of air and gases so as to obtain the maximum heat transmission. The plates are assembled in sections to facilitate withdrawal for renewal or repair, and the space occupied by the heater is less than by a tubular heater of the same surface.

WATER-TUBE BOILERS.

The principal advantages of water-tube boilers as compared with cylindrical boilers are :—

(1) Ability to use higher steam pressures (above 250 lbs.).

(2) Rapidity with which steam can be raised.

(3) Capability to endure forcing to a great extent.

(4) Reduced weight.

(5) Reduced space occupied.

Many factors of great complexity enter into the design of a watertube boiler in ensuring satisfactory combustion of the fuel, proper circulation in the tubes and the desired rate of evaporation and superheating. The fundamental criterion of performance is the weight of oil to be burned in lbs. per sq. ft. of furnace radiant heating surface per hour, since this provides, when considered in conjunction with the temperature of the air supply, a measure of the furnace temperature and, consequently, of the resistance of the boiler to brickwork failures. Values adopted range from 30 to 50 for naval vessels and from 7 to 20 for merchant vessels.

The efficiency at which a watertube boiler will operate is largely dependent upon whether an economiser and/or air heater are fitted. If neither of these units is supplied, the efficiency is a function of the generating surface provided but when an air heater and or an economiser is fitted, the generating surface must in any case be so proportioned as to ensure that these units perform their proper function under all conditions of load. The maximum air temperature for supply to the furnace is about 450° F. and the maximum feed water temperature as supplied at the outlet from an economiser should not be above 50° F. less than the saturation temperature at the boiler pressure.

Typical boiler efficiencies are as follows :—

No economiser or air heater	75–80 per cent.
With economiser	84 ,,
With economiser and air heater or with air heater alone, depending upon type of boiler	88 ,,

The surface of the superheater depends upon the steam temperature desired and the temperature of the gases at the position in which the superheater is placed and, as these vary very greatly, no approximate rule can be given.

The principal watertube boilers now in use are the following:—

Yarrow three-drum type.
Yarrow five-drum type.
Fairfield-Johnson controlled superheat.
Babcock & Wilcox header type.
Babcock & Wilcox integral furnace type.
Foster-Wheeler 'D' type.
Foster-Wheeler two-furnace type.

Life of Marine Boilers.

The life of a marine boiler depends to a certain extent on the care and attention bestowed on it during the first few months of its existence, provided that the plates have been properly treated at the building of the boiler—that is, all mill scale removed and the plates kept dry and free from atmospheric corrosion. The mill scale, if not removed, has a very irritant action on the clean metal of the boiler, and is most hurtful to the plates if allowed to remain on them. The greatest care and attention is needed for the first period of working of new boilers to keep the new metal free from corrosion. With water-tube boilers especially, nothing but distilled water should be used, and it is very desirable that air should be excluded from all boilers to prevent corrosion. In order to achieve this result the feed arrangements should prevent the water coming in contact with the atmosphere as much as possible, and a deaerator for removing air from the water incorporated in the system.

Rules and Regulations with Reference to Boilers of Steamships.

Standard Conditions for the Design and Construction of Marine Boilers.

A set of rules has been framed and agreed to by representatives of the Board of Trade, Lloyd's Register of Shipping, the British Corporation for the Survey and Registry of Shipping, and the Bureau Véritas International Registry of Shipping, and recommended for favourable consideration and adoption. An abstract of these rules is given on pp. 33 *et seq.*

Fuel.

Coal.

Coal is burnt by one of three systems:—

Hand firing.
Mechanical stoking,
Pulverised with air injection.

The first system, that of hand firing, is suitable for most boilers, cylindrical or water-tube, and the design of the boilers has been evolved to suit the conditions necessary for this type of combustion.

Mechanical stoking devices have been produced for both cylindrical and water-tube boilers. In some of the arrangments the coal is fed into a hopper by hand and in others by a mechanical elevator. From the hopper it is led into the front of the furnaces and gradually worked towards the back of the furnace by the movement of the bars, which may have a reciprocating motion, or a continuous backward motion, as in the chain type grate.

In water-tube boilers, especially where there is a large radiant surface, and where the service of the vessel involves frequent or unexpected stoppages in the steam supply, provision should be made for damping the fuel in order to prevent excessive blowing off. This is not so important with the cylindrical boiler where the relatively larger steam and water spaces act as a steam accumulator.

Considerable attention has been given to pulverised fuel in recent years, and high boiler efficiencies have been obtained. Special provision must be made with extra large combustion chambers and furnaces in order to give time for complete combustion before the gases pass into the small spaces inside or between the tubes. Arrangements should also be made to prevent the ashes causing inconvenience to passengers.

Oil Fuel.

The advantages of fuel oil as compared with coal are as follows:—

(1) Reduction in weight and space occupied by the boiler installation.

(2) Increased evaporation of water per lb. of fuel in the ratio of about 14 : 9 as compared with good quality coal.

(3) Utilisation of remote parts of the ship and of constricted spaces, such as the double bottoms, for stowage of fuel.
(4) Less manual labour and greater rapidity in stowage.
(5) No reduction in speed due to cleaning fires, difficulty in trimming coal from remote bunkers, or exhaustion of stokers.
(6) Reduced wages bill for boiler room staff, no trimmers, and comparatively few attendants for the burners being required.
(7) A prompt and effective control of the steam output due to the mechanical supply of the fuel, permitting of more rapid changes of speed than is the case with coal.
(8) Absence of smoke if air supply is properly controlled.
(9) No trouble due to accumulation of ashes; ash expellers or ejectors are dispensed with.
(10) In the case of naval vessels, fuelling can readily be carried on at sea.
(11) Cleanliness of ship during fuelling and less inconvenience to passengers.

Both water-tube and cylindrical boilers are now adapted for burning oil fuel, the direct-pressure system being the one most generally in use for naval and mercantile service.

Pressure pumps fitted in the boiler rooms have suctions from the oil tanks, and discharge at a pressure of from 50 to 150 lbs. per sq. in. through cold filters having fine mesh wire gauze grids; from thence the oil passes through a tubular heater, the oil being inside the tubes and heating steam outside. The temperature of the oil is raised to about 150° Fah. in the heater, and before finally reaching the burner it is passed through a second, or so-called hot, filter.

It is necessary to heat the oil in order to reduce its viscosity so that it can be atomised and forced through the fine passages of the burner, which are so designed as to give it a rapid whirling effect due to centrifugal force when liberated through tangential passages at the lip of the burner, and thus reduce it to a fine spray of conical formation. The air supply to the burner passes through the directing slots cut in a steel truncated cone, 12 to 15 ins. diameter and about 16 ins. long. The burner is fitted at the centre of the entrance to the cone, and the admixture of the air passing through the slots with the oil spray from the burner produces almost perfect combustion.

In the case of naval vessels the closed stokehold system is adopted, the air pressure in the boiler rooms being controlled to suit the output of the burners. For merchant steamers the arrangement of burners and air cones is similar to that described above, but the air supply is heated by the waste gases, as in the ordinary Howden forced draught system applied to coal burning. The area of the furnace front limits the number of burners which can be fitted, and it is desirable that the volume of the combustion chamber should be as large as possible. Oil fuel is also burnt in closed stokeholds under forced draught, or under natural draught in the merchant service. (See also pp. 1351 (Vol. I) 312 (Vol. II).)

Fuel Consumption.

Approximate consumptions for all purposes for the various types of propelling machinery on service with medium quality coal and oil are as follows.

Reciprocating Steam Engines with slide valves. Installations with cylindrical boilers, feed heaters, steam-driven auxiliaries, also refrigerators for ship's stores, and an allowance for heating and domestic purposes in the passenger vessels.

Vessel.	I.H.P.	Engine.	Press.	Superheat.	Draught.	Fuel.	Fuel/ I.H.P.
Cargo	3,000	Triple dependent air pumps	180	Nil	Natural	Coal	1·7
					,,	Oil	1·2
					Howden	Coal	1·6
					,,	Oil	1·05
Cargo .	3,000	Reciprocating Steam Engines with cam operated valves	220	150° F.	Howden	Coal	1·4
					,,	Oil	0·9 Equiv. I.H.P.
Cargo	3,000	Combination triple and exhaust turbine	180	Nil		Coal	1·3
						Oil	0·85

Turbines.—Note the consumption for turbines is given per s.h.p., so that in comparing with reciprocating engines the mechanical efficiency of the latter must be taken into account, also any decrease in propulsive coefficient if resulting from higher propeller revolutions.

Type of Vessel.	Screws.	S.H.P.	Turbines.	Trans-mission.	Boilers.	Pres-sure.	Total Temp.	Fuel.	Fuel lbs./S.H.P. Hr. All Pur-poses

Auxiliary Machinery

1. Reciprocating-Engined Vessels.

In the smaller vessels, driven by reciprocating steam engines, an arrangement of links and levers on one of the crossheads of the main engines drives the air pump, feed pumps, bilge pump, sanitary pump, evaporator feed pump, and in some cases the condenser circulating pump. This arrangement dispenses with the use of several independent units, which being small are very extravagant in the use of steam.

Provision has to be made in the size of the main engine cylinders for the power necessary to drive these dependent pumps, about 4 per cent. for the air, feed, bilge, and sanitary, and a further 3 per cent. for the circulating pump. In addition to these dependent pumps independent auxiliary feed, general service and ballast pumps are required for use in port and during emergency, the ballast pump also being used for circulating the auxiliary condenser.

A feed heater is very desirable, taking steam from the auxiliary exhaust range supplemented by steam bled from one of the main engine receivers.

There are two types of feed heater, the surface heater fitted on the discharge pipe between the feed pump and the boilers, and the contact heater fitted on the hotwell pump discharge, and placed high in the engine hatch so that the heated water has a gravity head to force it into the main feed pump suction. The main feed pump in this arrangement is independent, and is automatically controlled by a float so as to maintain a constant level of water in the heater. The contact heater facilitates the de-aeration of the feed water, which is very necessary with engine-driven air and hotwell pumps.

A feed filter is also desirable to prevent the lubricating oil used on piston rods and piston rings from entering the boilers.

In vessels on the home trade, where fresh water suitable for boiler feeding is available at frequent intervals, an evaporator is not necessary, but where the supply is unsuitable or the intervals are too great for the fresh-water storage capacity an evaporator should be carried for making up the loss of feed water. The evaporator should have a capacity of 3 tons per day per 1,000 h.p. for make-up feed, in addition to any requirements for distilling fresh water for drinking and other purposes for which latter a distilling condenser should be provided.

In a vessel fitted for oil burning the plant for supplying the fuel should consist of a fuel pump in duplicate, an oil heater, hot and cold oil filters, and probably a transfer pump for filling the oil fuel settling tanks from the bunkers every watch, or for transferring oil when trimming the vessel.

An independent circulating pump is desirable, and should be of the centrifugal type. It is capable of being regulated to give the desired vacuum with varying temperatures of sea water, and thus enables the condensate to be maintained always at the temperature which will give the greatest economy. In single-screw vessels, where there is only one circulating pump, it is good practice to fit two engines, one of which is idle and provides a standby.

It is also good practice to fit two fan engines if there is only one fan in a vessel fitted with forced draught.

In larger vessels the feed pumps are independent, and are fitted in duplicate.

In very large vessels the air, bilge, and feed pumps are all independent, and when the decrease in size and cost of the main engines is taken into consideration, the difference in first cost is not very great, and each auxiliary can be regulated to suit the requisite duty so as to obtain the greatest efficiency.

2. TURBINE-DRIVEN VESSELS.

The auxiliary machinery in connection with a turbine installation generally consists of independent units throughout, and is similar to that for reciprocating machinery with the addition of pumps for supplying oil to the forced lubrication system of the turbine and gear-case bearings and to the sprayers which supply oil to the teeth of the gearing. As a considerable amount of heat is transmitted to the turbine bearings from the hot casings and rotors by convection in addition to the heat generated by friction, oil coolers are necessary.

The oil pumps are always in duplicate, and the oil coolers usually, except in the smallest installations.

The circulating and air pumps are larger than those in a reciprocating installation in order to ensure the higher vacuum, which is an advantage with turbines.

The auxiliary exhaust from reciprocating auxiliaries is usually contaminated with oil from cylinder and piston rod lubrication, and while most of this impurity may be extracted by grease filters it is difficult to remove it completely. Turbines for driving auxiliaries do not require any internal lubrication, and on this account as well as being more suitable for using superheated steam they are now preferred for use with high-pressure water-tube boilers, especially for superheated steam where absolutely clean feed water is so desirable. The turbines being small are not so economical as direct-acting pumps, but since the exhaust is used for feed heating, this is not of great importance. Instead of the small turbines of each independent auxiliary it is more economical to generate the auxiliary power in the comparatively larger turbine of the main electric generating set, and drive the fans and the pumps for bilge, ballast, sanitary, fresh water duties, etc., by electromotors, and even the condenser circulating and forced lubrication pumps may be so driven with advantage.

In some cases the electric generators are driven by Diesel engines, and the fuel for driving the auxiliary machinery is reduced thereby. Where this arrangement is adopted the steam for feed heating is obtained by bleeding from one or more stages of the turbines.

Where cylindrical boilers are fitted the extraction of air and condensate from the condenser is usually performed by a reciprocating air pump with or without the assistance of a steam ejector. In other vessels the condensate is withdrawn by a rotary pump driven by turbine or motor, and the air removed by a two- or three-stage ejector. In this arrangement the feed water system from the condenser to the feed pump suction may be practically enclosed from the atmosphere and aeration of the water minimised to prevent corrosion of the boilers.

3. AUXILIARY MACHINERY—GENERALLY.

The capacities of the various pumps are determined to suit their respective requirements which can be readily determined in the case of feed and air pumps from the power and efficiency of the main machinery. The output of the circulating pump also depends on the size of the condenser and vacuum desired.

The number of the pumps which must be provided for bilge pumping in a passenger vessel is determined by the Board of Trade rules.

The diameter of the bilge pump suction pipe in inches is also determined by Board of Trade :—

$$\text{Diameter} = \sqrt{\frac{L(B + D)}{2{,}500}} + 1;$$

where L = length of vessel in feet.
B = breadth of vessel in feet.
D = moulded depth to bulkhead deck in feet.

The output of the pump in tons per hour must not be less than $3 \cdot 8 \times \text{diameter}^2$.

It may be observed that under conditions specified in their rules one of the bilge pumps is to be an emergency pump of a reliable submersible type, and the source of power should be available at all times and placed above the bulkhead deck. This emergency bilge pump is usually electrically driven, the current being taken from the emergency electric generator worked by an oil engine and placed on one of the upper decks.

It will be noted that in passenger vessels burning oil fuel the Board of Trade require that two or three fire pumps depending on the size of the vessel should be fitted having two-thirds the output of the bilge pumps. Independent bilge pumps would be accepted for this purpose if suitably connected, and not used for pumping oil fuel.

In vessels using oil fuel, leakage from the tanks to the bilge when pumped overboard contaminates the water in harbour, and as there are severe penalties for this offence in many ports, a separating tank is usually fitted on such ships to remove the oil from the bilge discharge. In addition to the purification of the bilge water this arrangement permits the oil to be recovered for use.

Sanitary pumps should have an output of from 50 tons per hour per 1,000 passengers and crew in emigrant ships, to 100 tons per hour in first-class liners, and fresh-water pumps about 20 per cent. of this amount.

The ballast pump, which may be included as a bilge pump for Board of Trade purposes, should have an output of about twice that of the bilge pump.

Where the exhaust from auxiliaries is used for feed heating the cylinders are proportioned to do their work when exhausting against a pressure in the exhaust line of about 5 lbs. gauge, which,

having a saturation temperature of 227° F., enables a feed temperature of 225° F. to be maintained with a contact heater and 205° F. with a surface heater, depending upon the ratio of surface to quantity of feed water.

In the case of important auxiliaries such as the lubricating oil pumps, where temporary stoppage might have serious results, it is good practice to legislate for two units being in service at all times, and instead of fitting two pumps, each capable of supplying the total quantity required, instal three pumps each having a capacity of 60 per cent. of the full duty, and work with two while the third is in reserve.

Auxiliary condensers are fitted principally for use in port, and the cooling surface is determined arbitrarily unless for the use of turbo-generators, where exact conditions of steam consumption are known and a definite vacuum maintained.

In cargo vessels with steam winches, 50 sq. ft. is usually allowed for each winch in the vessel, with additional surface for the electric generator, refrigerator, and pumps used in port. An auxiliary condenser so determined is usually more than ample for other purposes at sea.

If the steam consumption for auxiliaries is known an allowance of the following proportions may be adopted :—

Vacuum	Atmosphere	20"	20"
Sea temperature	85°	70°	85°
Lbs. of steam per sq. ft.	30	30	20
Lbs. of cooling water per lb. steam	20	25	35

It may be observed that the reduction in fuel consumption for all purposes at sea, when the auxiliaries are electrically driven and the generators are driven by Diesel engines, is about 3 per cent., as compared with auxiliaries driven by steam, which is subsequently used for feed heating but the saving in port is considerable, as it enables the boilers to be completely shut down.

Bearings.

The Michell Bearing.

Michell Bearings (thrust and journal) are largely used in modern marine practice, and in passenger and merchant ships the Michell Thrust Block is commonly used, both for reciprocating engines and steam turbines.

A standard thrust block used for light craft of all kinds is shown in fig. 5. This is self-lubricating, and can be arranged upon an extension of the engine-bed or upon a separate seating

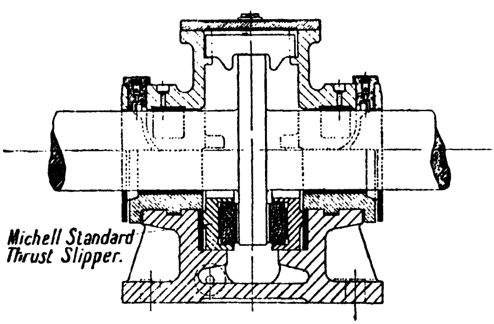

Fig. 5.—Michell Slipper Type Thrust Bearing.

immediately aft of the crankshaft coupling. The oil level in the thrust block is usually kept just above the under-side of the shaft. The bearing surfaces are lubricated by the thrust collar carrying oil upon its edge, and the oil is scraped from this by the scraper at top, thus giving a continuous cascade of oil on the pads. The pads are so pivoted that a film of oil is led into the space between pad and thrust collar, and this oil film can withstand a heavy pressure. A feature of the bearing is that as the speed increases, the pressure per square inch can be increased.

Michell thrust blocks have a single collar shaft with a series of pivoted pads arranged forward and aft, and it will be noticed from the illustration that the pads need only be in the bottom half of the bearing. Thrust blocks, however, can be designed to utilise an existing multi-collar thrust shaft.

Large engines are usually fitted with a thrust block arranged for continuous oil circulation and in these blocks the upper as well as the lower portion of the body sustains thrust load

Oil is introduced into the space behind the pads and compelled to trave radially across the thrust faces. This oil can be cooled and used over and over again. In these blocks the upper and lower parts of the body are keyed together, and liners for adjustment are fitted behind each of the rings which carry the pads.

The Michell principle is also applied to journal bearings, and fig. 6 illustrates one as fitted o a marine oil engine. When speeds are high the ring lubrication is replaced by a continuous

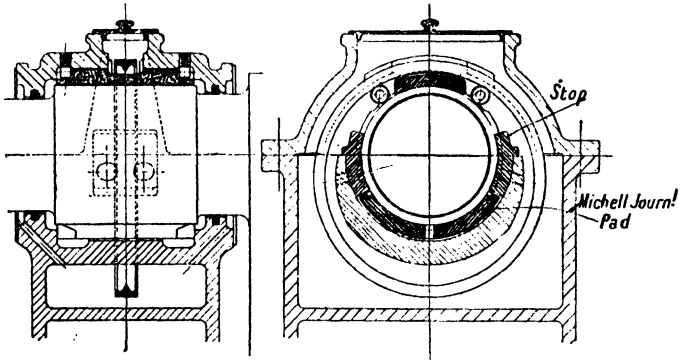

FIG. 6.—Michell Journal Bearing for Marine Oil Engine.

supply of oil from a pump. It will be noticed that the oil is taken on to the shaft by means of a ring, and this ring is always kept in a central position, even if the ship pitches, as the central part of the oiling ring is guided by grooves in rollers arranged upon the shaft.

Considerable economy in length is effected by this bearing, as a pressure of about 500 lbs. per square inch projected journal area is satisfactorily carried at any speed.

The pivoting principle, upon which all Michell bearings work, ensures, perhaps, the nearest approach possible to perfection in lubrication. Astonishingly high pressures are quite safely carried (under test as much as 5 tons per square inch has been successfully imposed), whilst speeds of any magnitude may be run by regulating the quantity of oil supplied. High speed is an advantage, inasmuch as oil film thickness increases with the speed.

SECTION XXIX

PART III

MARINE OIL ENGINES

(By A. P. Chalkley, B.Sc. Editor, 'The Motor Ship.')

The first large ocean-going motor ship, the *Selandia*, was completed in 1912. The war from 1914–1918 retarded further developments, but in 1919 rapid progress in the application of oil engines to ship propulsion was made. The following table shows the gross tonnage and machinery power of ocean-going motor ships built since 1935 :—

MOTOR SHIPS COMPLETED SINCE 1935.

Year.	No.	Gross Tonnage.	I.H.P. of Machinery.
1935	131	782,360	622,380
1936	167	1,075,480	848,860
1937	190	1,169,000	984,000
1938	223	1,461,000	1,198,000
1939	209	1,486,000	1,325,250
1946	110	625,000	572,000
1947	168	810,000	879,000
1948	272	1,250,000	1,100,000

During the period in question, the average tonnage of motor ships under construction throughout the world was 50 per cent. greater than that of steamers, and the last available Lloyd's Quarterly Returns (September 1948) showed that there were steamers of 1,610,732 tons gross and motor ships of 2,558,251 tons gross on the stocks. About 4½ million tons gross of motor ships were on order.

Whilst many different types of marine Diesel engine have been developed, about 90 per cent. of the motor ships built during the past few years have been equipped with six different designs, namely, Burmeister & Wain, M.A.N., Sulzer, Doxford, Werkspoor and Fiat. Since the building of the *Selandia* there has been a progressive improvement in marine Diesel machinery. The average fuel consumption has fallen from 0·42 lb. to about 0·36 lb. per b.h.p. hr., and the weight and space occupied are substantially lower. The *Selandia's* engines weighed 406 lb. per b.h.p., whereas modern two-stroke Diesel machinery does not exceed 130 lb. per b.h.p. Comparing the original *Selandia* with a second ship of the same name built 25 years later, the engine of the new *Selandia* weighs 30 per cent. less, develops 44 per cent. more power and gives the vessel a speed 32 per cent. greater.

In recent years oil engines have largely superseded steam machinery for the propulsion of coasters and other relatively small craft. Whereas with ocean-going ships, the economy in fuel and the increased deadweight capacity have been responsible for the increasing adoption of oil-engined propulsion, with coasters there is the further advantage that Diesel machinery provides greater flexibility of operation for the particular service involved. A coaster calls at a large number of ports with relatively short periods under way, and with an oil-engined vessel of this type the machinery can be shut down immediately the ship enters and started up at a moment's notice when required. Standby losses, which may be heavy in a steamer, are eliminated in a motor ship.

Diesel engines are being employed to an increasing extent in naval vessels. The only examples of motor battleships, however, were three German pocket battleships of the *Deutschland* class,

propelled by the highest-powered Diesel machinery yet constructed. It comprised eight two-acting two-stroke engines of 7,000 b.h.p. driving twin screws through reduction gearing. Apart from submarines, all of which are propelled by Diesel engines, there is an increasing application of this class of plant to auxiliary craft, such as escort and patrol vessels. In America a considerable number of destroyers are equipped with Diesel electric machinery and many submarine mother ships with Diesel generating plant and propelling motors were built during the 1939–45 War. In some of these the total output is 12,000 b.h.p. Even in certain classes of naval, commercial and pleasure craft where considerations of weight have hitherto rendered it necessary for petrol motors to be employed, high-speed Diesel engines weighing comparatively little more than the corresponding petrol type are now gradually being utilised, and, broadly speaking, there is no type of boat or ship requiring machinery from 50 b.h.p. to 50,000 b.h.p. that cannot be propelled by oil engines.

The number and tonnage of motor ships (of over 100 tons gross) in service in the various years from 1935 to 1948 are given in the following table. Later figures are not available :—

TONNAGE OF MOTOR SHIPS IN SERVICE.

Year.	Number.	Gross Tons.
1935	5,511	11,304,691
1936	6,128	12,290,599
1937	6,763	13,748,718
1938	6,912	15,232,953
1939	7,551	16,918,687
1948	7,119	16,789,084

TYPES OF MARINE OIL ENGINE.

All classes of oil engine have been utilised for ship propulsion, namely, four-stroke single-acting and double-acting, and two-stroke single and double-acting, but the four-stroke double-acting design is now no longer built, and the two-stroke engine has gained steadily in favour. In 1931, 46 per cent. of the motor ships built were equipped with two-stroke Diesel machinery, and in 1939 the percentage had risen to 80. The proportion is now approximately the same. In 1947 out of 84 ocean-going motor ships completed (one-half of the world total) 40 were equipped with Doxford type opposed-piston two-stroke engines. Eleven had Sulzer and 9 Harland-B. & W. two-stroke machinery, whilst 9 were equipped with Harland-B. & W. four-stroke engines mostly pressure-charged. Only 5 of the two-stroke engines were of the double-acting type. In Sweden, all of the 28 motor ships built in 1947 were propelled by two-stroke engines.

The utilisation of single-acting two-stroke engines has extended even to the highest powers, and three 12-cylinder Sulzer two-stroke single-acting engines of 12,500 b.h.p. each are installed in the motor ship *Oranje*. Many standard engines are constructed to develop an output of 1,000 b.h.p. per cylinder or more, as the following table shows. All are of the two-stroke design.

SIZES AND POWER OF LARGE MARINE OIL ENGINES.

	Bore. mm.	Stroke. mm.	Speed. r.p.m.	B.H.P. per cylinder.
Doxford . . (opposed piston)	725	2,250	120	1,350
Sulzer . . . (single-acting)	760	1,250	145	1,000
B. & W. . . (double-acting)	620	1,400	100	1,000
Harland-B. & W. . (single-acting)	750	2,000*	110	1,180
Fiat . . . (double-acting)	760	1,200	130	1,400
Kockum-M.A.N. . (double-acting)	720	1,200	115	1,000
Stork . . . (double-acting)	730	1,100	110	1,160

* Including exhaust piston.

All large four-stroke engines built for marine work are now pressure-charged. In some cases the Büchi exhaust gas turbo-charging system is employed, and in others the under piston system is utilised. Details of both of these are given later. It is found in practice, that the additional output thus obtained is at least 30 per cent. on a continuous rating basis, with a corresponding increase in mean effective pressure.

Mechanical injection of fuel is exclusively adopted with all classes of marine Diesel engine, a complete change having been effected in this direction during the past ten years. The elimination of the injection air compressor has represented an improvement of 5 to 7 per cent. in fuel consumption. The pump injection pressure is between 4,000 lb. per sq. in. and 6,000 lb. per sq. in. and there is a separate fuel pump for each cylinder. In some engines, exemplified in the Doxford type, the pumps are grouped together, and in others each pump is adjacent to the cylinder which it supplies, which has the advantage of equalising the length of piping to the various injection valves.

In addition to lower fuel consumption, mechanical fuel injection has the advantage of reduced maintenance charges since there is no injection air compressor, and with this in view, several systems have been developed for converting air injection Diesel machinery to the airless injection type.

Cylinder and piston cooling arrangements differ widely in various engines. In all of the Burmeister & Wain types, lubricating oil is employed for cooling the pistons and the same plan is adopted with the M.A.N. double-acting design and in some of the Sulzer engines. In the Doxford opposed piston unit, distilled water is invariably circulated around the pistons and in many Sulzer Diesel motors salt water is used. For cooling the cylinders and covers, most manufacturers adopt fresh water, and in the case of Doxford engines, distilled water.

Piston speeds vary between 1,000 ft. per min. and 1,200 ft. per min. Particulars of the average mean indicated pressures allowed under ordinary running conditions at sea are given in the table. The relatively high figure permitted for four-stroke pressure-charged engines is notable also the low mean indicated pressure of the two-stroke double-acting unit. Exception should be made, however, of the Burmeister & Wain two-stroke double-acting motor, in which the m.i.p. for normal output may reach about 90 lb. per sq. in. This is due to the fact that there is a 'through' scavenge. Scavenging air enters the cylinder through ports at the centre when uncovered by the piston and is discharged through exhaust valves at the top and bottom of the cylinder respectively. These valves, in the latest design, are of the same diameter as the cylinder, so that no cylinder covers in the ordinary sense are required. The valves are driven by eccentrics from the crankshaft. In all other double-acting two-stroke engines the exhaust gases are discharged through ports, which involve 'loop' scavenging, and with such an arrangement the permissible mean pressure is lower than with the through scavenge.

M.I.P. of Marine Diesel Engines.

Type.	M.I.P. lb. per sq. in.
Four-stroke (pressure-charged)	120–130
Two-stroke (single-acting)	90–95
Two-stroke (double-acting)	70–75

The advantage of the 'through' scavenge is obtained in some single-acting two-stroke engines by the employment of an exhaust valve in the cylinder head. This applies to the B. & W. type, also to the General Motors design, in which each cylinder has four exhaust valves. In the Doxford engine there is also a straight passage for the scavenging air, with the result that a higher mean effective pressure is employed than in the normal single piston engines with 'loop' scavenging. The pressure of scavenging air varies from about 1½ lb. per sq. in. to 2½ lb. per sq. in. In all designs, much experimental work has led to special shaping of the scavenging air inlet ports in order to provide a tangential flow of the air, and the necessary swirl which provides the best degree of combustion when the fuel is injected into the highly compressed air in the combustion chamber. It has been found that the shape of the scavenging air ports is of considerable importance in the attainment of the highest efficiency. In the early days of marine Diesel engine development, the scavenging air for two-stroke machinery in motor ships was usually supplied from separate electrically-driven blowers, and although this system is still sometimes maintained in high-powered vessels, it is more normal for the scavenging pumps, either of the piston or rotary type, to be driven from the engine.

In the general structure of marine oil engines, cast iron framework is usually adopted, sometimes with through bolts extending from the bottom of the bedplate to the top of the cylinders, to take the stresses arising out of combustion. In some recently built engines of large power, however, cast steel columns are adopted and a further development lies in the employment of a welded steel plate construction, of which the Doxford engine is a good example. It is probable that there will be a further development in this direction, in view of the increasing importance now being attached to the application of welding in all engineering industries. Fifteen years' experience with Doxford engines of this type has indicated that no troubles have arisen which can be traced in any way to the employment of the welded frame construction. In the latest B. & W. double-acting two-stroke engine with the exhaust pistons the same diameter as the cylinders, substantial use has been made of electric welding in the manufacture of the framework.

The trunk-piston engine has been found suitable for the propulsion of a considerable number of motor ships, although it is seldom adopted by British owners. On the Continent, such engines are built with outputs up to 6,000 b.h.p. in 12 cylinders, and they have been mainly employed where height is an important factor, as, for instance, in passenger or combined cargo and passenger liners. They usually run at a higher speed than the crosshead type engine, although the piston speed is about the same, namely, from 1,100–1,200 ft. per min. The main disadvantage has, hitherto, been the higher lubricating oil consumption in relation to the crosshead type, but some improvement has been effected in later designs. Both four-stroke and two-stroke trunk-piston engines are manufactured for propelling purposes, but they are mainly of the latter design.

The general features of construction of marine oil engines are similar to those of the larger stationary types. Cast iron is still largely employed for the cylinder covers and liners, although in some cases chrome steel with a tensile strength of 40–50 tons per sq. in. is adopted, and in other instances chrome molybdenum steel with a higher co-efficient of heat transmission. In order to reduce cylinder liner wear, which as an average for seagoing conditions may be taken as one-thousandth of an in. per 1,000 hrs., chrome hardening of cylinder liners has lately been adopted in a considerable number of ships. This system is costly but undoubtedly effects the required results, since operation with chrome hardened liners over periods ranging up to two or three years indicates that liner wear is reduced to an almost negligible figure. Unplated liners of normal good quality cast iron do not require grinding or polishing if turned to a good finish. A notable recent development is the employment of cast steel instead of forged steel crankshafts, although it cannot be said that complete success has yet been achieved in this direction.

It is now becoming common in marine installations to arrange for a tuned exhaust system. This is provided by designing the length of exhaust piping between the engine and silencer to give the correct periodicity to the exhaust gas waves, so that there is no interference, and, in fact, a suction effect is obtained. The requisite scavenging air pressure is thereby reduced, with a corresponding diminution in the output of the scavenging blower. In practice, with a correctly designed tuned exhaust system, the scavenging blower pressure is about 1 lb. per sq. in. less than with an untuned piston. It is usually necessary to subdivide the exhaust pipes in order to obtain the maximum effect. The principle of improved natural aspiration of the exhaust products from the cylinder through the exhaust pipe has been further developed by Kadenacy.

Auxiliary Machinery and Exhaust Boilers.

In the large majority of motor ships in which the propelling machinery installation totals over 2,500–3,000 b.h.p., the necessary auxiliaries, including lubricating oil, piston cooling and cylinder cooling pumps, are separately driven by electric motors. In single-screw vessels with engines up to the power mentioned, however, these pumps are in many cases engine driven. For instance, in the Doxford 2,500 b.h.p. three-cylinder unit, at the back of the engine is the scavenging air pump driven by levers from No. 2 cylinder crossheads. Below it, driven by links and a crosshead, are the forced lubrication pump (25 tons per hr.), the distilled jacket cooling pump (110 tons per hr.) delivering distilled cooling water to the cylinder jackets and pistons, and the sea water pump (160 tons per hr.) which circulates sea water for cooling the jacket water and lubricating oil. All of these pumps are of the piston type, but with the Werkspoor four-stroke pressure-charged engine used largely in single-screw tankers, all the auxiliary pumps are of the rotary design and are driven from two shafts in front of the engine, both of which are gear-driven from the crankshaft. When fresh water is used for cooling, it is delivered to coolers around which sea water is circulated. Where lubricating oil is employed for piston cooling, the whole of the lubricating oil, including that required for lubrication, is passed through a cooler in which the temperature is reduced by about 30–40 ° F. In order to diminish cylinder liner wear, which is considerably greater during the starting period than when running, it is usual to raise the circulating water to a temperature of about 120° F. before starting.

The employment of electrically driven auxiliaries is almost universal in ships in which the machinery is of moderate or high power. As stated, however, this does not, as a rule, apply to the blowers for the supply of scavenging air in two-stroke engines, nor to superchargers with four-stroke plant. Current is supplied from Diesel-driven generators and the tendency in recent years has been to install high-speed units, instead of the slow-running oil-engined dynamos which were provided in the earlier motor ships. Both two-stroke and four-stroke engines are utilised

for the purpose, the speeds being usually in the neighbourhood of 350–400 r.p.m., although higher revolutions are frequently adopted. For instance, in cross-Channel motor ships where reduction in weight is specially important, four-stroke Diesel engines running at 750 r.p.m. have been, on occasions, installed.

Scavenging pumps, when of the piston type, are either driven by beam lever at the back of the engine, or from the crankshaft, between two cylinders (Doxford type), or at the forward end of the engine. With Sulzer two-stroke engines it is now standard practice to have a separate side scavenge pump for each cylinder, driven by levers from the crossheads. Many four- and six-cylinder Doxford engines now have side scavenge pumps, two with a four-cylinder engine and three on a six-cylinder unit. The reduction in length is advantageous in a ship. Mechanical efficiency is perhaps slightly higher and the supply of scavenge air more regular.

Rotary scavenge blowers are usually of the positive displacement design with light cast-iron rotors bolted to the shaft. The speed of rotation is from three to four times that of the engine and the blowers are mainly chain-driven, although on small engines spur wheel drive from the crankshaft is sometimes adopted. There is a shock absorber between the blower coupling and the chain wheel, and the air is admitted from the engine room to the blower through a suction silencer. The clearance of the rotor vanes is about 24 thousandths of an inch with a tip clearance of 30 thousandths of an inch. Such blowers have an efficiency of about 85 per cent. and are usually divided into two separate units, which discharge into the scavenging air manifold through a change valve. The power absorbed in driving the blower is about 7 per cent. of the output of the propelling engine.

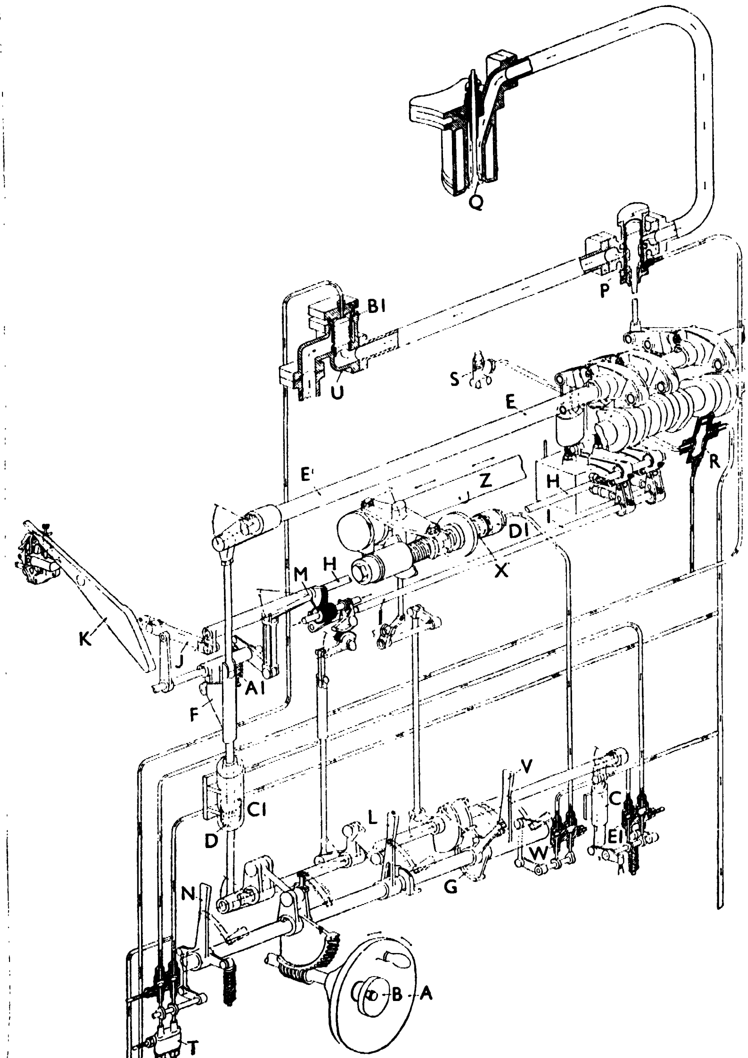
The inclusion of an exhaust gas boiler installation in a motor ship raises the overall efficiency between 5 and 8 per cent.; it is unusual for a vessel to be built in which such an installation is not made. The exhaust gas temperature from four-stroke engines is higher than that from the two-stroke type, consequently, the amount of steam generated is greater. With an average inlet temperature to the boiler of the exhaust of a four-stroke engine of about 750° F., or 400° C., approximately 1 lb. of steam is evaporated per b.h.p. at a pressure of 100 lb. per sq. in. With a two-stroke engine, the inlet temperature of the gases to the boiler being about 550° F. or 290° C., the steam production is usually under $\frac{1}{2}$ lb. per b.h.p. This figure has to be modified in the case of the Doxford engine, owing to the higher exhaust temperature, and a steam production of about $\frac{3}{4}$ lb. per b.h.p. is usually attained. Either simple or composite boilers are utilised, the latter being arranged for simultaneously firing the boiler with oil if the heat from the exhaust gases is insufficient. A further type is built in which the boiler can be fired separately by oil fuel or exhaust gases, but not by both together. If necessary, thermostatic control will enable the change-over to be made automatically. Waste heat boilers may be employed with four-stroke exhaust turbo pressure-charged engines, since the temperature of the exhaust gases falls but little in passing through the turbine before being discharged to the boilers.

In ships of moderate machinery power installations, it is usual to design the auxiliary plant so that sufficient steam is available from the exhaust boiler to drive all the steam-driven auxiliaries needed when the vessel is at sea. These include the steering gear, generator, bilge and ballast pump and compressor, the other auxiliaries being engine-driven. In this way the fuel consumption for the propelling engine represents the overall fuel consumption, including the auxiliaries, and the saving in fuel is substantial. In higher-powered ships (over about 3,000 b.h.p.) the steam is employed for heating the accommodation, in the galley, heating the fuel oil, and in some cases, for driving a stream turbo generator supplying part of the current required throughout the ship. With some installations in which the power is very large, the amount of steam generated is more than sufficient for these purposes, and it is used for distilling water. In the *Oranje*, with three 12,500 b.h.p. engines, 16,000 lb. of steam per hr. are raised from the propelling machinery at full output, and it is delivered to a distilling plant providing 300 tons of fresh water per day, which meets all the passenger requirements. In this instance, taking the exhaust heat recovery plant into consideration, the total thermal efficiency of the whole installation is raised from 31·6 to 54·2 per cent.

The Diesel engines installed in the machinery compartments of motor ships, coupled to generators for the supply of current, are of the normal stationary relatively high-speed type, the two-stroke and four-stroke designs being used to an approximately equal extent. The airless injection vertical type is invariably employed, but horizontal engines have, in some cases, been utilised in large refrigerated motor ships for driving the refrigerating compressors, the adventange being that they are of low height compared with the vertical unit.

Reversing Systems.

The basic principles underlying the systems of reversing marine Diesel engines are similar, although the manner in which they are worked out differ to a certain extent. Broadly speaking, the alteration of the timing of valves and pumps necessitated when reversing is effected either by partially rotating, or moving longitudinally, a shaft upon which the cams operating the necessary mechanism are mounted. Air or combined air and oil servo motors are utilised for providing the necessary movement, except in the case of the Doxford engine, in which, even in the largest izes, hand actuated mechanism is employed.



Reversing Mechanism of a Double-Acting Two-Stroke Marine Diesel Engine.

A typical example of starting and reversing mechanism for a large double-acting two-stroke marine Diesel engine is illustrated on page 310. The control wheel (A) with a small locking wheel (B) is rotated in a clockwise direction when it is desired to start up the engine. This moves the piston (D) in the oil cylinder of the servo motor, also the cam (F) in an upward direction. At the same time an angular movement is given to the control lever shaft (E) so that the fuel and starting levers are set in their correct position. Contact is made by the fuel pump lever with its cam (one lever for each valve) but the starting air lever remains clear of the cam. Through the upward movement of the control cam (F) an angular motion is given to the suction valve eccentric shaft (H) which alters the setting of the suction valve of the fuel pump. The starting air master valve (U) is kept shut, in the ' stop ' position.

The starting lever (N) is moved, causing air to be shut off from the master valve piston and the chamber (B1) above the valve (U) to be exhausted through the control box (T). This allows air to be delivered to the starting air operating valves (P) and (R) for the top and bottom cylinders. Meanwhile, air is supplied to the operating valve pistons through the starting air operating valve control box. In consequence, contact is made between the rollers of the operating valves and the starting air cams. Air is thus delivered to the starting air valves (Q) and (S) in the top and bottom cylinder covers respectively and the engine starts up. The handle (N) is then released and air is cut off from the operating gear. The rollers are lifted clear of the cams, since the springs come into operation. At this stage air is delivered to the chamber (B1) and the supply of compressed air to the engine is thereby shut off.

The engine is brought to the running position by a further movement of the control wheel (A) in a clockwise direction. This causes the suction shaft (H) to turn also the relief shaft (I), but this latter can be advanced or retarded independently through the lever (L) and the spiral gear (M). The engine is stopped by turning the control wheel (A) in an anti-clockwise direction. Fuel is cut off in consequence by the control cam (F) and the movement of the servo air cylinder control gear (O). The arrangement of this gear is such that air is admitted to the cylinder (D) at the position when the tappets lifting the levers are just in contact with the levers. When the ' stop ' position is reached air is cut off from the cylinder (D) and the chamber (O1) is exhausted by the control box (E1). The object of this is to avoid reverse loading whilst the engine is being started.

When reversing the control wheel (A) is brought to the ' stop ' position. There is an interlocking gear which prevents the engine being started unless this operation is carried out. The reversing lever (V) is moved, thus allowing air to enter the reversing cylinder (X) via the control box (W). The camshaft (Z) then moves in a longitudinal direction, bringing the respective cams in their correct positions for running in the astern direction. Movement of the lever (V) in the opposite direction cuts off the air supply to the reversing cylinder and the spring causes the cam shaft to move back to its original position. The Aspinall governor is provided to eliminate racing. The operating lever (K) is of cam shape, allowing contact with the roller at the end of the link (J). When the lever (K) is moved the link revolves the suction shaft (H) and the relief shaft (I) so that the fuel is shut off from the cylinders. When the engine is slowed down, the lever (K) is moved by the governor and the engine is set for normal running again by the operating spring (A1).

In the Doxford engine, with two horizontally disposed fuel valves for each cylinder, one at the back and one at the front, the former is used only when the engine is running ahead. There are two camshafts, at back and front respectively, and the reversing lever when moved causes the camshaft to slide longitudinally and brings the ahead or astern cams under the fuel and starting valve rollers as required. When the air starting lever is actuated, air is admitted to a relay cylinder and the starting air lever rollers come in contact with their respective cams, allowing starting air to enter the cylinders where the pistons are in a position to receive it. There is, finally, a manœuvring lever which controls the lift and timing of the fuel valves, and thereby the speed of the engine.

In the Burmeister & Wain two-stroke marine Diesel engine, an arrangement is employed by which, on reversing, the fuel cams remain stationary, the camshaft being turned through an angle of 120°. The cams are mounted on sleeves to allow this motion to take place, and as a result a single cam suffices both for ahead and astern rotation. The reversing lever, through the movement of which this operation takes place, also causes the cam disc of the starting air distributor to be set in the correct position for supplying air to the engine to start up in the reverse direction. In the Sulzer system for two-stroke single-acting engines, side-by-side cams are mounted on the cam shaft for ahead and astern operation of the starting air valves respectively. As a symmetrical cam is employed for actuating the fuel injection pump, no movement of this takes place during the reversing period. The actual operation of reversal is carried out by the actuation of the telegraph lever, which is a special feature of the Sulzer design. By its operation, pressure oil is delivered to a valve controlling the piston of a servo motor, according to the direction required. By the movement of this piston, the actual motion of the camshaft is effected.

In most four-stroke engines reversal is carried out on a similar principle, namely, by the longitudinal movement of the camshaft on which side-by-side ahead and astern cams are carried. In the Werkspoor four-stroke engine, however, the valve levers are pivoted on eccentrics which are fitted to the reversing shaft. This is rotated 180° and when the reversing lever is moved (through the action of a servo motor), the valve levers are raised. Due to the fact that they are mounted eccentrically at a slight angle, the levers move sideways and then, when lowered by the continued

movement of the servo motor, make contact with a second cam for operation in the astern direction. This motion involves the employment of two adjustable tappets for actuating the valves.

Air for starting and manœuvring purposes in marine Diesel engines is supplied at a pressure of 25 atmospheres, or about 355 lb. per sq. in. Lloyd's Rules call for compressed air receivers for starting air of sufficient capacity to permit 12 consecutive startings of each main engine without replenishment. The capacity of the starting air reservoirs differs substantially according to the ideas of the respective shipowners and varies so widely as from 4·5 cub. ft. per b.h.p. to 8·7 cub. ft. per b.h.p. An average figure of 6 cub. ft .per b.h.p. may be taken.

SUPERCHARGING.

It was stated previously that all marine Diesel engines of the four-stroke type are now pressure-charged. This development was rendered necessary in order to enable the engine to compete commercially with two-stroke machinery. Various supercharging systems have been utilised with marine machinery, but at present only two receive serious application. In each case the increase in continuous rated power is in the neighbourhood of 35–40 per cent., although in corresponding stationary installations with the Büchi exhaust pressure-charging system, an increase of 50 per cent. is accepted as a reasonable continuous rating. In this system, which has been adopted with engines developing up to 6,000 b.h.p., use is made of the heat energy in the exhaust gases which are supplied direct to a turbine coupled to a blower, from which combustion air for the Diesel engine cylinders is discharged at a pressure of from 5 to 7 lb. per sq. in above atmospheric. The exhaust and inlet valves are open simultaneously for short periods and the air pressure exceeds the average exhaust pressure above one-third of full load. Nearly one-third of the air supplied has a scavenging effect which cools the piston crown, cylinder cover and exhaust valve. The blower adapts itself automatically to changes of load. As the additional weight required for the turbo blower is not proportionate to the increased output, it is found that the total saving in weight of a supercharged engine compared with an unsupercharged type, is nearly 25 per cent. The inlet and exhaust valves must have a higher lift than those of a corresponding unsupercharged engine. As typical figures, assuming the opening of the inlet valve of an unsupercharged engine taking place at 21° before top dead centre and closing 21° after bottom dead centre, and having a lift of 62 mm., an exhaust turbo-charged engine would have inlet valves opening 70° before top dead centre, closing 25° after, and having a lift of 76 mm. The exhaust valves of the unsupercharged engine would open 41° before bottom dead centre and close 15° after top dead centre, and have a lift of 62 mm. The turbo-charged engine exhaust valves would open 20° before bottom dead centre, close 55° after top dead centre and have a lift of 76 mm.

In the Büchi exhaust turbo blower system, which has been very widely adopted, the exhaust pipes from the cylinders are subdivided and coupled up in such a manner as to prevent back pressure which might arise if the exhaust of all cylinders were discharged into one pipe. As an example a ten-cylinder 6,000 b.h.p. engine has four exhaust pipes, namely, from cylinders 1, 2 ; 9, 10 ; 3, 6, 7 ; 4, 5, 8 ; the firing order is 1, 4, 3, 2, 5, 10, 7, 8, 9, 6. With the engine in question, at full load (115 r.p.m.) and a mean indicated pressure of 8·25 kg. per sq. cm., or 117 lb. per sq. in., the exhaust gas quantity is 640 kg. per min. and the pressure 1·23 kg. per sq. cm. abs. The quantity of air delivered is 536 cub. metres per min. at a pressure of 1·30 kg. per sq. cm. abs. The lowest temperature at the exhaust valves is 390° C. and 450° C. at the turbine inlet. The increase in temperature after leaving the exhaust valves is to be noted. These figures relative to a Harland–B. & W. engine were given in a paper by Mr. C. C. Pounder before the Institute of Marine Engineers on 'Some Recent Diesel Installations and their Characteristics.'

An exhaust gas turbo-supercharging system has now been developed by D. Napier & Sons (English Electric Co.) and standardised units are being manufactured.

The alternative system of supercharging, under piston super-charging, has been applied to a number of different types of engines up to 5,000 b.h.p. with ten cylinders. The bottom of the main combustion cylinders is closed in, thus forming with the pistons low pressure compressors which supply supercharging air through the inlet valves. The suction and discharge manifolds are incorporated in the engine frame and there is a valve chest for each cylinder containing two suction and two discharge valves. By means of throttle valves between adjacent valve chests, the excess air on the downward stroke is pumped from one cylinder to another and low compression results. The supercharging pressure varies from 4 to 5 lb. per sq. in and there is an overlap between the opening of the exhaust and inlet valves, but to a smaller degree than is necessary with the exhaust turbo-charging system.

Supercharging has not, hitherto, been applied commercially with two-stroke engines, but experimental work has been carried out with this end in view, and it is probable that two-stroke supercharged engines will be built in future with an output 25 per cent. greater than that of unsupercharged engines of this class.

Diesel Engine Fuels.

Shipowners, oil engine manufacturers and oil suppliers are not agreed on the subject of fue oil specifications to give the most satisfactory operation. The characteristics of fuel vary in their influence according to the class of machinery, but three of the most important are: (1) viscosity, (2) ignition quality, (3) cleanliness.

The specific gravity, flash point, carbon residue, sulphur, pour point, and distillation range also have a marked influence. The difficulty of providing a standard specification that would apply to all engines may be illustrated by the fact that an oil which would comply with a manufacturer's demand for a certain carbon or sulphur content, may be far superior in its viscosity characteristic than is needed for that particular design. Most, but not all characteristics are subject to exact measurements, and among those which cannot be exactly specified are cleanliness, and in a certain degree, ignition quality, although methods have lately been developed for measuring ignition quality which may lead to standardisation. In regard to viscosity, the characteristics of two of the requirements are opposed, since the degree of viscosity should be such that the fuel will be properly atomised by the injection valves, and at the same time will penetrate thoroughly into the compressed air. Hence, minimum and maximum viscosity characteristics are sometimes specified for fuels. Ignition quality is more frequently specified in America than in the United Kingdom and may either be designated by Diesel Index or Cetane Number. There is no exact relationship between these two standards. As a rule, fuels with high specific gravities have a higher heat value than the lighter oils, to the extent of a maximum of 5 per cent., but the specific fuel consumption is somewhat higher, and the output per gallon is approximately the same. High sulphur content may, in some engines, give rise to corrosion, but it is substantially eliminated if cylinder liners are chrome hardened.

Standard specifications have been issued by the British Standards Institution as given below. The designation ' Heavy Diesel Fuel ' refers to the grade for slow-running direct-coupled Diesel engines in ocean-going ships, whilst the designation ' Marine ' applies to the engines of the faster-running type.

British Standard Specifications of Diesel Oil.

	Marine.	Heavy Diesel Fuel.
Flash point	150° F.	150° F.
Hard asphalt	--	4 per cent.
Ash	0·03 per cent.	0·1 per cent.
Viscosity Redwood No. 1	60 secs.	max. 750 secs.
Viscosity S.S.U.	67	840
Water	0·5 per cent.	1 per cent.
Pour point	30° F.	—
Conradson carbon	3 per cent.	8 per cent.
Sulphur	2 per cent.	—
Gr. Cal. value B.Th.U. per lb.	18,750	18,250

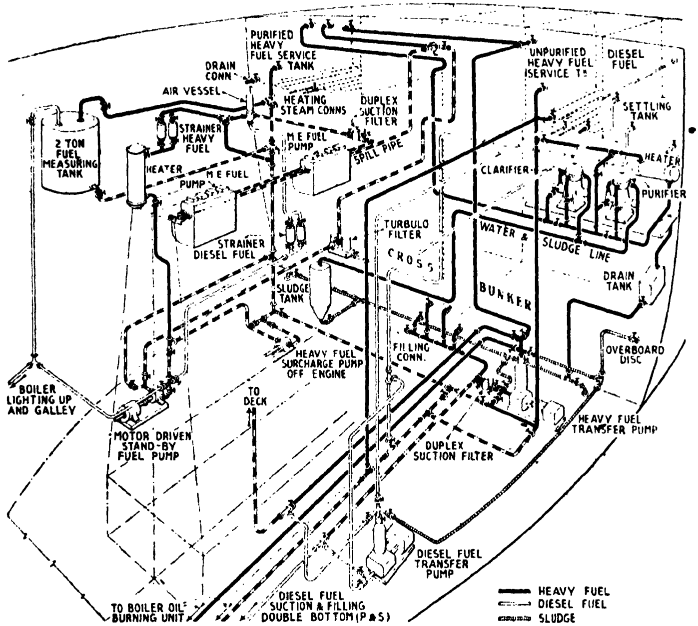
In all motor ships built in America for the United States Maritime Commission, a heavier residual oil is specified than is commonly employed by British shipowners, and the classification of the American Society for Testing Materials is adopted as a basis. The fuel is known as ASTM 4D and the following are the main characteristics specified :—

ASTM. Specification of Low-Grade Fuel for use in Diesel Engines.

Flash point ° F. minimum	140
Water and sediment per cent. by volume, maximum	0·5
Viscosity at 100 degrees F. Saybolt, seconds	140
Carbon residue per cent. by weight, maximum	3·5
Ash per cent. by weight, maximum	0·05
Pour point, ° F. maximum	35
Sulphur per cent. by weight, maximum	2
Cetane number, minimum	30

The usual practice in ships for the purification of the fuel oil is to pass it through a centrifugal separator, also as a rule through a fine filter, and in some cases, it is heated before being delivered to the fuel pumps. In modern American motor ships using the heavier grades now specified, the fuel is passed through a heater before reaching the separators, the temperature being raised to 180° F. After being discharged from the centrifuges, the oil is reheated, the temperature being thermostatically controlled, so that it is not below 180° F. when it enters the fuel valves. In the United States, a great deal of work has been carried out in connection with the use of heavier grade residual oils in Diesel engines, and the experience gained by engine manufacturers working on the problem indicates that the main factor limiting its use is its viscosity. The limit set is stated to be 1,000 seconds, Saybolt Universal, and it is claimed that fairly high percentages of carbon or residual asphaltum present no serious difficulties.

After prolonged experimental work a system has been adopted for the burning of boiler fuels in marine Diesel engines, in the machinery of the tankers of the Anglo-Saxon Co.'s fleet, based upon the investigations of Mr. John Lamb. The fuel is heated to a temperature of 180° F. and passed first through an ordinary De Laval centrifugal separator for the removal of water and suspended matter, and secondly, through a clarifier, when the last of the ash in the fuel is removed, the clarifier being a centrifugal machine with a modified form of bowl. The first ship to be so equipped, the *Auricula*, was placed in service in 1946.



Arrangement of system for using boiler oil in the machinery of the motor ship *Auricula*.

The arrangement adopted is seen in the illustration. The results after a year's working were published in a paper read before the Institute of Marine Engineers by John Lamb in December 1947,* and it was stated that the annual saving in the case of a 4,000 i.h.p. installation was £5,030 per annum. The cost of the equipment was £7,259, but this should be reduced. The mean wear of four cylinder liners was 0·648 mm. and the wear rate per 1,000 miles was 0·0093 mm. Mr. Lamb is confident that the amount of the liner wear compared with that in an engine burning Diesel oil is not excessive, and that the engine will operate over ten years before renewal of liners becomes necessary. The only stipulation made in regard to fuel is that the viscosity should not exceed 1,500 secs. Redwood 1 at 100° F.

Bearing on the question of the importance of various characteristics in Diesel engine fuel, it is to be added that detailed tests carried out at the Delft Laboratory showed that so long as the sulphur content of a fuel is not higher than about 1 per cent., the effect of this sulphur on cylinder wear is not important in comparison with that of other factors. As, however, the sulphur increases above 1 per cent., its effect on wear becomes more marked, and when it exceeds 2 per cent. the sulphur content has a strong influence on the rate of wear. On the other hand, in most cases a really high sulphur content is encountered only in heavier fuel, having also a high viscosity, also a measurable ash content. Hence, it is not always fair to attribute abnormally rapid liner wear solely to the sulphur compound present.

* 'Burning Boiler Fuels in Marine Diesel Engines.'

The Diesel fuel oil which has been mainly supplied for motor ships bunkering at British ports during the war, known as Pool Marine Diesel Oil, has the following approximate specification :—

SPECIFICATION OF POOL MARINE DIESEL OIL.

Specified gravity at 60° F.	max.	0·930
Closed flash point	min.	150 ° F.
Viscosity Redwood 1 at 100° F.	max.	85 secs.
Pour point	max.	30° F.
Sulphur	max.	1·8 per cent.
Conradson carbon	max.	2·5 per cent.
Water	max.	0·5 per cent.

It will be noticed that this specification agrees more closely with the British Standard Specification for Marine Diesel Fuel than that of Heavy Diesel Fuel. It will also be observed that there are various characteristics included in the American specifications which are omitted in the British, and vice versa. For instance, in this country no reference is made to ignition quality (Cetane Number). In America viscosity is almost invariably stated in terms of Saybolt Universal, and in Great Britain by Redwood No. 1. Roughly speaking, the following relationship holds good.

Redwood No. 1 = 1·2 Saybolt Universal at 100° F.

Weights and Sizes.

Diesel engines now built for installation in mercantile ships can be constructed with a weight 70 per cent. less than the earliest types in 1914. For instance, the four-stroke engines utilised at the latter date averaged 400 lb. per b.h.p., whereas the modern double-acting two-stroke engine weighs 115 lb. per b.h.p. Four-stroke single-acting pressure-charged machinery of modern design has a weight less than half that of corresponding engines manufactured 25 years ago.

In recent years the application of electric welding has substantially lightened Diesel machinery of various types. In the case of the Burmeister & Wain double-acting two-stroke engine, with the latest welded construction the weight has been brought down from 135 lb. per b.h.p. to 116 lb. per b.h.p., and in the welded frame Doxford opposed piston engine a reduction of 20 per cent. was effected. There will undoubtedly be new developments in the employment of welded construction in Diesel machinery, whilst it is probable that further diminution in specific weight will be effected by the increased adoption of light metals, even in slow running engines. For higher speed units this development will become even more marked.

The following table shows the average weights of various classes of marine Diesel engine as now manufactured. The weight of the engines of the pocket battleship *Deutschland* is included as a matter of interest, to indicate the extent to which reduction can be effected with special types of engine.

Trunk piston engines are considerably lighter than those of the crosshead design, the low figure of 130 lb. per b.h.p. being attained with the two-stroke single-acting class. Apart from other features, the considerably higher speed of rotation normally adopted with the trunk design leads to a marked weight reduction. It will be observed that there is little difference between the specific weights of two-stroke trunk-piston relatively high-speed engines and the modern two-stroke double-acting slow-running unit.

WEIGHTS OF MARINE DIESEL ENGINES.

Type.	Trunk or Crosshead.	R.p.m.	Weight per b.h.p.
Four-stroke single-acting	Crosshead	110	300
,, ,, (1914 type) . .	,,	115	400
,, ,, (pressure-charging) . .	,,	120	215
Four-stroke single-acting	Trunk	150	225
,, ,, (pressure-charging) .	,,	150	170
Two-stroke single-acting	Crosshead	110	150–160
,, ,, ...	Trunk	160	130
,, ,, ...	Opposed piston	100	170
Two-stroke double-acting	—	115	115–135
,, ,, (high-speed) . .	—	450	17·6*

* Machinery of *Deutschland* class of pocket battleship, 48·5 lb., including propellers, shafting, etc.

It has already been recorded that during a comparatively short number of years the size of marine Diesel machinery for given power has diminished substantially, and roughly it may be stated that engines may be installed in the same machinery space to-day as was required 30 years ago for machinery of half the power. The two-stroke double-acting engine is naturally the shortest of all types, and the following table gives particulars of some typical motor ships of comparatively recent construction, indicating the engine-room lengths, the power and the propeller speed. The question of height has also to come into consideration and the two-stroke double-acting design is at a disadvantage in comparison with the single-acting type. This may be of importance in passenger liners, and one of the reasons why single-acting engines were installed in the highest-powered motor ship yet built—the *Oranje*—was that the lower height of this type in comparison with the double-acting unit enabled an extra deck to be built above the engine room.

ENGINE-ROOM LENGTHS IN TYPICAL MOTOR CARGO SHIPS.

Ship.	Gross Reg. Tonnage.	Length b.p. ft.	ins.	Beam ft.	ins.	Speed Knots.	B.h.p.	E.R. Length ft.	ins.	Engine Type.	Propeller speed	Twin or single-Screw.

GEARED DIESEL AND DIESEL-ELECTRIC DRIVE.

British shipowners have hitherto adhered exclusively to the direct drive in motor ships, the Diesel engines being coupled to the propellers without intermediary gear. In America, however, the large majority of ocean-going oil-engined tonnage is being equipped with geared machinery. On the Continent the application of the geared drive is steadily increasing and Diesel-electrically propelled ships are being used to a substantial extent. It should be added, however, that the direct drive is still most commonly employed.

The advantages claimed for the indirect drive are (1) reduction in weight, (2) lower height, (3) less space occupied, (4) parts, being lighter, are more easily handled, (5) increased standardisation is possible, and (6) one engine can be stopped for overhaul or repair without seriously reducing the ship's speed. Against these advantages is to be set the higher overall fuel consumption due to losses in the gearing and the slightly lower efficiency of the high-speed engine.

The usual arrangement with geared Diesel installations comprises two or four units running at about 250 r.p.m. coupled to a single or to two propellers through reduction gear with a ratio of about 2½–1, to give a propeller speed in the neighbourhood of 100 r.p.m. Either hydraulic or electro-magnetic slip couplings are fitted between the engines and the gearing, so that the latter is not subjected to shocks due to cyclic irregularity. In the hydraulic couplings, lubricating oil is used as the medium for transmitting the power from the engine shaft to the propeller. In the electric slip coupling, which is a comparatively new development, there is an air gap between the two rotary members, one of which is mounted rigidly on the engine shaft and the other connected to the gear. The couplings act as disconnecting clutches by means of which the engines can be connected to or disconnected from the propeller instantly. The external member coupled to the engine shaft is connected to the ship's direct current auxiliary power supply for excitation. The inner member, which has a squirrel cage winding, rotates inside this field. The mechanical rotation of the field or outer member creates a rotating magnetic field which induces current in the squirrel cage winding. The interaction of the resulting magnetic field creates forces which cause the squirrel cage to follow the field except for a small slip. The efficiency of the coupling is in the neighbourhood of 97½ per cent. During manœuvring period, the engines need not be stopped and this is advantageous from the point of view of economy in starting air and reduced cylinder liner wear.

The Diesel-electric drive has been employed in this country to a small extent for tugs and in America also, for fairly high powered vessels of this class, and special ships such as dredges. In these vessels the direct current system of transmission is adopted, but in the ocean-going cargo ships which have been built in Europe with electric propulsion, alternating current is utilised. The usual arrangement is to install two, three or four three-phase 2,000 volt alternators driven by single-acting or double-acting two-stroke engines of about 3,000 b.h.p. each, running at a speed of 250 r.p.m. The propeller is driven by a synchronous motor at about 125 r.p.m. for full ship's speed. The current for operating the auxiliaries is applied from the main generators, hence, in such ships, A.C. motors are utilised for driving pumps, compressors, etc. The system described has been applied to a number of fast cargo ships and passenger liners.

In America, in some Diesel-electrically propelled ships of fairly high power, the current is supplied to high-speed electric motors which drive the propeller or propellers through reduction gearing, the object being to utilise light-weight motors occupying comparatively small space.

It is the opinion of many engineers and shipowners that in view of the increasing experience which has been gained with high-speed Diesel machinery, the adoption of this class of plant in conjunction with gearing or electric transmission will be developed to a considerable extent in the future, and that substantially higher speeds than 250 r.p.m. will be employed. The 1,000 r.p.m. relatively high-powered engine is visualised, whilst Mr. H. R. Ricardo has proposed the installation of a large number of small oil engines running at 1,500 to 2,000 r.p.m. coupled to the dynamos supplying current to a single propelling motor.

The comparative advantages of different classes of machinery for ships have been the subject of two important symposiums, namely, 'The Engining of Post-war Cargo Vessels of Low Power' (*Transactions of the Institute of Marine Engineers*, July 1944), and 'The Engining of Cargo Vessels of High Power' (*Transactions of the Institute of Marine Engineers*, January 1948). In both of these, the question of the employment of Diesel-electric machinery is examined at some length for relatively low- and high-powered plant respectively.

A comparatively large number of high-speed engines both for naval and commercial service have been developed in recent years, ranging from about 400 b.h.p. to 1,000 b.h.p. The large majority are of the four-stroke type and the following are the average characteristics, subject to variations, according to the individual design.

MODERATE POWERED HIGH-SPEED MARINE ENGINES.

Engine speed . .	. **1400–1500 r.p.m.**
Piston speed . .	. **1700–1800 ft. per minute**
Mean effective pressure .	**80 lb. per sq. in. unsupercharged** **110 lb. per sq. in. supercharged**
Specific volume .	. **5 cu. ins. per b.h.p.**
Weight . .	. **12–18 lb. per b.h.p.**

By the adoption of a high degree of supercharge, giving 50 per cent. more power than when unsupercharged, and the employment of specially high speeds the weight can be brought down to 10 lb. per b.h.p. The maximum piston speed employed with fast running engines is 2,000 ft. per minute.

American high-speed engines utilised in Naval craft, also in some mercantile Diesel-electrically propelled ships, are mainly of the two-stroke single-acting design, but the speeds for units up to 1,200 b.h.p. do not as a rule exceed 750 r.p.m. A double-acting two-stroke high-speed engine was used in Germany for motor torpedo boats. This is a development of the M.A.N. slow running engine and has a maximum output of 1,200 b.h.p. at 1,200 r.p.m., with a normal rating of 900 b.h.p. The mean effective pressure referred to brake power at maximum output is 51 lb. per sq. in. and it is recorded that the weight is only 4 lb. per b.h.p.

AUTOMOBILES.

Trend of Design.

General.—The general trend of design both for motor cars and commercial vehicles is, of course, towards greater efficiency and the outstanding tendencies of present-day design may be exemplified by improved performance, *i.e.* acceleration and braking in respect of motor cars, and lightness of weight and economy of operation in respect of commercial vehicles. The British system of taxation has in the past encouraged the development of small, long stroke engines for motor cars, and large carrying capacity for a minimum weight with the maximum fuel economy in all commercial vehicles, whether used for the carriage of goods or passengers. Since the revision of the motor-car tax, however, engines in this category show a tendency to become more nearly 'square,' *i.e.* with a stroke/bore ratio approaching unity, and engine size is on the upward grade. Petrol engines are universal in motor cars, and although extensively used in the lighter commercial vehicles, compression ignition engines consuming fuel oil are virtually universal in the heavier commercial vehicles.

The number of models now produced under 1·5 litres capacity (approximately 12 h.p. rating) has decreased, although it is safe to say that the majority of cars produced fall within this category. The great majority of cars under 2 litres capacity have four cylinders and those above have six or eight cylinders, the latter both in line and V-formation. In the case of commercial vehicles the much larger horse-power rating encourages the use of more cylinders, and engines of 4, 5, 6 and 8 cylinders are common. In the interests of standardisation of parts and the lowering of production costs it is quite usual to employ cylinders of the same size throughout a range of engines having various numbers of cylinders.

Recent research has proceeded along the lines of investigation into the causes of, and providing remedies for, mechanical wear, particularly with regard to bearings and cylinder bores, together with the development of light alloys and steels having high strength/weight ratios.

With constantly increasing road speeds, the question of safety, particularly in regard to stability, steering and braking, receives more and more attention.

Tables or charts purporting to exhibit trend of design are generally highly misleading, because they fail to take into consideration the number of cars of each model produced; no estimate of the popularity of any particular feature can be formed unless the sales of the model in which it is embodied are known.

Considering private cars and commercial vehicles as a whole, the following tendencies will be observed:—

Cylinders.—These are generally cast in one block with the crankcase, even in the larger engine sizes, thereby providing greater rigidity. Generally speaking, side valves are used in the lower-priced vehicles, but overhead valves are virtually universal in engines of high performance, however small, and are, of course, universal in compression ignition engines. Amongst the higher-priced cars there is a move towards the employment of overhead inlet and side exhaust valves. Close-grained low nickel iron is still the most popular material for cylinder blocks, straight cast iron having been superseded for this purpose. Cylinder liners are used extensively in commercial vehicle engines, the latest practice being to employ a liner having a slip fit in the cylinder block with dry liners, thus simplifying maintenance problems. Inserted valve seats in heat-resisting alloy are also common in commercial vehicles, often being faced with stellite. Considerable advance has been made in the development of heat-resisting valve steels and both exhaust and inlet valves are often stellite faced and tipped.

Pistons.—These are universally of light aluminium alloy generally of proprietary make, and developments in manufacturing technique have tended towards the use of pressure casting in preference to gravity castings. Improvement has occurred in the design and treatment of piston rings, reducing piston and cylinder wear and consequently decreasing oil consumption.

Crankshafts.—Following American practice, the employment of cast semi-steel or innoculated cast-iron (somewhat misleadingly called cast-iron) crankshafts is increasing, and much research

in this material has been carried out by the National Physical Laboratory. It has long been recognised that a stiff and heavy crankshaft is essential to eliminate torsional vibration, hence a high tensile alloy steel has no advantage, and the newer semi-steel alloys show satisfactory resistance to wear with relatively low production cost. Forged steel crankshafts are almost universally nitride hardened in commercial vehicle applications and recent research has indicated the necessity for attention to the finish of pin and journal fillet radii.

Bearings.—Strip bearings, comprising a thin steel strip to which is bonded an exceedingly thin lining of bearing material, are almost universal both for car and commercial vehicle engines. The bearing material is invariably white metal or copper-lead, indium flashed on the bearing surface, but the discovery of the ideal alloy is still the subject of research. Bearing pressures have been much increased, particularly in compression ignition engines, as also have rubbing speeds, and the governing factor for bearing life appears to be adequate high pressure lubrication.

Clutches.—There has been little change in the design of clutches. In the majority of small and medium sized friction clutches, the single-plate type is preferred for its simplicity. These embody a very light free member having a bonded asbestos friction surface and, of course, are used dry; refinements include sprung centres and laminated steel plates to which the friction material is attached. Multi-plate clutches are only employed on engines of the highest horse-powers and are occasionally centrifugally assisted.

Transmissions.—Although a large number of epicyclic gear boxes are in use and are giving satisfaction, both in private cars and commercial vehicles, there is little doubt that the general tendency is towards a good type of syncromesh arrangement. This affords perfect ease in changing up or down, is not unduly costly, and has the great advantage of being easy to adjust and repair, besides being generally trouble free.

A fluid flywheel in conjunction with a so-called 'self-changing' gear box is employed by a number of manufacturers both on private cars and commercial vehicles of the passenger-carrying type.

Rear Axles.—The spiral bevel continues to be the most popular rear axle arrangement for private cars, and with suitable precautions in manufacture is satisfactory. Its main objection is the necessity for a tunnel in the body to accommodate the propeller shaft. The hypoid bevel gear, which permits the centre-line of the bevel pinion to be situated below the axle centre, reduces the tunnel height, but to make possible a flat floor in the rear of the car the only solution appears to be a worm drive, where the propeller shaft is at its lowest. There has, therefore, been some increase in the use of worm gears. With regard to commercial vehicles the worm gear is virtually universal throughout the heavier ranges being underslung for passenger vehicles and overslung for goods where a high ground clearance is necessary. Amongst the lighter and cheaper commercial vehicles the spiral bevel still retains its popularity although the hypoid bevel gear is gaining ground. The use of two-speed axles is on the increase in commercial vehicle applications.

Front Axles.—Independent suspension of the front wheels is now practically universal on motor cars. The various designs, described later, being suitable for laminated, helical and torsion bar springing. The conventional I-beam front axle of the reversed Elliot type is still universal on commercial vehicles generally embodying laminated springs of the semi-elliptic type.

Frames.—Although the use of rigid, relatively heavy, and often cruciform-braced frames continues, there is a strong tendency towards what is commonly known as 'chassisless' construction in which the body and its framework, or at least the lower portion of it, forms the main structure to which the various units are attached. The practice persists, however, of securing the utmost degree of stiffness in the frame itself and attaching all the units, engine and gear box, radiator, etc., by means of flexible connections in which rubber is incorporated, thus avoiding direct metallic contact between the components. This method of construction contributes largely towards the successful silencing of modern vehicles, by eliminating resonance in one member due to vibration in another.

Brakes.—These are mostly of proprietary make, viz. Lockheed, Girling and Bendix, except on commercial vehicles where often the manufacturers' own brakes are operated by a proprietary make of vacuum servo or compressed air system. In every case brakes are fitted to all wheels. The three systems named are illustrated later. Front brakes are usually of the two leading shoe type.

Suspensions.—Since the advent of independent wheel suspension, this important subject has received greater attention with consequent improvement in suspensions generally. Independent front suspension is now virtually universal on motor cars, and both helical and torsion bar springs are used successfully in the various designs. Laminated springs are also used but to a far less extent; they are usually confined to conventional rear suspension systems. It is now the practice to incorporate a torsion bar stabilising device in conventional rear suspension systems, both for motor cars and double-deck bus chassis.

There has been considerable controversy regarding the general chassis layout and the disposition of the various units; cars have been produced with the whole of the driving mechanism, engine, gear box, transmission and driving wheels, at the front of the vehicle and also in the reverse position, *i.e.* at the rear of the vehicle. The results, however, appear to be negative and it is unlikely that the present practice will change for some time. Much more ingenuity has been shown by Continental designers in this respect who are masters of the unconventional.

With regard to commercial vehicles the present tendency in this country is towards placing the power unit below floor level, with the cylinders inclined or horizontal, either at the front of the vehicle or amidships, and applies to both passenger and goods vehicles. This practice of mounting the power unit horizontally below floor level in the amidships position is common among American heavy passenger vehicle manufacturers, virtually the only varient being to mount the power unit transversely at the rear of the vehicle with the cylinders vertical; in both cases the drive being transmitted to the rear axle.

Notes on Thermodynamics.

Boyles Law. PV = a constant.

Relation between Pressure, Volume, and Temperature of a perfect gas. PV = CT

where T = absolute temperature deg. F.
P = absolute pressure in lbs. per sq. ft.
C = a constant for the gas.
C = 53·29 for air.

so for air PV = 53·29T.

Isothermal equation for a perfect gas. $PV = P_0V_0$

where P_0 and V_0 are initial pressure and volume.

Adiabatic equation for a perfect gas. $PV^{\gamma} = P_0V_0^{\gamma}$

$$\text{where } \gamma = \frac{\text{Specific heat of gas at constant pressure}}{\text{Specific heat of gas at constant volume}}$$

for air $\gamma = 1{\cdot}4$.

Adiabatic Compression.—In calculating curves of pressure and temperature the changes are adiabatic and PV^{γ} = a constant, and if T be absolute temperature $TV^{\gamma - 1}$ = a constant.

When air in a cylinder is compressed to one-fifth of its original volume (a compression ratio of 5/1)

$$P_1 = P \times \left(\frac{V}{V_1}\right)^{\gamma}; \text{ so } P_1 = 14{\cdot}7 \times 5^{1{\cdot}4}.$$

If the initial air temperature were 519° F. abs. then after rapid compression to one-fifth of its volume its final temperature would be :—

$$T_1 = T \times (5^{\gamma - 1}) = 519 \times 5^{0{\cdot}4}$$

and the converse of this is true.

In a *petrol engine* the heat is added and rejected at the ends of the stroke, while the volume does not vary, hence its operation is on a *constant volume cycle*.

The thermal efficiency of this cycle depends upon the compression ratio only. If E = thermal efficiency, $E = 1 - \left(\frac{1}{r}\right)^{\gamma - 1}$ where r = compression ratio.

TABLE I.

ENGINE EFFICIENCES FOR VARIOUS COMPRESSION RATIOS.

r = compression ratio. E = Thermal efficiency, Constant volume cycle.

r.	E.	*r*.	E.	*r*.	E.
3·8	0·4138	5·1	0·4788	6·4	0·5238
3·9	0·4201	5·2	0·4829	6·5	0·5270
4·0	0·4256	5·3	0·4868	6·6	0·5300
4·1	0·4313	5·4	0·4906	6·7	0·5328
4·2	0·4367	5·5	0·4944	6·8	0·5355
4·3	0·4420	5·6	0·4980	6·9	0·5382
4·4	0·4471	5·7	0·4984	7·0	0·5398
4·5	0·4521	5·8	0·5050	7·5	0·5534
4·6	0·4569	5·9	0·5084	8·0	0·5647
4·7	0·4615	6·0	0·5116	9·0	0·5740
4·8	0·4660	6·1	0·5149	10·0	0·6020
4·9	0·4704	6·2	0·5180	11·0	0·6170
5·0	0·4747	6·3	0·5211	12·0	0·6290

It will be seen from the above table that the efficiency increases rapidly with the increase in compression ratio until a ratio of about 5 to 1 is reached; thereafter the rate of increase falls off

until at a ratio of about 12 to 1 the advantage of increasing compression ratio becomes relatively slight.

In the case of compression ignition (diesel) or constant pressure type engines air alone is come pressed, usually to a ratio of 15 or 16 to 1. The fuel is subsequently injected at a pressure of several thousand pounds per sq. in. The duration of the injection over part of the working stroke is controlled, and the temperature of the air due to compression ignites the fuel, the oil consuming the oxygen from the air.

The heat is discharged at constant volume at the end of the stroke, so the working cycle is partly at constant pressure, and partly at constant volume.

$$\text{The heat added } H = K_p(T_2 - T_1)$$

$$\text{and the heat discharged } H_1 = K_v(T_3 - T)$$

$$\text{The efficiency } E = 1 - \frac{K_v(T_3 - T)}{K_p(T_2 - T_1)}$$

$$\frac{K_v}{K_p} = \frac{1}{\gamma}; \text{ therefore } E = 1 - \frac{(T_3 - T)}{\gamma(T_2 - T_1)}$$

where

T = initial air temperature (abs.).
T^1 = temperature after compression (abs.).
T_2 = temperature after combustion (abs.).
T_3 = temperature at exhaust (abs.).

And it follows from this that in this cycle the thermal efficiency will depend on the maximum temperatures as well as the compression ratio. With increase of temperature the efficiency decreases.

Note.—The compression ratio in any internal combustion engine, viz. r, is

$$= \frac{\text{volume swept by piston + combustion space}}{\text{combustion space}}.$$

Power Calculations.

The piston indicated horse-power developed in the engine is expended as in other prime movers by friction in the engine itself and by the resistance of the vehicle, the latter being composed of: (1) friction in the mechanical parts of the chassis; (2) the rolling resistance to the wheels on the road; (3) the surmounting of gradients; (4) the resistance of the air, and, when all these are accounted for, the remaining power is available for (5) acceleration. Item (1) consists largely of heating losses due to churning of the lubricant in gear box and rear axle. According to circumstances from 10 to 15 per cent. of the brake effective horse-power is thus accounted for, hence from 85 to 90 per cent. of total brake horse-power reaches the driving wheels.

Tractive Factor.—This is the ratio of the torque in pounds at the driving wheels/the gross weight of the vehicle in lbs., viz. $\frac{Tw}{W}$ and this ratio determines the whole performance of the vehicle.

Rolling Resistance.—For pneumatic tyres the resistances given in Table II are typical, but approximate only.

TABLE II.

ROLLING RESISTANCES, PNEUMATIC TYRES.

Concrete	9·5 lbs. per 2240
Asphalt	10·25 " " "
Stone sets	16·70 " " "
Good macadam	22·00 " " "
Poor "	46·00 " " "
Clay	66·00 " " "
Sand	200·00 " " "

Gradient Resistance.—A gradient of '1 in 7' means that in passing over 7 ft. a height of 1 ft is attained, hence G the gradient $= \frac{h}{s} = \sin \alpha$, where α = angle of slope and if P = force required to propel vehicle up the slope and W is the gross weight of vehicle in pounds $P = \frac{W}{G}$

Air Resistance.—This varies as the speed[2] thus

$$\text{Air resistance} = kV^2A$$

Where k is a constant varying from 0·0024 to 0·0006, and A is the frontal area in sq. ft.

The total tractive resistance thus becomes

$$T_R = W\left(\frac{R + 2240}{G}\right) + kV^2A$$

Here, W = gross weight in *tons*, R = rolling resistance lbs. per ton, G = gradient, V = velocity in ft per sec., and A = the projected area of vehicle (with k = 0·0024 to 0·0006).

Acceleration.—The force required $f = ma$, where m = gross weight in lb./grav. and a = acceleration required. Whence, $a = f/m$. f in this case being the tractive effort available at the road surface.

Tractive Effort.—The tractive effort at the road is equal to the torque of the engine in lb. ft. × total gear ratio between engine and back axle/radius of tyre in ft. × mechanical efficiency of chassis, *i.e.* 0·85.

Horse-power.—For a 4-cycle engine,

$$\text{H.P.} = \frac{2\pi RnW}{33{,}000}$$

where

H.P. = brake horse power.
R = radius of dynamometer arm in ft.
W = weight lifted on dynamometer arm in lbs.
n = revolutions per minute.

Horse-power may also be expressed as :—

$$\text{H.P.} = \frac{T_f \times 2\pi n}{33{,}000}$$

where

T_f = torque in lb. ft.

$$\text{or H.P.} = \frac{p \times V \times n}{33{,}000 \times 24}$$

where

p = brake mean effective pressure (b.m.e.p.) in lbs. per sq. in.
V = total swept volume of the engine in cu. ins.

Torque.—$T_f = \dfrac{5250 \times \text{H.P.}}{n}$ lb. ft.

$$T_i = \frac{63{,}000 \times \text{H.P.}}{n} \text{ lb. in.}$$

where

T_i = torque in lb. in.

Brake mean effective pressure.

$$p = \frac{262\cdot1 \times T_i}{d^2sN} \text{ lbs./sq. in. } (d \text{ and } s \text{ in cms.})$$

$$p = \frac{192 \times T_f}{d^2sN} \text{ lbs./sq. in. } (d \text{ and } s \text{ in ins.})$$

$$p = \frac{16\cdot53 \times 10^6 \times \text{H.P.}}{d^2sNn} \text{ lbs./sq. in. } (d \text{ and } s \text{ in cms.})$$

$$p = \frac{1\cdot009 \times 10^6 \times \text{H.P.}}{d^2sNn} \text{ lbs./sq. in. } (d \text{ and } s \text{ in ins.})$$

where

N = number of cylinders.
d = bore of cylinder.
s = stroke of piston.

In an internal combustion engine, the maximum torque is always delivered at considerably below the maximum speed, a graph of the torque showing a curve which first rises and then falls as the speed increases. As the sum of the vehicle resistances is a rising curve, it follows that the two curves must cross at some point beyond which speed cannot be increased.

Wheel Adhesion.—Apart from any question of engine power the performance of a vehicle is limited by the amount of adhesion between the driving wheels and the road surface. The coefficient of friction at this point is comparatively high, varying from about 0·7 on normal roads to over 1·0 in certain circumstances. The latter figure occurring with certain forms of tyre surface

and *slightly* yielding macadam roads. Except in special vehicles (four-wheel drive) only a portion of the gross vehicle weight is available for promoting wheel adhesion, hence the maximum acceleration is

$$a = \frac{w\mu_r \times 32\cdot 2}{W}$$

where w is the weight in lbs. on the driving wheels, μ_r is adhesion factor of wheels, and W is the gross vehicle weight in lbs.

The same remarks apply to the availability of the tractive effort generally which cannot exceed $w\mu_r$ in any circumstances.

Horse-Power Rating Formulæ of Various Countries.

(S.M.M. & T. and R.A.C.)

Notation :—

H = horse-power rating. d = bore of cylinder.
N = number of cylinders. S = stroke of piston.
V = swept volume of one cylinder. r = engine revolutions.

Australia (Queensland, South Victoria)
British Guiana
Canada
Columbia
Dominican Republic
Federated Malay States
Great Britain
Gibraltar
Hayti
Lebanese Republic
Northern Ireland
Porto Rico
United States of America

$$H = \frac{Nd^2}{2\cdot 5}$$
where d is in in.

$$H = \frac{Nd^2}{1613}$$
where d is in mm.

NOTE.—In Great Britain taxation is now £10 per car, irrespective of horse-power, plus the usual petrol tax.

Australia (Western).
$$H = \frac{Nd^2S}{12}$$
where d and S are in in.

Austria, Luxembourg.
$$H = 0\cdot 3Nd^2S$$
where d is in cm. and S is in meters.

Belgium.
$$H = Kd^2SNc$$
where d is in decimetres.
S is in decimetres.

Category.	Revs. per Min.	K.	C.
(1) Light vehicles . .	Under 1,500	4·25	1
(2) ,, ,, . .	Over 1,500 and under 2,400	4	1·5
(3) ,, ,, . .	2,400 and over	3	2·4
(4) Heavy vehicles including tractors light and heavy . .	—	4·25	1

NOTE.—When vehicles of (2) and (3) categories are over 6 years old (2) becomes (1) and (3) becomes (2).

Bulgaria.
$H = 0\cdot 5Nd^2S$ (for private cars)
$H = 0\cdot 3Nd^2S$ (for trucks)
where d is in cm. and S is in meters.

Cochin China, Tangier. $H = KNd^2Sr$

where
K = 0·00020 for 1 cylinder.
K = 0·00017 for 2 cylinders.
K = 0·00015 for 4 cylinders.
K = 0·00013 for more than 4 cylinders.

d and S are in cm.
r = maximum engine revs. per second.

Czecho-Slovakia.

NOTE.—Taxation is based on the capacity of the engine.

$$\text{Capacity in litres} = \frac{0 \cdot 785 N d^2 S}{1{,}000{,}000}$$

where d and S are in mm.

Denmark, Finland.

As Austria for four-stroke engines. Special factory ratings are adopted for two-stroke engines.

Eire. $H = \frac{Nd^2}{2 \cdot 5}$ (for engines having 1 piston per cylinder)

$H = \frac{Nd^2}{1 \cdot 6}$ (for engines having 2 pistons per cylinder)

where d is in in.

France. $H = KNd^2Sr.$

where $K = 0 \cdot 00015$, d and S are in cm.

r = engine revs. per second, which are fixed at :—

30 for cars and light vans up to 1,250 kgs.

25 for public service or goods chassis which, including tyres, weigh from 1,250 kgs. to 2,250 kgs. unladen.

20 for public service or goods chassis which, including tyres, weigh over 2,250 kgs. unladen.

NOTE.—All fractions of horse-power are taken to the nearest whole figure.

Germany.

NOTE.—Taxation is based on the capacity of the engine.

$$\text{Capacity in c.c.} = 0 \cdot 00078 N d^2 S$$

where d and S are in mm.

Hungary. $H = \frac{Nd^2}{20}$, where d is in cm.

Italy, Rhodes (Aegean Sea). $H = 0 \cdot 08782 N V^{0 \cdot 6541}$

where V is in c.c.

and $V^{0 \cdot 6541}$ is an exponential function of V.

Japan (Tokio). $H = \frac{Nd^2}{3}$, where d is in in.

Spain. $H = 0 \cdot 08(0 \cdot 785 d^2 S)^{0 \cdot 6} N$ (for four-stroke engines)

$H = 0 \cdot 11(0 \cdot 785 d^2 S)^{0 \cdot 6} N$ (for two-stroke engines)

where d and S are in cm.

NOTE.—$0 \cdot 6$ is an exponential function of the product in the brackets.

Sweden. $H = \frac{Nd^2Sr}{K}$

where

$K = 180{,}000$ (for Diesel engines).

$K = 200{,}000$ (for four-stroke engines using petrol or oil).

$K = 210{,}000$ (for two-stroke engines ignited by compression).

d and S are in cm.

r = max. engine revs. per minute.

South Africa. $H = \frac{Nd^2S}{200{,}000}$

where d and S are in mm.

Switzerland. $H = 0 \cdot 4 N d^2 S.$

where d is in cm. and S is in metres.

Syria (Aleppo). $H = 0 \cdot 06 N d^2$

where d is in cm.

Fuel.

Petroleum hydrocarbons are divided into four classes in the gasoline range, paraffins, naphthenes, aromatics, and olefins. They can be present in different proportions, straight run gasoline having mainly paraffins and naphthenes, when obtained from one source and a high proportion of aromatics when obtained from another.

Olefins are unsaturated hydrocarbons and are found in cracked gasolines.

Specific Gravity.—The specific gravity of a gasoline is expressed as the ratio of the weight of unit volume of the gasoline at 60° F. to the weight of unit volume of water at 60° F.

A difference in specific gravity of two gasoline samples does not necessarily mean that the lower value gasoline is of better quality except when it is known that both samples have been distilled from the same crude oil.

Specific gravities usually fall between 0·720 and 0·780.

Distillation.—The volatility of a gasoline can be determined by a distillation test.

Cold starting can be assessed from the '20 per cent. point,' whilst intercylinder distribution and crankcase dilution can be assessed from the '70 per cent point,' these being the temperatures at which the quoted percentages are recovered.

The remaining points of the distillation curve are not so important. I.B.P. and F.B.P. are determined and give an indication of the 'cut' of the gasoline. The I.B.P. cannot be determined with great accuracy. The F.B.P. shows if any heavy ends are present. 'Loss' is that proportion of light or volatile components which are not recorded, whilst 'residue' is that proportion remaining when the distillation is completed.

Octane Number.—The octane number gives the knock rating or detonation limited performance of gasoline and is determined by a standardised procedure and equipment. It is determined by referencing the test gasoline against a blend of iso-octane and heptane or known secondary reference fuels. The percentage of iso-octane, by volume, in the blend is given the term 'octane number.'

Tetra Ethyl Lead.—Tetra Ethyl lead ($Pb(C_2H_5)_4$) is used on a very large scale as an additive in gasoline to suppress detonation, thereby giving an appreciation in octane number.

The appreciation of octane number by the addition of T.E.L. varies with different gasolines dependant on their composition..

This appreciation diminishes with successive additions of T.E.L. until a point is reached where further additions are no longer justified on an economic basis.

Present-day motor gasoline has a T.E.L. content slightly in excess of 1 c.c. per imperial gallon.

Tetra Ethyl lead is combined with ethylene dibromide and dichloride in such proportions that when burnt in the cylinders the T.E.L. will be evacuated as lead bromide and chloride. It is poisonous and dangerous to handle.

Sulphur.—Gasoline is refined to remove both free sulphur and sulphur compounds. However, traces remain and if in a free state or as mercaptan or sulphuric acid derivatives, they can be corrosive. They also give an objectionable odour to the gasoline.

The corrosive properties of a gasoline are usually determined by the copper strip test. There must be no change in the surface of the copper strip after immersion at stated conditions in the fuel.

Gum.—Gum is undesirable in gasoline due to its effect on the functioning of the engine, such as valve sticking and deposits in the carburetter and induction system, causing incorrect metering of the gasoline. It is non-volatile and therefore remains when gasoline is evaporated.

The gum content of cracked gasoline may increase in storage due to the presence of unsaturated hydrocarbons in the gasoline.

Colour.—Unleaded gasoline is usually water white in appearance and will remain so unless deterioration, due to the presence of unsaturated hydrocarbons, takes place.

Leaded gasolines are usually coloured by the addition of a dye to distinguish the different grades. Present motor gasoline is coloured orange.

Bromine Number.—The bromine number is obtained as a laboratory test to determine the presence of cracked gasoline in any given sample.

It is necessary to know the value for the cracked gasoline itself before this assessment may be made, owing to the fact that this value varies considerably.

Vapour Pressure.—The vapour pressure of a gasoline is controlled to comply with considered safe limits. Too high a value may give rise to vapour locks in the fuel system. The maximum safe value is determined relative to the existing climatic conditions.

Fuel Oil.—Many attempts have been made in the past to employ very low grades of fuel in compression ignition engines, but although these are practical in emergency, the use of a standardised grade of fuel oil is now established. A thin oil of low viscosity with a specific gravity of 0·85 is typical, the viscosity would be in the range of 2·0–6·0 centistokes at 100° F. The calorific value of this fuel differs but little from that of petrol and approximates to 19,000 B.Th.U. per lb.

Petrol Engines.

Multi-cylinder engines are universal for cars and commercial vehicles and generally embody 4, 6 or 8 cylinders: occasionally 2, 3, 5 or 12 cylinders are used but these are the exception to the rule and are usually employed in special purpose vehicles. The popularity of the two-cylinder engine for motor-cycles is increasing, particularly the vertical transverse twin. The disposition of the cylinders and the consequent order of firing affects balancing and torsional stresses. Since automobile engines are generally operated on the 4-cycle principle, each cylinder fires every two revolutions.

In a two-cylinder engine having both cylinders on the same side of the crankshaft and with the crank-pins co-incident, the result is one impulse per revolution and the reciprocating parts entirely unbalanced. With two cylinders on the same side of the crankshaft and the crank-pins at 180°, there are two impulses in one revolution and none in the next, but the reciprocating parts are balanced. In the case of a two-cylinder engine in which the cylinders are on opposite sides of the crankshaft and the crank-pins at 180°, there is one impulse per revolution and perfect reciprocal balance.

Four-cylinder in Line Engine.—The crank pins are arranged at 180°, cranks 1 and 4 being coincident as also are cranks 2 and 3. Here there are two impulses per revolution 180° apart and the reciprocating parts are balanced. The firing order may be 1, 3, 4, 2 or 1, 2, 4, 3.

Six-cylinder in Line Engine.—In this case the cranks are arranged at 120° and there are, therefore, three impulses per revolution 120° apart. The firing order may be, 1, 5, 3, 2, 6, 4, in which case cranks 1 and 2 are in the same plane; cranks 3 and 4 in another plane, and cranks 5 and 6 in a third plane, or 1, 5, 3, 6, 2, 4, in this case the two end cranks 1 and 6 are in the same plane; cranks 2 and 5 in another plane and 3 and 4 in a third plane. A variation of the latter arrangement will provide a firing order of 1, 4, 2, 6, 3, 5. Firing orders of 1, 5, 3, 6, 2, 4 or 1, 4, 2, 6, 3, 5 are preferable to 1, 5, 3, 2, 6, 4 as explosions occur in alternate ends of the shaft and never in adjacent cranks as in the latter arrangement.

Eight-cylinder in Line Engine.—In this arrangement the cranks are disposed at 90° with the result that there are four impulses per revolution 90° apart. There are very many possible arrangements of firing order but for various considerations, which it is impossible to discuss here, one of the following orders is preferable to any of the others.

(i) 1, 3, 2, 4, 8, 6, 7, 5.
(ii) 1, 3, 7, 4, 8, 6, 2, 5.
(iii) 1, 3, 2, 5, 8, 6, 7, 4.
(iv) 1, 3, 7, 5, 8, 6, 2, 4.
(v) 1, 6, 2, 4, 8, 3, 7, 5.
(vi) 1, 6, 7, 4, 8, 3, 2, 5.
(vii) 1, 6, 2, 5, 8, 3, 7, 4.
(viii) 1, 6, 7, 5, 8, 3, 2, 4.

These arrangements are obtained by means of a crankshaft having the four centre cranks in the same plane and the four end cranks in a second plane at 90° to the first, the crank pins being coincident as follows :—

Nos. 1 and 8, nos. 2 and 7, nos. 3 and 6, and nos. 4 and 5.

The most favoured firing order is 1, 6, 2, 5, 8, 3, 7, 4.

Eight-cylinder 'V' Engine.—There are two possible crank arrangements for the V-8 engine, the first in which the cranks are all in the same plane, similar to the four-cylinder in line engine, with cranks 1 and 4 coincident, also cranks 2 and 3. In the second arrangement cranks 1 and 4 are 180° apart in one plane and cranks 2 and 3 are also 180° apart but in a second plane at 90° to the first. From the point of view of balance the latter arrangement is to be preferred.

With the 180° or flat crankshaft the firing order may be 1R, 4L, 3R, 2L, 4R, 1L, 2R, 3L, or 1R, 4L, 2R, 3L, 4R, 1L, 3R, 2L.

With the 90° crankshaft the firing order is 1R, 1L, 4R, 4L, 2L, 3R, 3L, 2R.

Balancing.—It is impossible to discuss here the many and complicated problems relating to balancing; briefly, however, the main sources of vibration or unbalance are the cyclic torque variations which act upon the crankshaft assembly due to varying piston loads and connecting-rod obliquity, the unbalanced effects of centrifugal forces on rotating members, such as the crankshaft and camshaft, and the unbalanced effects caused by the reciprocating members of the engine, such as the pistons and upper parts of the connecting-rods, the valves and springs. The reciprocating forces produce rocking moments about some point in the length of the crankshaft, these are modified by the angularity of the connecting-rods which produces harmonic vibrations of 2, 4, 6 or more times the fundamental frequency. The higher orders of harmonics above the second need not be considered, but analysis of the second harmonics shows that with two cylinders on the same side of the shaft and the cranks 180° apart, fundamental vibrations are balanced but octave harmonics are not. In a two-cylinder horizontally opposed engine with cranks 180° apart, fundamentals and octaves are balanced.

In a four-cylinder in line engine, the fundamentals balance but the octaves do not; while in a six-cylinder engine both fundamentals and octaves are truly in balance.

The second harmonics of twice engine frequency act along the cylinder axis and produce a force :—

$$F = \frac{Mr\omega^2}{g}\left(\frac{r}{l}\cos 2\theta\right)$$

where θ = crank angle.
M = reciprocating mass (piston + small end).
r = crank radius.
l = length of connecting rod.
ω = angular velocity of shaft.

hence F is of maximum value when $\cos 2\theta = \pm 1$, *i.e.* at 0°, 90°, 180° and 270°.

Crankshafts.—The greater the number of cylinders, and consequently the longer the crankshaft, the greater is the tendency to torsional vibration, and this can only be overcome by increasing the dimensions, and the weight, of the shaft. The result is a shaft in which the specific stresses are low and for this reason the use of a low grade of cast semi-steel is justifiable. It is usual also to employ a friction or bonded rubber damper attached to the free end of the shaft to damp out the torsional vibration, but it is, nevertheless, impossible to eliminate it altogether, hence the use of flexible engine mountings embodying rubber cushioning blocks, to insulate the engine from the chassis frame.

For the reasons stated above the 'V'-cylinder formation is to be commended for engines having 8 or more cylinders; not only does this arrangement permit the use of a comparatively short stiff crankshaft but it enables the overall dimensions of the engine to be retained within reasonable limits for installation purposes.

From the symmetrical form of the crank arrangement it follows that the centrifugal forces due to crank-webs, crank-pins and big ends are balanced, but where adjacent crank-pins are

coincident the centrifugal and inertia forces impose a very heavy load on the common bearing which must be of adequate dimensions to support this. If adjacent cranks are placed 180° apart the mutual balance of opposing cranks is more direct, and bearing loads are much reduced. The rear main bearing must also be of adequate dimensions in order to withstand any misalignment between the flywheel and clutch.

Bearings.—Generally speaking, bearings are the product of specialists and, in view of the very high specific surface pressure imposed by modern design, 'Thin wall' or 'Strip' bearings are becoming universally popular both for big-end and main bearings. These bearings comprise a thin steel shell only about one-sixteenth of an inch thick lined with white metal, the thickness of which is kept to a minimum consistant with proper adhesion about 0·008 in. They are finished to extremely fine limits and with the perfection of surface finish that may now be obtained by diamond turning and boring operations, it is possible to assemble the shells without any further treatment whatever, the flexibility of the shell enabling the true form to be maintained by the rigid and accurately machined big-end or bearing housing. The peripheral length of the bearing must be very carefully controlled in order to provide the necessary 'nip' on assembly.

For heavy duty loading, such as occurs in high-speed compression ignition engines, copper lead or 'lead bronze' lining materials have been developed, the bearing surface being treated with an electrically-deposited flash of lead and/or indium, thermally infused into the lead.

These bearings are located by means tangs, pressed out of the shells at the bearing joint, fitting in machined slots in the big-end or bearing housing and the respective bearing caps, alternatively cylindrical dowels may be used. The crankshaft is located by means of flanged centre or rear main bearings, alternatively split bronze washers retained against rotation by means of tabs or dowel pegs may be used. The end thrust imposed by clutch withdrawal is also taken on the rear-most bearing flange or pair of split washers.

Bearing clearances are usually of the order of 0·001 in. per 1 in. shaft diameter.

The value of the PV or load factor, which is the product of bearing pressure and rubbing velocity, determines the behaviour of the bearing and is limited by the coefficient of friction and the viscosity of the oil.

Cylinders.—In the interests of rigidity, in addition to economy in manufacture, the cylinder block is usually cast in one with the upper half of the crankcase, the only disadvantage of this form of construction being that of weight, but even this is outweighed by the advantages gained.

Owing to the complicated design a free flowing iron is essential and as phosphorus is objectionable a high silicon content is used. Nickel chromium iron, of which the following analysis is typical, is in general use :—

Chromium Alloy Cast-Iron.

Total carbon	3·15
Combined carbon	0·55
Manganese	0·98
Nickel	0·09
Chromium	0·25
Sulphur	0·10
Phosphorus	0·25
Silicon	2·20

In addition to nickel and chromium, molybdenum is employed for producing close fracture grey cylinder irons having excellent wearing qualities. The percentage composition being usually within the following limits :—

Total carbon	3·1 –3·4
Graphitic carbon	2·5 –2·8
Combined carbon	0·5 –0·7
Silicon	1·8 –2·4
Manganese	0·5 –0·8
Phosphorus	0·12–0·20
Sulphur	0·10–0·12
Chromium	0·10–0·50
Nickel	0·25–1·50
Molybdenum	0·10–0·70

The tensile strengths of these irons vary from 15·5 to 18·0 tons per sq. in.

Where cost is not the primary consideration the use of detachable cylinder liners offers many advantages. A much harder material can be used such as a very hard cast iron centrifugally cast to ensure homogeneity, or nitrogen hardened steel.

Liners may be of wet or dry types, the latter having the advantage that they may be pre-finished to such a degree of accuracy as to provide a slip-fit in the cylinder block, thus enabling the liners to be fitted by hand with the engine *in situ*, without the need for special tools.

Cylinder Heads.—The contour given to the inside of the cylinder head determines the form of the combustion chamber, which itself has a profound effect on the running of the engine. A homogeneous mixture of air and petrol vapour is essential and gas turbulence during and after

compression is therefore of paramount importance. There is no unanimity of practice, but for side valve engines a variation of the form introduced by Ricardo is generally adopted (fig. 1). The combustion chamber more or less of D form, extends over the valves and something less than one-half of the cylinder bore ; the sparking plug being more or less equidistant between the axes of the cylinder and the two valves.

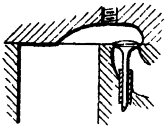

FIG. 1.

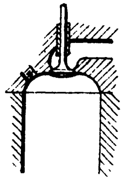

FIG. 2.

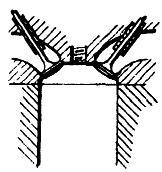

FIG. 3.

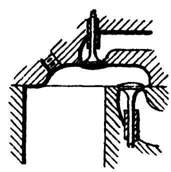

FIG. 4.

There are innumerable variations of the overhead value arrangement in which the combustion chamber approximates to a hemispherical form with the valves either vertical or inclined and the sparking plug either to one side or in the centre. Fig. 2 illustrates a typical commercial arrangement and fig. 3 the arrangement usually adopted in high performance engines.

The overhead inlet and side exhaust valve arrangement has some supporters and has the advantage of permitting the use of large inlet valves without increasing the cylinder centres ; it also enables a high compression ratio to be combined with a good form of combustion chamber and excellent scavenging. Fig. 4 illustrates this arrangement.

In all cases it is essential to provide adequate cooling for the exhaust valves and care must be taken to ensure that the water passages completely surround them circumferentially, care must also be taken to avoid any pockets where steam could accumulate.

Adequate depth of the cylinder head is necessary to ensure rigidity, ample water passages between cylinder and head are desirable and very careful attention should be paid to the positioning and quantity of cylinder head studs, a general guide for the latter being ' as many as possible.'

Cast iron is still the most popular material for cylinder heads although aluminium alloy is not uncommon.

Poppet Valves.—The effective valve area governs the entire performance of the engine and the mean gas velocity through the valve ports ranges from 250 to 370 ft. per sec. for maximum engine speeds of 3,000 to 4,000 r.p.m.

The mean gas velocity may be obtained from the following formulæ :—

$$Vg = \frac{VsN}{360Av} \text{ ft. per sec. . . . . (1).}$$

Where:

Vs = swept volume of one cylinder in cu. in.
N = crankshaft r.p.m.
Av = valve area in sq. in.

$$\text{or } Vg = \frac{VsN}{911 \cdot 4Av} \text{ . . . . (2).}$$

where Vs and Av are in c.c. and sq. c. respectively.

If the gas speeds are calculated at a crankshaft speed of 2,000 r.p.m. these formulæ become :—

$$Vg = \frac{5 \cdot 55Vs}{Av} \text{ ft. per sec. . . . (1a).}$$

$$\text{or } Vg = \frac{2 \cdot 19Vs}{Av} \text{ ft. per sec. . . . (2a.)}$$

The effective valve area can be calculated, assuming the usual face angle of 45°, as follows :—

Effective area = $3 \cdot 1416(0 \cdot 707Dh + 0 \cdot 3535h^2)$ sq. in.

where D = port diameter in ins. and h = valve lift in ins.

Valve Acceleration.—The question of the inertia forces due to the weight and acceleration (or deceleration) is of considerable importance in valve-spring and cam design. Acceleration and spring strength can be obtained as follows :—

If n = r.p.m. of crankshaft.
n_2 = r.p.m. of camshaft.
E = effective throw of cam (fig. 5).
θ = instantaneous angle of cam and tappet.
W = weight of reciprocating parts, lbs., *i.e.* valve, tappet, spring cotter and collar, and ½ the weight of the spring.
g = 32·2 ft. per sec.²
A = acceleration at any angle θ.
F = inertia force at θ.

then $A = \dfrac{4\pi^2 n^2 E \cos\theta}{3{,}600 \times 4 \times 12}$

$= \dfrac{n^2 E \cos\theta}{4{,}378}$ ft. per sec.^{2}

and $F = \dfrac{WA}{g}$

$= \dfrac{Wn^2 E \cos\theta}{141{,}000}$ lbs.

At full lift $\theta = 0$ and $\cos\theta = 1$.

whence $A \doteq \dfrac{n^2 E}{4{,}378}$ ft. per sec.^{2}

$F = \dfrac{Wn^2 E}{141{,}000}$ lbs.

Whereas a nickel-chrome high tensile steel is usually quite suitable for inlet valves, exhaust valves, in view of the higher operating temperatures, require the use of special heat-resisting steels, such as silicon-chrome, stainless steel, cobalt-chrome or the high nickel-chromium steels belonging to the austenitic class.

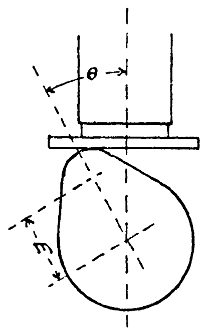

FIG. 5.

In the case of austenitic valves it is necessary to give the value stems a high surface finish in order to avoid valve guide 'pick-up' and to provide hardened tips for the tappet or rocker contact area. It is usual to weld a button of hardened steel or to stellite the tip of the stem. For heavy duty engines requiring long life a flash of hard chrome is deposited along the stem and the seating face is stellited. While valves must be light, they must possess sufficient material to conduct away the heat.

Valve guides are of centrifugally cast iron, and tappets usually of the flat 'barrel' type, the latter are often offset in relation to the cam in order to promote rotation of the tappet and thus equalise the wear; for the same reason the valve and tappet are frequently offset in side-valve engines.

Valve seat inserts in heat resisting alloy are common, particularly in commercial vehicle engines where they are usually stellite faced. A recent development for aluminium cylinder heads is the use of a high expansion coefficient nickel-chromium-manganese steel for valve seat inserts.

Valve Springs.—Valve springs must be heat treated after coiling, apart from the maximum **stress, the stress range must be kept as low as possible to avoid effects of fatigue. This should be about one-half the maximum stress and the latter may be from 20,000 lbs. per sq. in. to 60,000 lbs. depending on the material used. Chrome vanadium steel gives the best results. Failures often occur through resonance in the spring where its natural frequency coincides with the forced vibrations. When the forced vibration is a simple multiple of the free wave-length of the spring a condition of resonance occurs. If the wave-length is long, and such that an integral number of free wave-lengths of the spring are completed during the cycle of the valve, the forces will be** in phase and the resulting wave in the spring becomes cumulative and destructive. The natural frequency of a helical spring is

$$N = 589 \cdot \sqrt{\frac{R}{W}} \text{ cycles/minute.}$$

where **R = rate of spring in lbs. per in.**
W = weight of active portion of spring in lbs.

The following formulæ can be used :—

d = diameter of wire in ins.
r = mean radius of coil in ins.
N = number of coils.
C = a constant based on modulus of transverse elasticity = 180,000.
K = stress per sq. in., *e.g.* 20,000 lbs. per sq. in.
Safe load = Kd^3/r.

Load to deflect spring 1 in. (rate per in.) = Cd^4/Nr^3.

In high speed engines it is usually necessary to use two helical springs to each valve, the springs being nested; besides permitting a lower stress in the steel, this arrangement tends to damp out resonant vibrations.

TABLE III.—CONSTANTS OF ROUND STEEL WIRE FOR HELICAL SPRINGS.

Valve Timing.—The valve timing must be such as to furnish optimum results in respect of charging the cylinder with explosive mixture, and also of scavenging the burnt gases. It is largely a question of compromise between disadvantageous circumstances.

A typical timing arrangement would be as follows :—

Inlet opens	5 to 15° before T.D.C.
Inlet closes	40 to 45° after B.D.C.
Exhaust opens	45 to 55° before B.D.C.
Exhaust closes	5 to 15° after T.D.C.

It is thus seen that inlet and exhaust valves are *both* open at top and bottom dead centres, with an overlapping period of 10° to 30° at the top, and from 85° to 100° at the bottom. The period of overlap being greater for high- than for low-speed engines and, in the case of high-speed racing engines may be as much as 80° at T.D.C. and 160° at B.D.C.

Pistons.—These exhibit great variety of design. Lightness combined with strength is the first essential, and apart from transmitting the piston pressure to the crankpin, the functions of the piston include dissipation of heat to the cylinder walls, preventing passage of oil into the combustion chamber, and the provision of adequate support for the gudgeon pin. They are generally relieved on the sides to reduce friction, and the skirt is ground tapered and oval. Three or four rings are usually fitted above the gudgeon pin the bottom of which is an oil control or scraper ring, occasionally a second oil control ring is fitted below the gudgeon pin. It is quite common in commercial vehicle engines to provide a groove for a bottom oil control ring below the gugdeon pin but to omit the ring when the engine is originally built. The ring being fitted by the operator as dictated by oil consumption.

Piston rings are of cast iron, concentric, and hammered to equalise the spring effect throughout the circumference. They are ground on the outside diameter and both sides and fit closely into the grooves.

Owing to the high coefficient of expansion of the aluminium alloy used for piston manufacture a liberal clearance is necessary at the piston crown which is decreased as described above, as the skirt is approached. The actual amount of clearance is dependent on the general design both of piston and cylinder, the service for which the engine is intended, and other considerations.

Piston Inertia.—A simple method of calculating piston inertia is due to Ricardo, as follows :—

p = inertia pressure in lbs. per sq. in of piston area.

w = total weight of reciprocating parts (including connecting rod) in lbs. per sq. in. piston area.

n = r.p.m.

s = stroke in ins.

r/c = ratio of crank to connecting rod.

then at top of stroke

$$p_t = 0{\cdot}0000142 wn^2s\,(1 + r/c).$$

and at bottom of stroke

$$p_b = 0{\cdot}0000142\, wn^2s\,(1 - r/c).$$

It generally happens that the nertia pressure is greater than the gas pressure. The former occurs four times in two revolutions and the latter only once in the same period, the combined effects are thus best shown by means of a polar diagram.

Piston Acceleration and instantaneous velocity are determined by the usual methods.

Gudgeon Pins.—Made of casehardened steel of very light tubular section, ground and externally lapped; they always float in the piston and frequently in the small end of connecting rod as well. In the pistons the pin runs direct on the aluminium and generally with only oil vapour lubrication.

Fully assembled with gudgeon pins and rings, pistons must be held closely to limits of weight; a maximum tolerance of $\pm\frac{1}{4}$ ounce is permissible, but the best practice is less than this to avoid a rough running engine.

Connecting Rods.—Connecting rods are of steel, stamped to required form, but when lightness is essential duralumin or hyduminium stampings are used, alternatively the steel rod is machined all over. They are of H section with the small end either solid or semi-split, the big-ends in halves and with only two bolts. Steel rods are bronze bushed for the gudgeon pins ; light alloy rods not.

For the big-end bearings, see ' Bearings.'

Camshafts.—These, as in the case of crankshafts, are not subject to high specific stresses as they must be of adequate diameter to ensure rigidity ; this is the more easily attained since the journal bearings must be large enough to pass the cams through.

The design of cams is too complex a subject to be treated here, and involves prolonged study to reconcile antagonistic factors, *e.g.* adequate lift of valve without prohibitive acceleration,

rapid closing without noise, etc.; again, base circles must not be so large as to cause too high rubbing speed; finally it must not be of such a contour that it cannot readily be ground. See Section XXVIII (III), page 219.

Camshaft Drives.—**With a side valve engine the camshaft is inside the crankcase and a simple 2 to 1 reduction gear, either spur or helical, suffices. The same applies to overhead valves where the shaft remains in the crankcase, and operates the valves through push rods. Where, however, the camshaft is in the cylinder head more complex gears are necessary. Dr. H. E. Merritt (*Proc. I.A.E.*) remarks as follows:—**

With side-by-side valves there are two general types—(*a*) chain; (*b*) spur or helical gear. Silence of operation is important, and the chief obstacle to this centres round the uneven torque of the drive. This may result in a wave motion in a chain drive, introducing considerable stresses and limiting the allowable velocity of the chain. With tooth gear the silence of operation depends largely on the accuracy of manufacture. In many cases helical teeth are used in place of the straight tooth, with improved performance. This introduces, however, an end-thrust on the crankshaft and camshaft, and a transverse torque on the intermediate gear. In correctly designed helical teeth the degree of overlap should not be less than one pitch, and with double helical gear end-thrust is eliminated.

Camshaft brakes may be used to secure uniformity of driving torque, in which case the breaking torque must be at least equal to the maximum forward accelerating torque, due to a closing valve spring.

Another method is to drive an auxiliary, such as the fan, water, or oil pump from the free end of the camshaft, thereby providing the necessary constant resistance.

The majority of camshaft drives are taken from the front end of the crankshaft with the object of accessibility, but in this position crankshaft torsional vibrations may produce severe fluctuations in tooth pressure. For minimising gear noise, the use of non-metallic gears is very common. Due to their resilience and high inter-molecular friction, the energy of tooth impact is absorbed, which prevents the bounce of the teeth.

Owing to the greater centre distance between an overhead camshaft and the crankshaft a variety of drives is possible, and representative arrangements are shown in fig. 6.

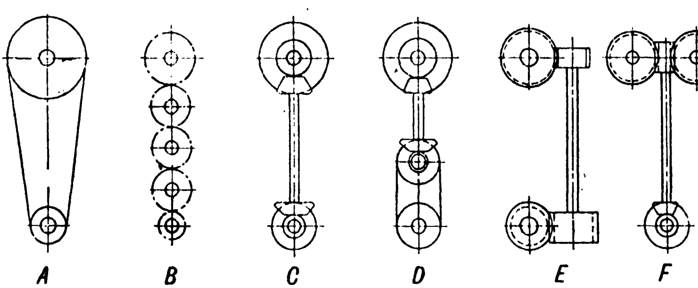

FIG. 6.—Types of Overhead Camshaft Drive.

A. Chain. D. Chain-bevel.
B. Spur Gear. E. Helical gear.
C. Bevel. F. Bevel-worm.

The train of spur gears (B) has a large number of points at which wear may occur, and is liable to be noisy. The bevel drive demands care in layout. Bevel gears require very accurate location in every direction, means for axial adjustment, and thrust bearings. Straight-tooth bevel gears are the most difficult of all gears to get to run quietly, and the tendency is to use spiral bevels, but this type calls for the greatest accuracy in cutting and assembly.

The unequal expansion of the cylinder block and the vertical shaft has an important effect on gear mesh and tappet clearance, and this can be provided for by the use of a telescopic vertical shaft. With the spiral and worm drives a wide range of gear diameters is possible. Another advantage is that there is no necessity for precise adjustment for end float on either crankshaft or camshaft, or expansion of the vertical shaft. On the other hand, the contact between spiral gears is only point contact and the intensity of tooth pressure is very high.

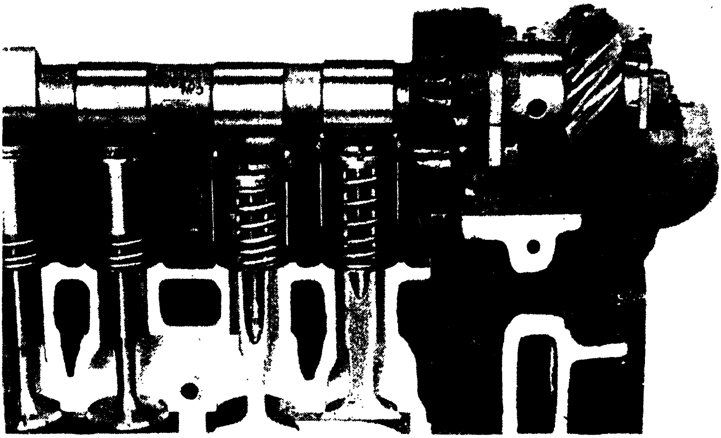

FIG. 7.

Fig. 7 illustrates the overhead camshaft and valve gear on the Wolseley ' Four Fifty ' and ' Six Eighty ' engines in which the drive is provided by means of spring-loaded split wormwheels.

Engine Efficiency.—**The mechanical efficiency can best be determined by running on a dynamometer. The torque is first measured over the whole speed range and from this the speed at maximum brake h.p. is determined. The engine is then run at this speed with one of each of its cylinders cut out in turn. The h.p. missing under each of these conditions is the indicated h.p. of the cylinder cut out, and their sum is the total indicated h.p. Thus if**

T = full torque at maximum power lbs .ft.

T_1 = mean torque with one cylinder cut out.

N = number of cylinders.

T_2 = indicated torque, lbs. ft.

$T_2 = N(T - T_1)$ from which total i.h.p. can be calculated by the formula

$$\text{i.h.p.} = \frac{nT_2}{5252} \qquad n = \text{r.p.m.}$$

Volumetric Efficiency can be measured by connecting the carburettor air intake to an accurate meter, *e.g.* an accurately balanced gas holder, and comparing the measured volume drawn in with the swept volume of the engine.

It can also be shown that the density of the charge in the cylinder at the end of the suction stroke is a direct measure of its volumetric efficiency ; it is, therefore, only necessary to compare the density of the charge with the density of the ambient air in order to obtain the volumetric efficiency.

The volumetric efficiency representative of the average modern engine is 0·75 to 0·85.

Thermal Efficiency.—**This is the proportion of the heat liberated by the combustion of the fuel which appears as B.Th.U. on the piston, *i.e.* i.h.p. × 42·4, compared with the calorific value of the fuel consumed. The following are typical thermal efficiencies observed.**

Explosion Pressures.—The general expression for the explosion pressure is :—

$$P_s = \frac{0\cdot3\,(r-1)}{1-r^{-\cdot3}}\left\{P_i + P_o \cdot \frac{r}{r-1} \cdot \frac{r^{\gamma'-1}-1}{\gamma'-1}\right\}$$

where

r = compression ratio.

P_s = explosion pressure, lbs. per sq. in. absolute.

P_o = pressure at the end of the suction stroke, which is assumed to lie between 12 and 14 lbs. per sq. in. absolute.

P_e = brake mean effective pressure, lbs. per sq. in.

γ = ratio of specific heats ; this for the explosion curve is assumed to be 1·3, and for the compression curve, where the ratio is denoted by $\gamma' = 0\cdot64 + 0\cdot05P_o$.

P_i = theoretical mean indicated effective pressure, and may be written $P_i = \frac{P_e}{\eta K}$ where η is the mechanical efficiency, and K the diagram factor representing the proportion of the actual indicator diagram to the sharp-cornered constant-volume cycle diagram assumed in the calculations.

The above equation may be reduced to the equivalent form :—

$$P_s = (0\cdot72 + 0\cdot482r)\left\{\frac{P_e}{\eta K} + 5\cdot427 + 0\cdot780\,P_o + r(0\cdot642\,P_o - 4\cdot801)\right\}$$

which agrees with above exact equation to within one part in 400.

A well designed engine may be expected to show 120 lbs. per sq. in. b.m.e.p. running under good normal conditions, but (see Supercharging) far higher pressures are frequently attained.

Compression-Ignition Engines.

Much of the foregoing mechanical data relating to petrol engines is applicable to the compression-ignition engine (also known as the oil engine, or popularly though somewhat erroneously as the diesel engine). Parts subject to forces arising from gas pressure will usually be of heavier construction, however, as higher maximum cylinder pressures are encountered.

C.I. engnies operating on both four- and two-stroke cycles are in common use for stationary and marine purposes, but the four-stroke cycle is almost universal (with a few notable exceptions) for the higher speed engines used in road transport vehicles. The fuels used vary from heavy end cuts for the large slow-speed engines to light gas oil distillates for the high-speed road transport engines. The term ' heavy oil engine ' is thus a misnomer in the latter case.

In all modern engines, the so-called ' solid injection ' principle is used, in contradistinction to the ' air blast injection ' system used on earlier engines. The fuel is sprayed towards the end of the compression stroke, through an injector into the air contained in the combustion space, by means of an engine-driven pump, which usually serves both to time the injection and meter the precise quantity of fuel required to carry the engine load (see under Fuel Injection Equipment). Compression ratios vary between 12 and 20 to 1, giving rise to compression pressures of from 400–600 lb./in.^{2} The injection pressure may rise to as high as 10,000 lb./in.^{2}, and it is the conversion of the pressure energy into velocity at the injector nozzle which produces the required atomisation of the fuel into a finely divided spray, able to penetrate the dense, highly compressed air in the combustion chamber and seek out the oxygen required for complete combustion. It is the high expansion ratio associated with these high compression ratios which gives rise to the greater thermodynamic efficiency of the C.I. engine in comparison with the petrol engine, in which compression ratio is limited by the onset of detonation. There is no similar limitation in the case of the C.I. engine although ratios higher than these quoted are not used as any further slight gain in thermodynamic efficiency is offset by reduction in mechanical efficiency.

Following upon the commencement of injection at a point just before top dead centre on the compression stroke, combustion proceeds in three more or less distinct stages, as first put forward by Ricardo. First there is a delay period during which no tangible combustion takes place, but in which the particles of fuel first injected are being raised in temperature by contact with the hot air, enabling surface vaporisation to take place. The length of this delay period varies with the ignition quality of the fuel and the temperature and density of the air into which it is injected, also to some extent on the degree of atomisation of the fuel and the turbulence of the air. The second stage follows upon the initiation of combustion at the end of the delay period, and in it combustion spreads almost instantaneously through the mixture already present in the cylinder, producing a rapid rise in pressure to a value approaching the maximum which will be reached during the cycle. It is this high more or less uncontrolled rate of pressure rise which produces the so-called ' diesel knock ' commonly obtained with these engines. The high rate of pressure rise and the associated knock can be reduced by keeping the quantity of fuel introduced during the delay period to a minimum, either by shortening the delay period by the use of high ignition quality fuels or by reducing the rate of, or interrupting, fuel injection during the delay period. The third stage of combustion is that in which fuel which may still be issuing from the injector is burnt under comparatively controlled conditions according to the rate of fuel feed, and serving to maintain pressure near the maximum until fuel injection is cut off.

The cycle is thus ideally a mixture of a constant volume (or Otto) cycle and the constant pressure (or Diesel) cycle. In practice the second and third stages tend to merge indistinguishably, particularly in high-speed engines where the length of the delay period in terms of crank angle

necessitates a large proportion of the fuel being burnt at constant volume. The diagram (fig. 8) showing pressure on a line crank angle base is typical of the latter engines.

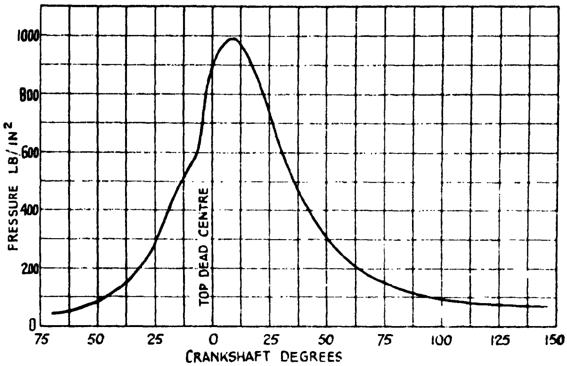

FIG. 8.

Maximum pressures usually occur shortly after top dead centre, and range from 600–1,600 lbs. per sq. in. depending on compression ratio and on the relative proportions of constant volume and constant pressure combustion. This mixed cycle has an efficiency intermediate between that of the Otto and Diesel cycles, and which will be higher with the greater proportion of combustion taking place at constant volume. It follows that the efficiency of the cycle tends to increase with reduction in quantity of fuel injected as engine load is reduced since the constant pressure stage becomes progressively diminished or even eliminated. This improvement in efficiency with reduction in load, modified of course by an increasing proportion of mechanical losses, is a further factor in the overall improvement in the efficiency of the C.I. engine in comparison with the petrol. The petrol engine is restricted in the range of air-fuel ratios in which spark-ignition can take place; hence both air and fuel charges must be reduced (by throttling the mixture) when load is reduced, and no corresponding improvement in cycle efficiency takes place.

Combustion Chambers.—Almost every manufacturer has his own particular variety of combustion chamber, but these may be grouped into four main categories, with however, numerous borderline and overlapping examples. The diagrams (fig. 9) show typical examples of each group.

(1) *Open Chamber or Direct Injection.*

The combustion chamber is formed by a recess provided in the cylinder head or in the crown of the piston, or partly in both, into which fuel is directly injected. In view of the necessity of accommodating the values in the cylinder head it is usual for the chamber to be situated in the piston crown.

(2) *Precombustion or Antechamber.*

A portion of the air is transferred during the compression stroke into a chamber separated from the engine cylinder by a restricting orifice or orifices, and in which injection and the initial stages of combustion take place.

(3) *Swirl Chamber.*

Somewhat akin to (2), but the connecting passage is relatively unrestricted, and is so arranged as to give an ordered rotation or swirl to the air transferred to the chamber during the compression stroke.

(4) *Air Cell.*

Air is again partly transferred to a separate chamber, but fuel is not injected directly into the latter but is arranged to spray from outside into the air passing through the connecting passage during the compression and expansion strokes.

The aim of all these combustion chambers is to bring the particles of fuel issuing from the injector nozzle into contact with the air in the combustion space in such a manner that each particle seeks out its own proportion of unused air and is thus enabled to burn completely without the mixture at any part becoming over rich. It will be realised that this ideal is very difficult to achieve as fuel usually enters from only one point in the combustion chamber, and it becomes progressively more difficult for the particles entering later to reach air which has not been consumed by those burning in the earlier stages.

For this reason, it is seldom that more than 70 per cent. of the air available can be utilised without signs of local incomplete combustion, as indicated by the release of free carbon or smoke in the exhaust.

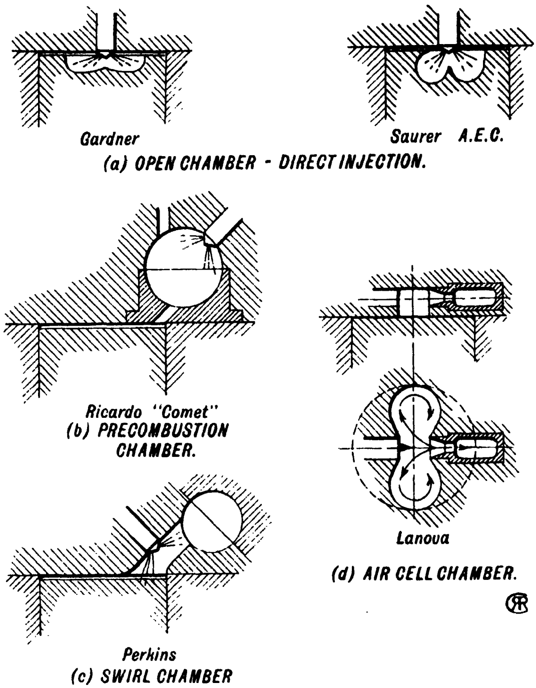

FIG. 9.

The relative importance of air movement and fuel droplet dispersion in bringing about the maximum utilisation of air varies in the four categories of combustion chamber. Type (1) can produce only a limited degree of air movement, and therefore relies greatly on suitable atomisation, penetration and direction of the fuel sprays. Types (2) and (4) rely almost entirely upon air turbulence, in these cases of a more or less indiscriminate nature, while in Type (3), air movement. although of an ordered nature, can have insufficient intensity to play a major part in the process. These later types can therefore operate with less refined injection equipment, but suffer in efficiency in comparison with type (1) owing to increased thermal and pumping losses brought about by the greater areas of exposed surface available for cooling losses, and by the transfer of air through restricting passages.

In Great Britain and Europe, owing to the high importance attached to fuel consumption, the direct injection engine has become increasingly popular, but in the U.S.A. the indirect types (2, 3 and 4) still hold sway, partly because they can generally accept a wider range of fuel qualities and partly because they can give good combustion over a wider range of rotational speed. The increase of fuel consumption of the indirect over the direct type is of the order of 5 to 15 per cent.

Two-stroke engines.—Compression ignition is particularly suitable for the two-stroke cycle, as there is no problem of direct loss of mixture during the scavenging process as with the carburettor engine. Inlet ports are piston controlled, and exhaust ports similarly in the case of the 'Loop Scavenge' engines, or by mechanically operated exhaust poppet valves in the head in the case of 'Uniflow' engines. Sleeve valves have also been employed. By careful study of the timing of inlet and exhaust events and of the scavenging process, both systems have attained a high degree of efficiency in recent years, and develop outputs closely approaching twice that from four-stroke engines of the same capacity. A blower has to be provided to obtain such results, however, partly offsetting the size and weight advantage, and the two-stroke engine presents more severe problems of waste heat disposal and injection equipment design.

Construction.—Owing to the inherent higher gas pressures, the scantlings of compression-ignition engines must be more generous than with spark-ignition engines of similar duty, and piston and bearing areas must be adequate for the increased gas and inertia loadings. The weight therefore tends to be correspondingly greater but adoption of improved materials has kept the increase to a minimum, and except for high duty applications such as for aircraft, C.I. engines are seldom objected to on this score. Specific output for a given capacity and speed of rotation is now little below that for spark-ignition engines, so that unless the more limited speed range is a factor, C.I. engines are not notably larger in size.

Fuel Injection System.

The fuel injection equipment of a ' solid injection ' type oil engine comprises the fuel injection pump, the injector nozzles and nozzle holders, and a suitable fuel filter. In addition, a fuel feed pump is included where there is insufficient gravity head from the fuel tank or where the latter is below injection pump level. A governor may be fitted to the injection pump as required for the particular duty. The fuel filter is a very necessary part of the system, as the finest dust or other abrasive material can ruin an injection pump if allowed to pass through with the fuel.

Fuel Injection Pump.—The great majority of oil engines are equipped with injection pumps manufactured by specialists in this field. The class of fit and finish demanded by the pump elements, delivery valves, etc., is of an exceptionally high standard, and calls for special skill and manufacturing facilities quite beyond those of the general engineering shop. The function of the injection pump is to meter the fuel to the highest degree of accuracy and to deliver it into the engine cylinder in quantities proportional to the load at any moment, carefully timed and at a pressure of 1,200 to 4,500 lb. per sq. in. (80 to 300 atm.) or even higher, to secure adequate atomisation and penetration.

The ' jerk ' type injection pump is almost universal; single and multiple element pumps are in common use, each cylinder being supplied by its own element. There are two main types of pump, the enclosed camshaft type complete with tappet mechanism, and arranged for drive from a suitable shaft or point on the engine, and the flange-mounted type for engines in which the camshaft forms a part of the engine proper.

Size of Injection Pump Required.—In making a preliminary selection of the size of fuel injection pump to employ for any given engine, a number of factors have to be taken into account; the following formula is suggested by C.A.V. Ltd., to enable the pump delivery to be determined :—

$$F = \frac{\text{b.h.p.} \times 3{,}520}{\text{r.p.m.}}.$$

Where F = required fuel delivery in cu. mm. per cycle per cylinder.
b.h.p. = maximum output per cylinder.
r.p.m. = camshaft speed tor four-cycle engines and crankshaft speed for two-cycle engines.
3,520 = a constant based on average fuel consumption and specific gravity of gas oil.

In selecting a pump size by means of this formula, it should be borne in mind that for average engine applications the useful output from any fuel pump plunger is usually not more than 70 per cent. of the maximum value calculated from the pump dimensions. Fig. 10 illustrates, in part section, a typical four-cylinder enclosed camshaft injection pump.

6. Delivery valve nut.
7. Delivery pipe.
8. Delivery valve spring.
9. Delivery valve.
10. Pump barrel.
11. Pump plunger.
12. Dipstick.

Governors.—Various types of governor are fitted to compression ignition engines according to the duty; all of these control the speed and power of the engine by regulating the amount of oil injected. The usual type of C.A.V. mechanical governor for road vehicles regulates both maximum and minimum (idling) speeds within predetermined limits, while still leaving the control of the engine between these points directly under the influence of the accelerator pedal. This governor comprises centrifugally actuated weights complete with suitable linkage, which transmits the motion of the weights to the injection pump control rod. For marine, agricultural and certain industrial duties, a variable speed governor is often fitted. Another governor in extensive use is the pneumatic type; the pump control rod in this case is operated by a diaphragm, the movement of which is effected by means of inlet manifold pressure variation. A flexible pipe couples the diaphragm chamber with a venturi unit in the manifold, and the induction pressure differences are thus utilised to operate the pump control rod.

Fuel Oil Filters.—A typical fuel oil filter is shown in section, in fig. 11; here the filter medium consists of a felt pack element, and with relatively clean fuel and filter element a flow capacity of 3·5 to 4·5 pints/min. is available. The fuel, on entering through the inlet connection in the top

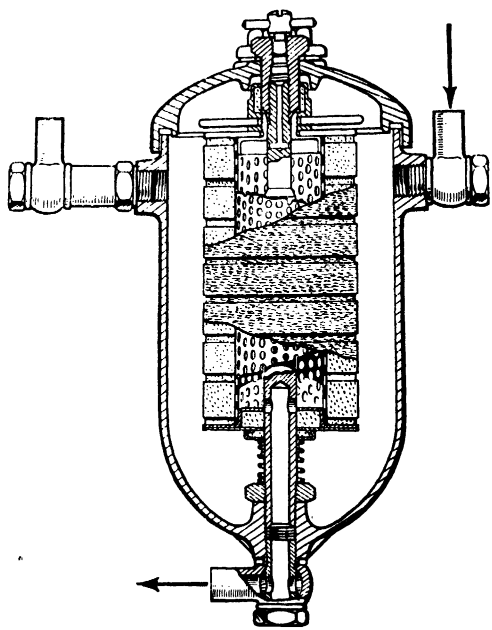

FIG. 11.

of the bowl, passes through the felt pack element and the perforated cylinder. It then flows into the stand pipe, and out into the main pipe line through the outlet connection in the base of the bowl. The filter can be dismantled with ease for cleaning and inspection by unscrewing the cap nut and removing the cover. The filter element can then be easily withdrawn from the bowl. Both 'downflow' and 'crossflow' types of filter are commonly supplied.

Injector Nozzles and Nozzle Holders.—The type of nozzle used depends on the requirements of the combustion chamber; typical types of chamber have been referred to earlier, and it will be clear that a considerable variety of nozzle designs is called for. A number of typical types is illustrated.

Fig. 12 (C) shows a single hole nozzle; the fuel is sprayed through the single central orifice when the needle is lifted by pump pressure. The hole can be any diameter from 0·2 mm. (0·008 in.) upwards. A variation of this type is the conical end nozzle, as at D, fig. 12.

In this the hole is at an angle to the centre line as required. It will be noted that the fuel reaches the nozzle tip through holes drilled from the groove of semi-circular section in the nozzle face to the oil gallery just above the needle valve seat.

Multi-hole nozzles, a typical example of which is seen in fig. 12 (B), can have any number of holes up to seven drilled in a small ' dome ' or ' teat ' formed under the nozzle mouth ; the holes are usually arranged radially in a circle about the axis of the nozzle, the number, size and ' hole angle ' of the holes depending on the requirements of the engine.

In direct-injection combustion chamber engines where, owing to the restricted space between valves in the cylinder head it is not possible to provide cooling of the nozzle in the usual way, an alternative form of nozzle has been developed. This type is known as the ' long stem ' nozzle

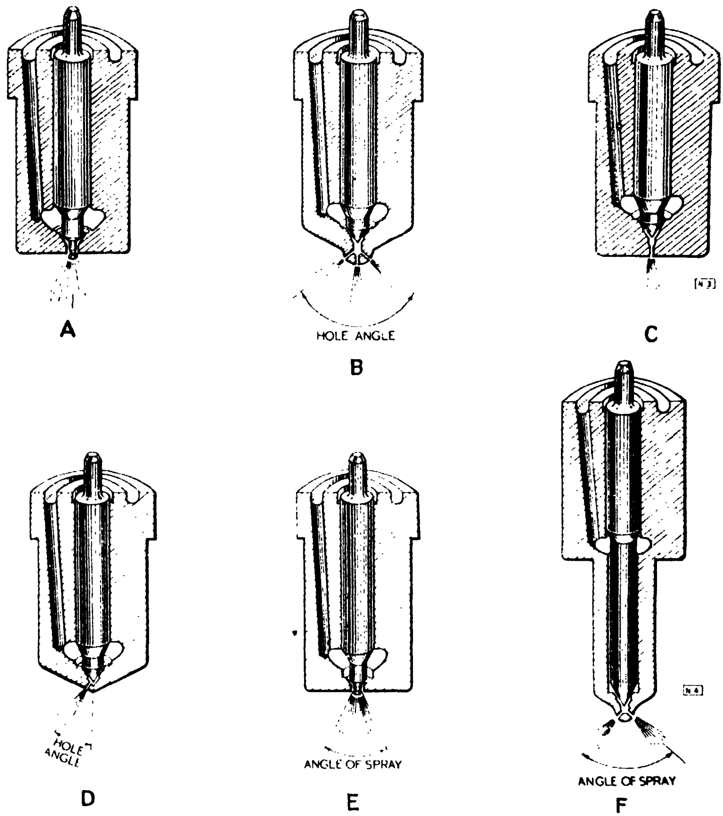

Fig. 12.

(F, fig. 12), and has an extended body at the tip of which is provided the valve seating and dome for the spray holes. The valve stem is a clearance fit in the body, but is located on the lapped portion remote from the seat.

Engines of the ' air-cell ' or pre-combustion chamber type frequently use a pintle nozzle (E, fig. 12). The needle valve is extended to form a pin or pintle which protrudes through the mouth of the nozzle body. The angle of the cone of spray can be varied by varying the size and shape of the pintle. A further variety of nozzle is the ' delay ' type, in which the pintle is modified so that the rate of injection increases towards the end of the delivery. An example is shown at A, fig. 12 (the details of these nozzles are necessarily drawn somewhat out of scale to enable them to be seen clearly).

Many types of nozzle holders are in use, some designed for bolting to the cylinder head, some for screwing in; they carry the valve spring against which the nozzle valve opens, and means of adjusting this to provide varying injection pressures. A typical example will suffice to illustrate the general design features.

Fig. 13 shows a C.A.V. nozzle holder and nozzle in position in a cylinder head. The principal parts are indicated. The slight leakage of fuel which accumulates within the nozzle holder and which serves to lubricate the nozzle, can be led away by a pipe connected to the leak-off nipple provided.

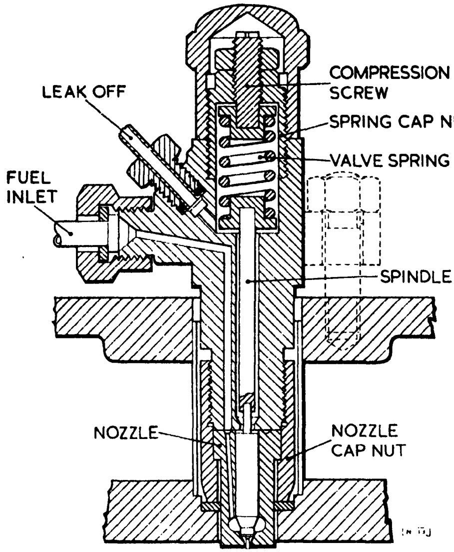

FIG. 13.

Engine Cooling.

In water-cooled engines the heat is carried away from the hot surfaces of the cylinder, cylinder head, valve pockets, etc., by a moving stream of water which gets rid of the heat to the atmosphere by means of a radiator. In air-cooled engines the heat is carried outwards from the cylinder by means of metal fins over which currents of air are passed. In some engines where so-called evaporative cooling is used, the cooling medium is a nearly stationary body of water which is allowed to boil and pass off steam to a surface condenser. The condensed water is returned to the cylinder jacket by a pump, but the circulation is very slow as the water vapour passing to the condenser carries off 20 to 100 times the heat as compared with the same weight of water in a normal system. The condenser is made in the form of an ordinary radiator. With this method of evaporative cooling an invariable engine temperature is maintained—viz. 212° F.—for sea-level conditions. With air cooling higher temperatures will be obtained, and with water somewhat lower.

In a well designed petrol engine with pump circulation the water outlet temperature is about 140° F. In a Diesel engine this may be raised to 160° F. With thermo-syphon cooling higher temperatures up to 205° F. are common. The actual wall temperatures of the cylinder are considerably higher. Herreshoff (*Proc. S.A.E.*) gives the following figures:—

Type of Engine.	Heat to Cooling Medium.
Aviation	30 B.Th.U. per b.h.p. per min.
Valve in head	50 ,, ,, ,,
Side valve	70 ,, ,, ,,

The variations are due to different types of combustion chambers and sizes of valves; the figures are on the high side.

In a Diesel engine the figure is about 33 B.Th.U. per b.h.p. per min. As a safe figure 60 to 70 B.Th.U. for a petrol engine and 40 to 50 B.Th.U. for a Diesel may be taken, depending on the load factor which varies from 30 per cent. in a private car to 100 per cent. for a heavy lorry.

The true mean water temperature is not the arithmetic mean of the inlet and outlet temperatures but something lower. Thus if these are respectively 100° and 200° the true mean temperature is about 132° F.

For a honeycomb radiator the performance was found by Miall to be in accordance with the following equation :—

$$B = 0\cdot 007\ AV^{0\cdot 856}\,(1 - e^{1\cdot 77t});$$

where

B = B.Th.U. per minute per degree temperature difference between air and true mean of water temperatures.

A = frontal area in sq. ft.

V = velocity of air in ft. per min.

***t* = effective thickness of core in ft. (length of tubes between bulges at ends).**

***e* = base of Napierian logarithms.**

For a tubular radiator the following equation applies :—

$$H = (0\cdot 00012 - 0\cdot 0000089\ R)\frac{V^{0\cdot 85}}{d^{0\cdot 32}}$$

where

H = B.Th.U. dissipated per sq. ft., per second, per degree F. difference.

V = Air speed ft. per second.

R = Ratio $\frac{\text{Air surface}}{\text{Water surface}}$

***d* = Bore of tube in ft.**

It is found that with pump circulation the tube surface is always more efficient owing to greater turbulence in the water stream, and a radiator for thermo-syphon cooling requires to be nearly twice the size of one for pump circulation.

The most suitable pump is a centrifugal one, and the speed of circulation over the tube surface should not be less than 1 ft. per sec. In round figures a delivery of about 0·33 gal. per b.h.p. of engine per minute is required.

The fan for air circulation through the radiator is of the first importance, but little attention as a rule is paid to it. As a result, although a large volume of air is handled by the fan, it is at the expenditure of considerable power which falls to be deducted from the effective power of the engine.

Reliable data on this subject is largely wanting, but for maximum efficiency, blades of aerofoil section should be used, the fan should be fully cowled and the radial blade tip clearance reduced to a reasonable minimum. The fan blade tip speed should also be maintained at a minimum in order to reduce the noise level.

Supercharging.

The object of supercharging is to enable the engine to draw in a greater quantity of fuel mixture during the suction stroke, thus maintaining the volumetric efficiency at high speeds and increasing the power output. For very high output performance in petrol engines the supercharging is carried to a point where considerably over 100 per cent. volumetric efficiency is obtained. It may be remarked here that the supercharger is nearly always arranged to draw through the carburettor, thus handling a petrol-air mixture. The result is perfect admixture of the fuel and air, and cooling of the supercharger by the evaporation of the petrol.

Three types of blower are now employed :—

(*a*) The Roots Blower.

(*b*) The Eccentric Vane Type.

(*c*) The Centrifugal Fan.

(*a*) is difficult to make and above 10 to 12 lbs. discharge pressure is extravagant in power; (*b*) is used for engines of racing cars, etc., and (*c*) mainly for aviation work as it is by far the lightest and its noise is immaterial. Its speed is usually from 20,000 to 25,000 r.p.m.

Fig. 14 shows two examples of eccentric vane blowers of a type suitable for 20 to 30 lbs. per sq. in. discharge pressure. They are usually coupled direct to the crankshaft at the front end for engine speeds up to 7,000 r.p.m.

Dealing first with supercharging petrol engines. The effect is to increase the pressure and to some extent the temperature of air in the cylinder after compression.

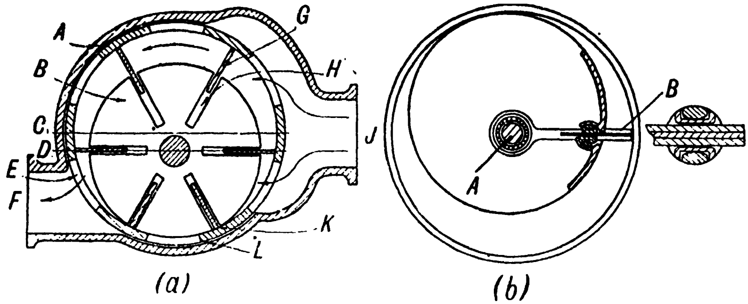

FIG. 14.—Eccentric Vane Blowers.

A. Casing. B. Rotor. E. Rolling drum. F. Outlet. G. Blade. J. Inlet.

A. Layshaft central to casing, eccentric to rotor. B. Blade.

It follows that if detonation is to be avoided, the ratio of compression must be reduced. Using 83 octane value Ricardo found the following relationship between supercharge pressure and h.u.c. (columns 1 and 2).

Supercharge in Hg.	h.u.c.	b.m.e.p.
0 in.	6·55	145
2 ins.	6·30	158
4 ins.	6·10	170
6 ins.	5·90	182
8 ins.	5·70	195

In obtaining the third column readings the octane number of the fuel was raised from 78 to 88 to compensate for increased tendency to detonate running at *constant* compression and not at figures given in column 2.

In a petrol engine it is thus shown that the limit to supercharging is detonation (assuming the engine is designed to withstand the high pressures reached).

In a Diesel engine this limitation is absent as there is no fuel in the cylinder during compression, there is also more rapid ignition when it starts.

O. Thornycroft considers that in a Diesel engine working at 6 ins. Hg. supercharge, maximum b.m.e.p. is increased by 13·5 per cent., with fuel consumption unchanged; combustion knock reduced, and total weight of engine increased by 5 per cent.

Thus the supercharged power/weight ratio would be greater.

Note.—In supercharged petrol engines used for racing an output of 187 b.h.p. per litre has been recorded.

Size of Supercharger.—For a Roots or Vane type the following formulæ apply :—

$$P = \frac{B \times D_e \times S_e \times 14 \cdot 7}{V/2}$$

$$B = \frac{P \times V/2}{D_e \times S_e \times 14 \cdot 7}$$

where

B = blower capacity litres per revolution.
V = engine capacity litres per revolution.
D_e = discharge coefficient.
S_e = suction coefficient.
P = absolute discharge pressure lbs. per sq. in.

D_e is a figure experimentally determined which varies from 0·7 at 2,000 r.p.m. to 0·9 at 7,000 r.p.m

$$S_e = \left(\frac{P_s}{14\cdot7}\right)^{0\cdot715} = \sqrt[1\cdot4]{\frac{P_s}{14\cdot7}}$$

where P_s is absolute suction pressure.

Carburettors and Manifolds.

The function of the carburettor is to provide an approximately correct mixture of two very dis-similar substances, an oily liquid and air, in an average ratio of about 1 to 17·5 by weight respectively, at any engine speed. The function of the manifold is to distribute this very unstable mixture to each cylinder in equal quantities. Except when a supercharger is interposed between the carburettor and the manifold this condition seldom obtains. The effect of the supercharger by its beating action, is to heat and thoroughly mix the two ingredients, which are then conducted under pressure to each cylinder. With defective distribution wide variation will be found between the power developed in each cylinder. In a case recorded by O. O. B. Beale the indicated power varied from 11·8 to 21·2 between cylinders, and in another case, by gas analysis the following figures were recorded.

Fuel Distribution to Cylinders.

TABLE VI

Tests made on a standard four-cylinder 22·5 h.p. car showed the ollowing values, the latter being determined from gas analysis.

Cylinder No.		CO_2 in Exhaust. Per Cent.	Air Fuel Ratio.	Distribution Per Cent.	Excess or Deficiency. Per Cent.
A.	1	8·1	10·9	28·5	+14·0
	2	8·4	11·1	27·4	+ 9·6
	3	12·0	13·5	21·8	−12·8
	4	11·6	13·3	22·3	−10·8
B.	1	9·0	11·5	27·2	+ 8·8
	2	9·5	11·9	26·6	+ 6·4
	3	11·4	13·1	23·2	− 7·2
	4	11·9	13·4	23·0	− 8·0

A = tested at 15 m.p.h. up a 4 per cent. gradient. B = tested at 30 m.p.h. up a 4 per cent. gradient.

The tests show that the two front cylinders (Nos. 1 and 2) are subject to 'loading-up,' particularly at the lower speed.

With a 'wet' mixture there is difficulty in keeping droplets of fuel in suspension which depends on (1) the speed through the pipe, (2) the fineness of the petrol spray, (3) the pressure, and (4) the mixture temperature.

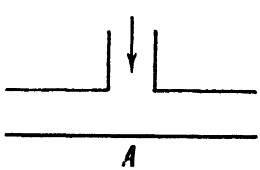

FIG. 15.

Where the direction has to change, which must happen at least once for each cylinder, a round bend is undesirable, since speed round the inside of the bend may amount to no more than say one-half the speed round the outside. Deposition of liquid is bound to occur; angular branches may prevent this.

With a downdraught carburettor there is a short pipe leading to the horizontal distributing pipe. In a four-cylinder engine the mixture has to oscillate to right or left once for every revolution. The result is that some deposition of petrol takes place at A (fig.15) and if allowed to accumulate will build up and ultimately be sucked into one or other of the arms with resulting disturbance

of running. The remedy is to apply local heat to the point A, which is achieved by forming a hot-spot, either by bolting the inlet and exhaust manifolds together at this point or casting them integrally. The hot-spot may be thermostatically controlled. The same conditions will apply to six- and eight-cylinder engines although the problems of manifold design assume such complexity that they cannot be dealt with here.

The mixture ratio to give the best results is by no means constant over the whole range of engine speed; at idling speed the mixture must be rich, then normal throughout most of the range, increasing in strength slightly at the highest speed where maximum power is needed.

Carburettors.

Fig. 16 illustrates the Solex downdraught carburettor Models 26 AIC and FAI which represent the simplest form of modern 'static' carburettor and in which compensation is effected by means of an air correction jet in conjunction with an emulsion tube.

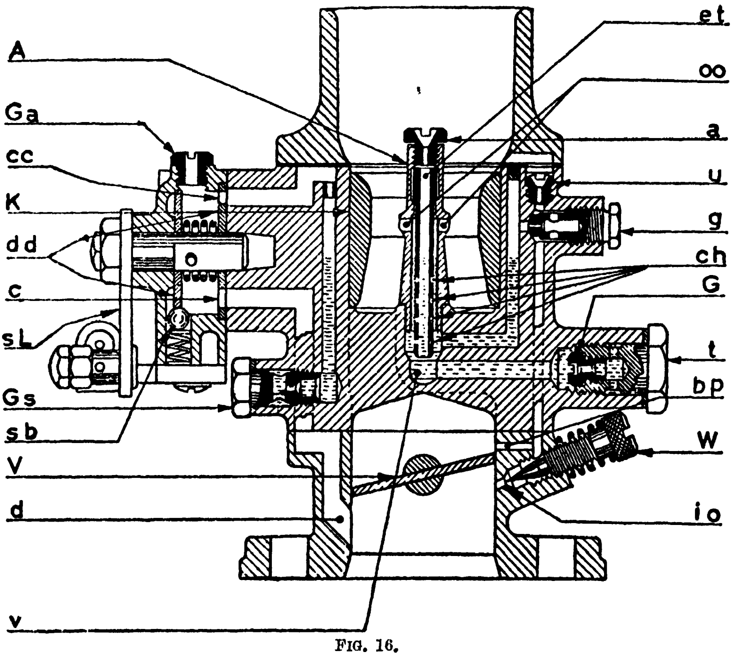

FIG. 16.

These carburettors embody the Solex 'Bi-starter' unit which is a small auxiliary carburettor integral with the main carburettor and ensures easy starting from cold.

The 'Bi-starter' consists of a disc valve controlled mixing chamber fed via the petrol jet (Gs) and the air jet (Ga), it is operated by the lever (sL) which rotates the discs until the drillings in the right hand disc register with the entry duct (cc) and exit duct (c), through which the petrol and eventual mixture flow respectively. The mixture finally passing through the delivery duct (d) below the throttle. When the lever (sL) is operated throughout its full travel, a rich mixture is provided for starting under very cold conditions. With the lever (sL) at the intermediate position the mixture provided is less rich, due to a very much smaller drilling in the inner disc coming into operation, its effective position being located by the spring loaded ball; thus a weaker mixture is produced on which the car can be driven away from cold without fear of over-dosing. When the engine is fully warmed up the lever (sL) is returned to the 'off position' by pushing the dashboard knob fully home. The starter is then isolated from the main carburettor, allowing the latter to function normally.

The main jet (G) is secured in the carrier (t) and meters the fuel drawn from the float chamber; the metered fuel then passes into the spraying well (A) via the reserve well (v) where it meets air drawn downwards through the calibrated air correction jet (a). This passes out through the emulsion holes (ch) into the annulus, where an emulsion is formed with the petrol, and the resultant mixture rises to the four spraying orifices, of which two are shown (oo) in the waist of the choke tube (K). Here the emulsion is absorbed by the main air current and passes down to the induction pipe of the engine via the Butterfly throttle (V).

It will be seen that as the air flow is increased by opening the throttle, the level of the petrol within the emulsion tube (et) drops until the highest of the emulsion holes (ch) are uncovered; as the level continues to fall, further emulsion holes are uncovered, thus decreasing the suction in the metering orifice. These emulsion holes may, therefore, be regarded as compensators, and by suitable determination of the size of the air correction jet (a), any desired degree of weakening or enriching the mixture can be obtained. The pilot jet draws its petrol from the main jet and thus ceases to operate when the main jet is in normal operation.

The Solex downdraught carburettor Model 32PBI–2 is the most elaborate of this type of carburettor and incorporates a two-phase acceleration and economy device. The main carburettor and ' bi-starter ' are as described above.

The acceleration device consists of a box-like structure situated at the side of the float chamber and fitted with a jet (Gu) on the exterior—see extreme right of fig. 17. The internal components comprise the following :—

1. A pump shaft ultimately actuating a ball valve (H), in front of which is a light spring. The shaft passes through and is affixed to the centre of a flexible membrane (Mm).

(2) To the right of the membrane (Mm) is a chamber containing a compression spring (r). This chamber is subject to induction depression via the duct having its exit at a point in the throttle chamber on the engine side of the throttle (V).

(3) Further still to the right is another chamber, one wall of which consists of the flexible membrane (M), spring loaded, and centrally from which protrudes a short rod in clearance contact with fulcrumed lever (L). The lever (L) slides on to a spring loaded horizontal rod, the effective length of which is determined by the adjustment of the nut (e) or by a split pin. The rod is fixed at its end to a small lever fitted to one end of the carburettor throttle spindle.

The chamber through which the pump shaft passes to the left of membrane (Mm) is in communication with the chamber containing the compression spring to the left of the membrane (M). Both chambers are filled with petrol, via the ball valve at the base of the assembly, prior to the functioning of the device, and the contents of both are equally affected thereby.

Function and Economy Action.—When the butterfly (V) is nearly closed and the vehicle travelling at very low speed, the central chamber containing the spring (r) is subject to high induction depression. The membrane (Mm) to which the pump shaft is affixed, subject to the same depression, flexes to the right, compressing the spring (r) and the ball valve (H) is on its seating, being held firmly thereon by pressure of the light spring to the left of it.

At this stage the lever (L) is lightly in contact with the end of the rod affixed to the centre of the membrane (M).

On opening the throttle to accelerate, the immediate sequence of events is as follows :—

The lever (L) forces the rod, and consequently the membrane (M) to the left, compressing the spring on the inner side and discharging the petrol contained in its chamber, through to the chamber on the left of the membrane (Mm), so displacing the petrol contained therein. This displacement forces the ball valve (H) off its seating, and the petrol is discharged via the ' pump ' or ' Speed jet ' (Gp), from the Injector tube (i) into the central air stream passing down the choke tube (k).

Next, the induction depression rapidly falls in the central chamber as the throttle opens, and the spring (r) expands, flexing the membrane (Mm) to the left thereby discharging the residue of petrol contained in the chamber to the left of it, to emerge via the injector tube (i) as just described.

Now let us consider the function of the jet (Gu) often referred to as the ' economy jet ' since such is its effect in the final stages of carburation.

Consider first of all what takes place at high speeds with the throttle fully, or almost fully open.

The depression in the induction manifold is low and consequently negligible in the central chamber containing the spring (r). Thus the ball valve (H) is pushed off its seating and petrol is free to flow from the float chamber through the chamber on the left of the membrane (Mm) and so past the ball valve (H) to the injector tube (i).

The calibration of the speed or pump jet (Gp) is determined to ensure the best acceleration, and the main jet of such a size that its output supplemented by that of the speed jet is equal to the requirements of the engine at major throttle openings.

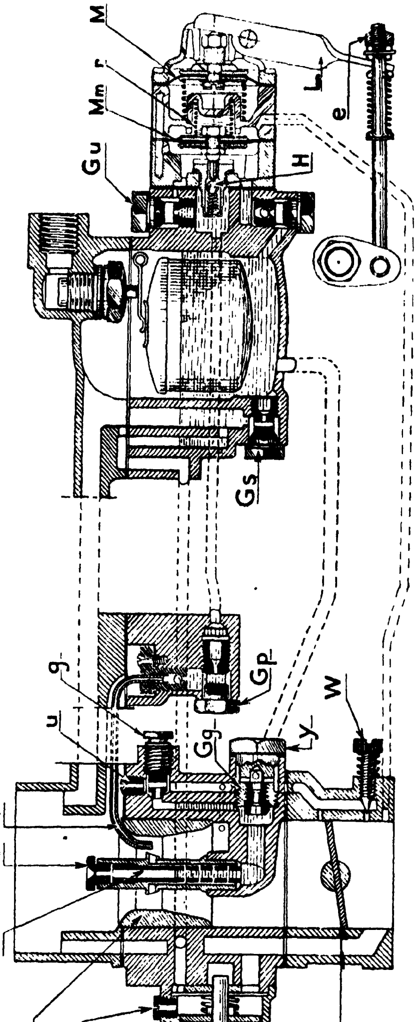

FIG. 17.

At lower throttle openings, when the depression in the central chamber is high and the ball valve (H) in consequence seated, the main jet may be too small for optimum carburation efficiency, and supplementary petrol is therefore needed to maintain the correct standard of output.

Thus the economy jet (Gu) is installed, and it will be obvious that with the pump valve closed, petrol is free to flow from the carburettor float chamber through the valve chamber and thence via the economy jet (Gu) and the speed jet (Gp) to emerge at the injection tube (i).

On the size of (Gu) therefore depends the fuel flow needed by the engine for good performance and maximum economy in the circumstances described viz., at ' cruising ' speeds.

The Zenith ' V ' type vertical model is illustrated in fig. 18, in which compensation is effected by means of an additional jet. The main and compensating jets feed into the choke through the emulsion block, and it will be seen that as the petrol in the well of the capacity tube is consumed,

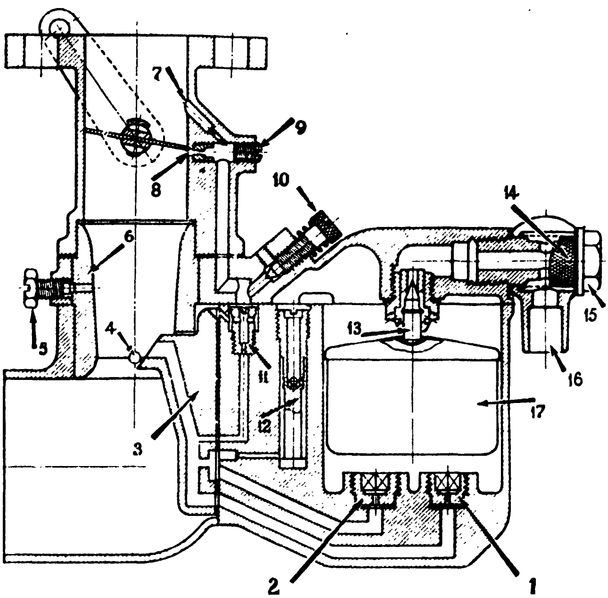

Fig. 18.

17. Float.

and as the top of the well is open to the atmosphere, petrol issuing from the compensating jet will be air bled from atmosphere. As depression increases the compensating jet supplies a weaker mixture, whilst the main jet delivers more petrol. The fuel issuing through the main jet will meet the emulsified petrol from the compensating jet in the common channel. This will tend to break up the petrol from the main jet also, so that when the supply from both sources is eventually drawn from the emulsion block nozzle into the choke tube complete atomisation is assured. On certain models the jets are removed from underneath the float-chamber after first removing cover plugs.

The operation of the Zenith horizontal and downdraught 'V' type carburettors is similar to that described above. The slow running jet draws its supply of petrol from the main and compensating jets, and therefore ceases to function when the latter are in normal operation. Two types of automatic starting device are available for the Zenith 'V' type carburettors, the air valve type illustrated in fig. 19, and the dip tube type in which the mixture strength is automatically controlled by means of an air bleed in the dip tube.

Fig. 20 illustrates the Stromberg downdraught carburettor type DBV-36, 42 which is compensated by means of radial holes in the main discharge jet (14), air being drawn through the high speed bleed (12). The acceleration pump is linked to the throttle lever and, the pump suction valve (18) being of the non-return type, when the throttle is opened suddenly the petrol contained under the pump piston (17) is discharged through the pump jet (24). The economy device is operated by the by-pass vacuum piston (5) which, when the depression in the suction pipe (7) is high, *i.e.* at small throttle openings, is inoperative. When the depression falls below a certain level, however, the piston spring (6) is no longer overcome and forces down the piston which in turn depresses the stem of the by-pass valve beneath it. This opens the valve and allows an extra supply of petrol to flow through the by-pass jet (10) to the base of the main discharge jet (14).

The S.U. controllable jet carburettor operates on the constant vacuum principle. In this the flow of air is controlled by a rising and falling piston to which is attached a taper needle which moves in and varies the area of the jet orifice. When the engine is idling, the piston is in its lowest position shutting off most of the air passage; at the same time the largest diameter of the jet needle is within the jet, almost shutting off the petrol flow.

The piston is connected to a suction disc operating in a cylinder which is in communication with the throat of the carburettor. When the throttle opens, the upper part of the suction disc chamber is subjected to increasing vacuum, and the suction disc is lifted together with the piston, allowing more air to pass through the choke way, whilst the taper needle recedes from the jet orifice and allows more petrol to pass. The operating factor is the partial vacuum in the throat of the carburettor, so that by pneumatic control alone the size of the airway and the delivery of fuel are made to adjust themselves to the rising engine speed.

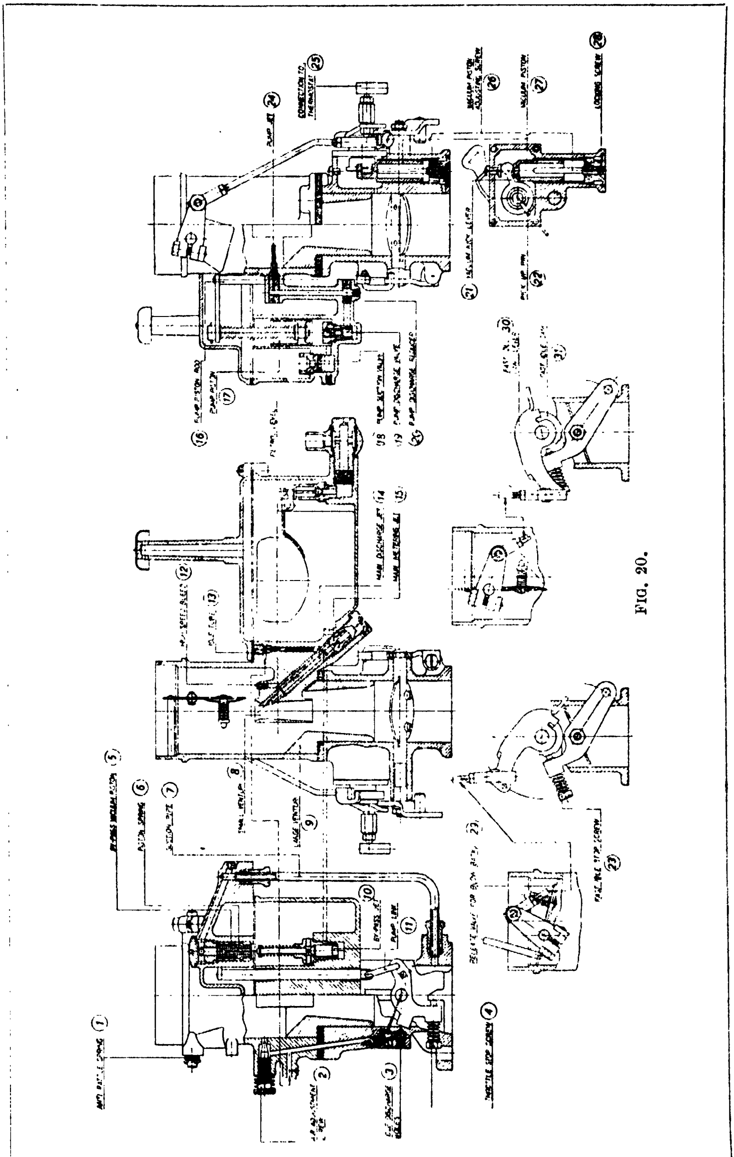

FIG. 20.

The air speed through the choke is actually constant throughout the whole range of engine speed, while the fuel is accurately metered by means of the taper jet needle. By raising or lowering the needle relatively to the piston, the mixture can be varied through wide limits, and any desired petrol-air ratio obtained.

The jet itself, by means of a bell-crank lever operated by hand from the dash, is capable of being raised or lowered relatively to the needle valve; when in its lowest position the area available for petrol is greatest, thus providing a rich mixture for starting, and the air orifice is not interfered with.

An auxiliary starting carburettor of the thermostatically controlled type is available for all S.U. carburettors.

Petrol Injection Systems.—A considerable amount of work on the development of petrol injection equipment has been undertaken of recent years, both on manifold and direct cylinder injection systems. The method of injection is similar to that employed on compression-ignition engines. Petrol injection solves many distribution problems and results in an increase in volumetric efficiency, the equipment is, however, costly, and cannot, as in the compression-ignition engine be offset by the elimination of the ignition system. It is still very much in the development stage.

General.—In view of the considerable increase in export trade the following table is of interest:—

TABLE VII.

HORSE-POWER AT VARIOUS ALTITUDES.

Altitude.	Percentage Horse-Power.
Sea-level	100·0
1,000 ft.	96·5
2,000 ,, ...	93·0
3,000 ,, ...	89·5
4,000 ,, ...	86·5
5,000 ,, ...	83·0
6,000 ,, ...	80·0
7,000 ,, ...	77·5
8,000 ,, ...	74·5
9,000 ,, ...	71·5
10,000 ,, ...	69·0

Clutches and Flywheels.

The clutch is a mechanical device for connecting and disconnecting the engine from the transmission gear at the will of the driver. It is invariably operated by a pedal at the extreme left of the driver; depressing the pedal disengages the clutch which automatically re-engages when it is released. Apart from the driver's control, there are two forms of clutch in which the re-engagement of the clutch is only completed when a certain engine speed is attained; these are (*a*) the so-called 'fluid flywheel,' which is really a turbo-pump, the kinetic connection being furnished by a fluid, set in motion by one set of blades, delivering its energy against another set oppositely inclined; (*b*) the centrifugal clutch which can be released by the pedal, but which is only completely closed at a certain speed by centrifugal force. These two devices make it impossible for the clutch to be engaged with a jerk. In the ordinary friction clutch there are two members, one attached to the engine shaft, the other to the first gear-box shaft; each is provided with suitable friction surfaces normally held in contact by springs but separable by means of a pedal when the clutch is to be disengaged.

The heaviest parts of the clutch rotate with the engine and act as (and largely in substitution for), a flywheel while the disengageable portion is made of very thin sheet steel as light as possible. The compressed asbestos fabric friction surface is riveted to the sheet steel so that the steel itself is not subject to friction with resulting heating and buckling.

Largely on account of their weight, cone clutches have become obsolete, and, for the same reason, the multidisc type is only used for very high powers.

The requirements of a friction clutch are:—

(1) High coefficient of friction under all conditions, which must not be affected by oil, water, or reasonably high temperatures.

(2) Gear-box member must be very light.

(3) Spring pressure must not be excessive, and adequate leverage for operating is necessary.

(4) Slipping must never take place even at the highest engine torques.

(5) Friction surface must have a long life, and be capable of withstanding a certain amount of intentional slipping without damage.

(6) The engagement must be smooth.

(7) **Heat must be capable of rapid dissipation.**
(8) **Lubrication of all working parts must be adequate and very simple to maintain.**

All parts of a clutch must be accurately in rotational balance.

When fitted with compressed asbestos fabric a clutch can absorb energy at the rate of 24,000 to 30,000 ft.-lbs. per sq. in. of facing per minute so long as the temperature is below 500° F.

Clutch calculations are very simple and the problem is to make the clutch torque equal to the engine torque plus a safety factor of 25 per cent.

Using the following symbols :—

H.P. = horse-power transmitted.
T_i = engine torque in lb.-ins.
n = r.p.m.
S = *total* spring pressure in lbs.
N = number of friction surfaces in contact.
R = effective radius of friction disc.
R_i = inner radius of friction disc.
R_o = outer radius of friction disc.
μ = coefficient of friction.

Then $T_i = \frac{63{,}024 \text{ H.P.}}{n}$ **and allowing for the necessary factor of safety the clutch torque will be** $1 \cdot 25\ T_i$

$$R = \frac{2\,(R_i^2 + R_i R_o + R_o^2)}{3\,(R_i + R_o)}$$

then $\quad 1 \cdot 25 T_i = s \times \mu \times N \times R.$

whence $\quad s = 1 \cdot 25\ T_i/\mu NR.$

Note.—**S is generally distributed over 3, 4, 6, or 8 separate helical springs, a single central spring being difficult to arrange, and heavy. N may of course be 1 or as many more as required.**

The dimensions of clutch friction discs is now standardised by the S.M.M. and T., ranging from 6 ins. × 4·5 ins. dia. up to 18 ins. × 13·5 ins. dia. The thickness ranging from ⅛ in. up to ⅜ in.

It is undesirable for the surface speed at the effective radius R to exceed about 7,000 ft. per min. and rivet heads must be sunk well below the rubbing surface.

Flywheels.—**A flywheel is necessary to smooth out variations in torque and to maintain an approximately constant angular velocity. Formerly flywheels of considerable mass were employed, but as engine speeds have increased they have become less necessary, and the present demand for rapid acceleration is incompatible with their use. All that is necessary is a substantial disc of mild steel to which the driving member of the clutch can be secured. The flywheel effect depends upon the polar moment of inertia. For a plain disc,** $I_o = \frac{\pi}{32} D^4$ **and for a hollow cylinder** $I_o = \frac{\pi}{32}(D^4 - d^4)$.

Again, for a plain disc the radius of gyration $k = (D/2) \times \sqrt{0 \cdot 5}$

and for a cylinder $\quad k = \sqrt{(D^2 + d^2)/8}.$

For high speed engines the rim tension is important and is approximately equal to $v^2/10$ **where** v = **velocity in ft. per sec.**

Ignition Equipment.

The ignition equipment on the modern car is invariably of the battery-coil type, whilst magnetos are more generally used on industrial, marine, tractor and motor-cycle engines.

The function of the ignition equipment is to provide a succession of accurately timed, high voltage sparks to ignite the explosive mixture in the engine cylinders. Since in a six-cylinder engine, three sparks are produced for each revolution of the engine, the ignition equipment is called upon to supply anything up to about 12,000 or more sparks per minute, each of which must be carefully timed to less than a thousandth part of a second.

Coil Ignition.

Coil ignition equipment, a typical diagram of which is shown in fig. 21, consists essentially of :—

(*a*) the battery which supplies the electrical energy ;
(*b*) the ignition coil, which transforms the battery voltage into a high voltage of the order of at least 6,000 volts to produce a spark at the plug gaps ;
(*c*) the contact-breaker, which opens and closes the primary circuit through the coil, and to which a condenser is connected in parallel ;
(*d*) the distributor which delivers the spark to the correct cylinder ; and
(*e*) the ignition switch for disconnecting the battery when it is desired to stop the engine.

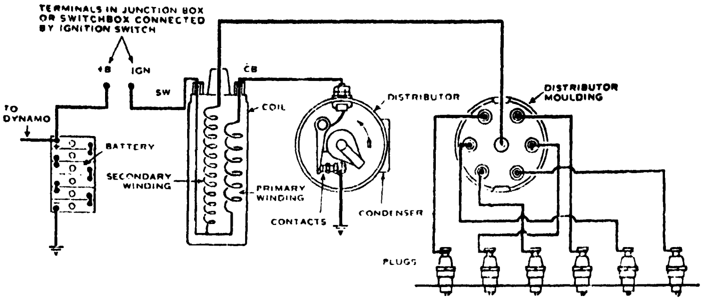

FIG. 21.

The ignition coil has a laminated iron core, around which are two windings ; a secondary winding of many thousands of turns of very fine wire, and on top of this, a primary winding of comparatively few turns of thick wire. The core and windings are housed in a cylindrical metal container filled with an insulating compound which effectively seals the coil winding and prevents the ingress of moisture.

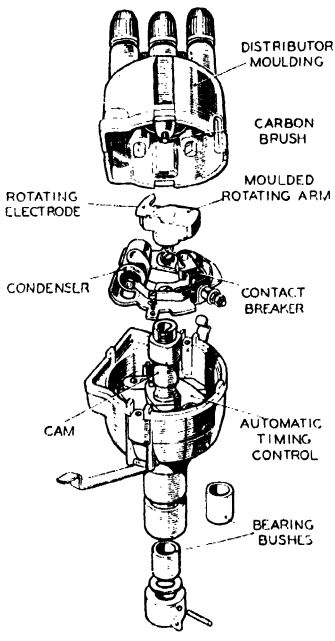

FIG. 22.

The contact-breaker and distributor form a combined unit which is gear-driven by the engine (fig. 22). The former consists of two contacts, one fixed and the other mounted on a pivoted lever provided with a spring which tends to bring the contacts together. The movement of this contact is controlled by a bakelised fabric heel which presses on the surface of a cam, having, either four

or six lobes according to the number of engine cylinders. When the distributor shaft is rotated, the contacts are made to separate at the appropriate instant by the cam lobes lifting the heel on the contact-breaker lever (fig. 2.).

The distributor comprises a rotating arm and a moulding containing on the inside a number of metal segments which are connected, via the terminals, to the sparking plugs by means of the high-tension cables.

When the ignition is switched on, current flows from the battery, throguh the primary winding of the coil and then on to the contact-breaker. On pressing the starter switch, the engine rotates, so driving the distributor shaft carrying the cam, and causing the contacts to make and break alternatively. Each time the contacts open, the collapse of the primary current in the coil gives rise to the high secondary voltage, which is passed from the coil to the rotating distributor arm. From here, it jumps the gap to one of the metal inserts in the distributor moulding, which in turn is connected by cable to one of the sparking plugs, with the result that a spark is produced at the plug points.

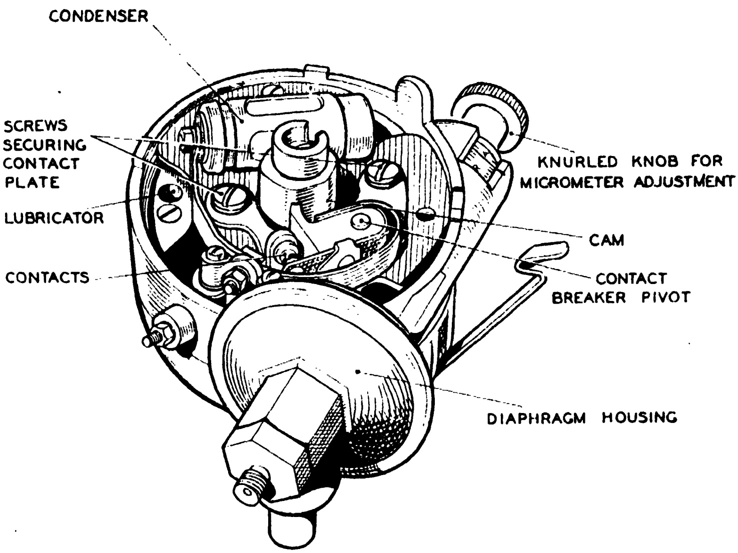

FIG. 23.

Immediately after the spark occurs, the contact-breaker closes and the cycle of operations will be repeated for the spark to occur in the cylinder next in the firing order.

A condenser is connected across the contact-breaker, the purpose of which is to obtain a quick break of the current and to control sparking at the contacts.

The equipment is provided with a centrifugally-operated automatic timing control. This mechanism is housed beneath the contact-breaker and takes the form of a governor which alters the position of the contact-breaker cam with relation to the driving shaft. The mechanism consists of two weights which tend to move outwards against the tension of a spring as the engine speed increases, causing the cam to move in the direction of the drive and thus advancing the timing.

In addition, a vacuum-operated timing control is incorporated on many types of distributor (fig. 23), the purpose of which is to alter the ignition timing according to the engine load. Advantage is taken of the fact that at any fixed engine speed the intake manifold suction is roughly inversely proportional to the engine load ; that is to say, with a light load the suction in the intake is of a comparatively high order, whilst on full load it is of low value. This variation of pressure is utilised to give the most suitable ignition timing at all loads. The control consists of a flexible diaphragm enclosed in a metal housing. The diaphragm is linked so that when acted upon by the vacuum in the induction pipe of the engine, its movement produces rotation of either the complete distributor head or contact-breaker base.

Magneto Ignition.

Two types of magneto are in general use (*a*) the rotating armature and (*b*) the rotating magnet; the operation of both types is based on the same general principle, namely, the rapid change of magnetic flux in a laminated iron core carrying a suitable winding.

In (*a*) the magnetic flux is provided by an inverted U-shaped permanent magnet and the reversal of the flux, relative to the core, is caused by the rotation of the armature between the laminated pole pieces of the magnet. The armature is provided with two windings, a primary winding consisting of relatively few turns of thick wire and a secondary winding consisting of a large number of turns of thin wire. In (*b*) the flux is provided by a permanent magnet, which is fitted with two laminated pole pieces and forms the rotor. This revolves between another pair of laminated pole pieces which are bridged by a laminated core on which are the primary and secondary windings. In both types the contact-breaker is arranged to open circuit the primary winding at the instant a spark is required.

In operation the rotation of the rotor produces an alternating magnetic field in the laminated iron core of the coil. This, in turn, generates an alternating low tension current in the primary winding. At about the instant when this current reaches its maximum value, one of the lobes of the cam is timed to strike the contact-breaker lever, so separating the contacts and causing a high voltage to be induced in the secondary winding. This high voltage is conducted to each sparking plug in the order of firing by means of the rotating distributor arm, and produces a spark at the plug points.

Magnetos are often fitted with an impulse starter in order to improve the low speed performance and retard the ignition for hand starting purposes. This unit consists essentially of two couplings which are flexibly connected by means of a coil spring. One coupling is fitted on the driving shaft, while the other is secured to the magneto spindle. As the engine is slowly rotated by hand, a pawl prevents the movement of the magneto rotor, whilst the driving member continues to rotate, thereby stressing the coupling spring until such time as the pawl is tripped by means of a cam in the impulse starter. When this occurs, the magneto rotor is accelerated rapidly through the sparking position and a powerful spark is produced, the timing of which is retarded for ease of starting. The sequence is repeated until the engine fires and continues to run, the pawls being held out of engagement at a comparatively low speed by centrifugal force.

A centrifugally-operated automatic timing device may also be fitted for certain applications.

The Dynamo.

The dynamo in general use on cars and commercial vehicles is cylindrical in form, consisting of a welded steel shell or yoke and with usually a two-pole magnet system and a conventional armature and commutator.

In most cases, the dynamo is of what is known as the swung mounted type and is driven by a belt which also forms the drive to the engine cooling fan. Many dynamos are of the ventilated pattern in which cooling air is drawn through the machine by a centrifugal fan integral with the driving pulley. For special conditions, however, such as on tractors where excessive dust is encountered, it is often the practice to employ totally enclosed dynamos.

The output from the dynamo varies in accordance with the strength of the magnetic field and with the speed at which the dynamo is being driven and as the machine is called upon to operate over a very wide speed range, a means of controlling the dynamo output must be provided.

Two methods generally employed have been the 'third-brush control' which has now been superseded entirely by 'compensated voltage control' of the dynamo output.

Third-brush Control.—The third-brush dynamo depends for its regulation on the armature reaction produced by the generated current. The fact that the field winding is connected between one of the main brushes and the auxiliary or third brush in such a manner that distortion of the main field as a result of armature reaction, causes a reduction of the voltage impressed on the field system. The chief merit of this method of control is its simplicity, but it has a serious disadvantage in that the current which the dynamo gives is a function of the voltage of the system. This means that as the voltage of the system becomes higher, the current which the dynamo will give before the regulating effect of the armature reaction comes into play, also becomes higher. Such a machine will, therefore, deliver a heavier current to a fully charged battery during a daylight run with the lamps switched off than it delivers to a partially discharged battery with the lamps in use. This would, of course, result in overcharging the battery during long daylight running periods, with a tendency to discharge the battery if the vehicle is used for long night runs without corresponding periods of daylight running.

To minimise this effect, the two or three charge rate system was adopted, in which a resistance is automatically inserted in the field system when the lights are switched off and short circuited when the lights are switched on. An added refinement usually provided is to have two alternative daytime positions of the charging switch, one giving maximum reduction in charge for summer running and the other a small reduction in charge for daylight running in winter. The operation of switching on the lights short circuits all the resistance and permits the generator to give its maximum output.

While this system of output control was reasonably successful in meeting the needs of the average motorist, it had limitations; one of the most serious being that the insertion of the resistance to reduce the dynamo output, also has the effect of raising the cutting-in speed of the dynamo

This is very undesirable for vehicles used for short runs only in heavy traffic or on vehicles used under conditions necessitating frequent starting and stopping.

Compensated Voltage Control.—This equipment comprises a specially designed dynamo and a regulator unit which varies the dynamo output according to the load on the battery and its state of charge. The dynamo is similar in appearance to the third-brush machine, but is wound differently and the third brush is omitted. The regulator unit is usually housed on the dash, and is integral with the cut-out, fuse and junction box. A wiring diagram is shown in fig. 24.

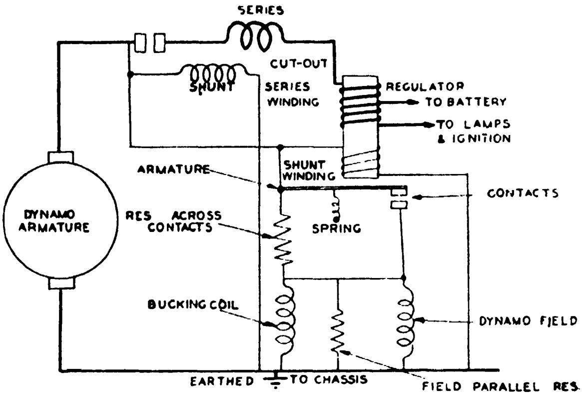

FIG. 24.

The operation of the regulator depends upon the fact that the voltage of a battery varies between certain fixed limits according to the state of charge of the battery, the voltage being, of course, a maximum when the battery is fully charged, and a minimum when the battery is fully discharged.

The regulator is combined structurally with the cut-out. The regulator and cut-out are, however, electrically separate, employing separate armatures, though they possess field systems which are common over a portion of the magnetic path.

The windings consist of a voltage winding connected directly across the dynamo and two current windings, one of which carries the full current from the dynamo to the battery, while the other winding carries the current of the lighting, ignition and accessory loads. These coils assist each other in energising the magnet system and thus in effecting movement of the armature.

When the dynamo voltage reaches a predetermined value, the magnetic field due to the voltage winding becomes sufficiently strong to attract the armature. This causes the contacts to open, thereby inserting the resistance in the field circuit. This reduction in field current lowers the dynamo voltage, and this, in turn, weakens the magnetic field due to the voltage coil. This allows the armature to return to its original position, thus closing the contacts, so that the voltage returns to the predetermined maximum. The cycle is then repeated, and the armature is set into vibration.

As the speed of the dynamo rises above that at which the regulator comes into operation—about 20 m.p.h.—the amplitude of vibration increases and the periods of interruption increase in length, with the result that the mean value of the dynamo output undergoes practically no increase once the operating speed has been attained.

The series windings provide a compensation on this system of control, for if the control were arranged entirely on the basis of dynamo voltage there would be a risk of very seriously overloading the dynamo when the battery was in a low state of charge, particularly if the lamps were simultaneously in use. Under these conditions the dynamo would be forced to give an output to bring the voltage of the system up to the same value as if the battery were in its normal fully charged condition, and this, with a battery of low internal resistance would necessitate an extremely heavy current far beyond the normal capacity of the machine. The series winding assists the voltage coil, so that when the dynamo is delivering a heavy current into a discharged battery the regulator comes into operation at a somewhat reduced voltage, thus limiting the dynamo output accordingly.

By means of the temperature compensation the voltage characteristic of the dynamo is caused to conform more closely to that of the battery under all climatic conditions. In cold weather the voltage required to charge the battery increases, whilst in warm weather the voltage required is lower.

The method of compensation takes the form of a bimetallic spring suspension for the armature of the regulator, which causes the operating voltage of the regulator to be increased in cold weather and reduced in hot weather, and thereby compensate for the variation in charging current which would otherwise occur due to the changed characteristics of the battery.

The Starting Motor.

The electric starting motor is a four pole machine having an extended shaft to carry the engagement gear. Smaller motors are series wound, while larger machines usually have series-parallel field connections. The starting motor is of similar construction to the dynamo except that heavier copper wire is used in the construction of armature and field windings, as it must be remembered that the current consumption of the motor is very high. The average 12-volt starter under normal conditions takes 450–500 amperes at about 7 volts. Series-wound machines have two brushes, and series-parallel machines four brushes, fitted 90° to each other.

The starter drives in general use consist of three main types—the Lucas ' S ' type, the ' SB ' type and the ' rubber ' type. The construction and operation of these drives are described briefly below to assist in differentiation.

' *S* ' *Drive.*—The pinion is mounted on a threaded sleeve which is carried on splines on the armature shaft, the sleeve being arranged so that it can move along the shaft against a compression spring so as to reduce the shock loading at the moment engagement takes place. When the starter switch is operated, the shaft and screwed sleeve rotate and, owing to the inertia of the pinion, the screwed sleeve turns inside the pinion, causing the latter to move along the sleeve into engagement with the flywheel ring. The starter will then turn the engine.

As soon as the engine commences to run under its own power, the flywheel will be driven faster by the engine than by the starter. This will cause the pinion to screw back along the sleeve and so draw out of mesh with the flywheel teeth. In this manner, the drive safeguards the starter against damage due to being driven at high speeds by the engine.

On many drives of this type, a pinion restraining spring is fitted over the starter shaft to prevent the pinion being vibrated into contact with the flywheel when the engine is running.

' *SB* ' *Drive.*—This drive is similar in principle to the ' S ' type, but the pinion rides directly on the starter shaft so that a smaller pinion can be used to provide a larger gear ratio between starter and engine.

' *Rubber* ' *Drive.*—There are several different designs of this type of drive, in which a rubber coupling is used to transmit the drive from the starter shaft to the engine, but the basic principle of operation is the same in each case.

The drive embodies a combination of rubber torsion member and friction clutch in order to control the torque transmitted from the starter to the engine flywheel and to dissipate the energy in the rotating armature of the starter at the moment when the pinion engages with the flywheel. It also embodies an overload release mechanism which functions in the event of extreme stress, such as may occur in the event of a very heavy backfire, or if the starter is inadvertently meshed into a flywheel rotating in the reverse direction due to rocking back off compression.

When the starter is energised, the torque is transmitted by two paths, one via the outer sleeve of the rubber coupling and through the friction washer to the screwed sleeve, while the other path is from the outer to the inner sleeve through the rubber coupling and then directly to the screwed sleeve.

The torque through the rubber limits the total torque which the drive transmits and since the rubber is bonded to the inner sleeve, under overload conditions slipping will occur between the rubber bush and the outer sleeve of the coupling. Slipping does not take place under normal engagement conditions, when the rubber acts merely as a spring with a limiting relative twist on the two members of approximately 30°. Under conditions of unduly severe overload which might cause damage to the drive or its mounting, however, the rubber slips in its housing so that a definite upper limit is set to the torque transmitted and to the stresses which may occur. The bonding of the rubber to the inner sleeve is a recent design alteration, as a result of which the drive is capable of absorbing a torque 50 per cent. in excess of the non-bonded unit.

Splined Shafts.

Tests carried out on actual shafts show that the elastic limit for a splined shaft is lower than for a plain shaft of a diameter equal to the base diameter of the splines. This varies with the form of the spline for the following reason. In fig. 25 a section through two splines is shown.

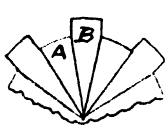

FIG. 25.

When the shaft is twisted, the sectors A and B become helices of which the lengths are different, both being functions of the diameters, respectively A and B, *i.e.* measured round the helix, B is longer than A, the difference being $\pi DB - \pi DA$, and this sets up a shearing stress along the radial lines. Constant stress reversal ultimately fractures the shaft into perfect sectors. It follows that the greater the difference between the respective diameters, the sooner will this result, hence a large number of small splines is considerably stronger than a small number of relatively large ones. In round figures the imposition of splines reduces the shearing strength of the shaft by from 5 to 7½ per cent., depending on their number. If the specific stress can be kept low (sometimes a difficult problem) the effect is minimised, but it is always present in some degree.

Where sliding is not to take place, continuous serrations are often substituted for square splines. When sliding is required the outer component is ground in its inner bore, and the corresponding surface of the shaft at A is also ground so that the top of the spline makes no contact. Splines are also applied to tapered shafts.

Splined shafts of all kinds are almost universally finished by grinding in special machines, and the corresponding parts broached to finished size.

The sections of splined shafts have been standardised by the British Standards Institution, and in the U.S.A. by the S.A.E., but the tables are too extensive for inclusion here.

Standardised broaches for forming these are also obtainable.

***Note.*—If the splines are completely supported between two adjacent components their shearing strength can be added to the shaft as there is no helical deformation. In practice however, this cannot often be arranged.**

Gears.

Spur Gearing.—For many years a pressure angle of 14½° was in use for involute gears and a stub form of tooth was general. The accepted practice for spur-gear teeth now, however, is to use a full depth involute tooth having a pressure angle of 20°.

Reference should be made to the B.S.I. Specification No. 436—1940 for straight spur and helical gear calculations and to Dr. H. E. Merritt's 'Gears.'

The following table gives the comparative pitch and module sizes in general use :—

TABLE VIII.

COMPARATIVE PITCH.

Diametral Pitch.	Circular Pitch.	Module British.	Module Metric.
1	3·1416	1·0000	25·3995
2	1·5708	0·5000	12·6998
3	1·0472	0·3333	8·4665
4	0·7854	0·2500	6·3499
5	0·6283	0·2000	5·0799
6	0·5236	0·1666	4·2333
7	0·4488	0·1428	3·6285
8	0·3927	0·1250	3·1749
9	0·3491	0·1111	2·8222
10	0·3142	0·1000	2·5400
P	*p*	*m*	Mm/m.

$$p = \frac{\pi}{P} \qquad P = \frac{\pi}{p} \qquad m = \frac{p}{\pi} = \frac{D}{T} = \frac{1}{P}$$

Tangential Load.—The tangential load per inch of face width for *wear* may be expressed as

$$L = \frac{X_c Z S_c}{K}$$

and for ***strength*** as —

$$L = \frac{X_b Y S_b}{P}$$

where

K = Pitch factor.
X_b = Speed factor for strength.
X_c = Speed factor for wear.
Z = Zone factor.
P = Diametral pitch.
S_b = Bending stress factor.
S_c = Surface stress factor.
Y = Strength factor.

The allowable tangential load for any pair of gears is the least of the four figures for wheel and pinion.

For automobile gear-boxes in which each individual gear is usually only subjected to occasional use, higher stresses may be allowed and the speed factor, in the above formulæ, may be expressed as follows, for both wear and strength :—

$$X = \frac{15 + G_f}{30} \text{ for forward gears,}$$

$$\text{and } X = \frac{15 + G_f}{25} \text{ for reverse gears.}$$

The value of the gradient factor G_f is obtained by the following formula :—

$$G_f = \frac{100\ MR_t}{W_g\ r}$$

where

M = Maximum engine torque, lb. in.

R_t = Overall reduction in the gear considered.

$= \frac{\text{Engine r.p.m.}}{\text{Roadwheel r.p.m.}}$

W_g = Gross laden weight of the vehicle, and trailer (if any), pounds.

r = Rolling radius of tyre, ins.

NOTE.—The values of the various factors used in the above formulæ may be obtained from B.S.I. Specification No. 436—1940.

Bevel Gearing.—For bevel gear calculations reference should be made to the B.S.I. Specification No. 545—1947 and to Dr. H. E. Merritt's 'Gears.'

Tangential Load.—The tangential load for *wear*, considered to be applied at the pitch radius of the gear may be expressed as :—

$$L\ (\text{pinion}) = \frac{X_{cp}S_{cp}ZF}{K\Omega_c}\left(\frac{C - F}{C}\right)\sqrt[3]{\frac{27,000}{1,000 + U_d}}$$

and

$$L\ (\text{wheel}) = \frac{X_{cw}S_{cw}ZF}{K\Omega_c}\left(\frac{C - F}{C}\right)\sqrt[3]{\frac{27,000}{1,000 + U_d}}.$$

The tangential load for *strength*, considered to be applied at the pitch radius of the gear may be expressed as :—

$$L\ (\text{pinion}) = \frac{X_{bp}S_{bp}Y_pF}{P\Omega_b}\left(\frac{C - F}{C}\right)\sqrt[7]{\frac{26,200}{200 + U_d}}$$

and

$$L\ (\text{wheel}) = \frac{X_{bw}S_{bw}Y_wF}{P\Omega_b}\left(\frac{C - F}{C}\right)\sqrt[7]{\frac{26.200}{200 + U_d}}.$$

where

C = Cone distance.	X_b = Speed factor for strength.
F = Face width.	X_c = Speed factor for wear.
K = Pitch factor.	Y = Strength factor.
P = Diametral pitch.	Z = Zone factor.
S_b = Bending stress factor.	Ω_b (omega) = Bevel gear helix angle factor.
S_c = Surface stress factor.	Ω_c (omega) = Overlap ratio factor.

U_d = Desired total running life of the gears in hours at full load, the usual value of which is 26,000.

For automobile bevel gears higher stresses may be allowed and the speed factor in both wear and strength formulæ expressed as follows :—

$$X = \frac{15 + G_f}{30}.$$

The value of the gradient factor G_f is obtained as described above.

NOTE.—The values of the various factors used in the above formulæ may be obtained from B.S.I. Specification No. 545—1947.

TABLE IX.—BASIC SURFACE AND BENDING STRESS FACTORS.

The following values for S_c and S_b are typical but reference should be made to the tables in the publications previously mentioned.

Material.	Min. Ult. Tensile Strength. (tons/sq. in.)	Min. Brinell Hardness No.	Basic Surface Stress Factor S_c.	Basic Bending Stress Factor S_b.
Cast iron	12	165	1,000	5,800

4¼ per cent. nickel chromium steel	100	441	5,500	49,500

***Tooth Pressures.*—The actual tooth pressures, per inch of tooth width, obtained in ordinary practice vary over wide limits; thus, 1,500 lbs. per in. width may be taken as a suitable figure. In the case of racing cars much higher figures are common; thus in the 'Blue Bird' car of 1933 the gear box was designed for a tooth pressure of 2,700 lbs. per in., but the engine power having been increased this rose to 5,400 lbs. steady top gear load. This was with plain spur gears. In the case of the rear axle bevels, the steady load amounted to 6,000 lbs. per in. These pressures were only made possible by a very careful selection of steel, and the very short load period per tooth. The spur gears were ground after hardening and the lubricant was a castor base oil.**

Gear Boxes.

Very numerous efforts have been made, especially in the United States, to devise mechanical arrangements to simplify gear changing. In Great Britain practice has crystallised into two types, the epicyclic with pre-selector mechanism, or a simple type generally modelled on the old clash gear pattern, having all the gears in constant mesh or sliding, but in either case employing synchromesh clutches to effect engagement. In its simple form this consists of a pair of small cone clutches which are engaged before the gears are slid into mesh, or in cases where the gears are in constant mesh (as when helical gears are used), the dog clutches engaging them. The result is that the gears or clutches cannot be brought into contact until they are revolving at appropriate speeds and silent engagement is assured. This mechanism is usually applied to each speed except first.

***Number of Speeds.*—When there are more than four speeds one of them is generally an overdrive, which given sufficient engine power is very advantageous.**

The gear ratios should approximate to a geometric progression from high to low; but latitude is found in this.

Suspension.

Satisfactory and safe suspension has been rendered more difficult with increase of speed and rapid braking. The laminated spring is not so universally used as formerly, other forms having been called for with the tendency to use independent springing at each wheel, where it is extremely hard to find room for the laminated type; in conventional designs it will continue in use from its relative cheapness, simplicity, lateral stiffness, and its high internal friction, which acts as a damper. It has also the advantage that damage takes place slowly—usually one leaf at a time—so there is warning before total failure.

Some successful attempts have been made to use rubber cushion springs, which while functioning well are open to criticism on account of their weight.

There can be no doubt as to the improvement effected in suspension by doing away with the transverse axle common to two wheels; any obstruction met with by any wheel is surmounted without disturbing the equilibrium of the other corners of the chassis. It is, generally thought that the torsion-bar spring represents the direction of most probable development. In earlier models of independent springing, helical springs have been employed which have the advantage of being silent and not needing any lubrication. Both helical and torsion-bar springs, possessing no internal friction, demand more elaborate damping arrangements.

The usual device adopted for individual springing is a two-link parallel motion in which the links are of triangular construction in plan, the fixed ends being splayed apart to resist stresses occurring

longitudinally to the chassis, *i.e.*, as when braking; the construction has been given, from its form, the name of 'wish-bone.' Laminated, helical, or torsion bar springs can be incorporated in the design.

Figs. 26 and 27 illustrate typical independent front wheel suspension systems, the former employing torsion bar and the latter helical springs.

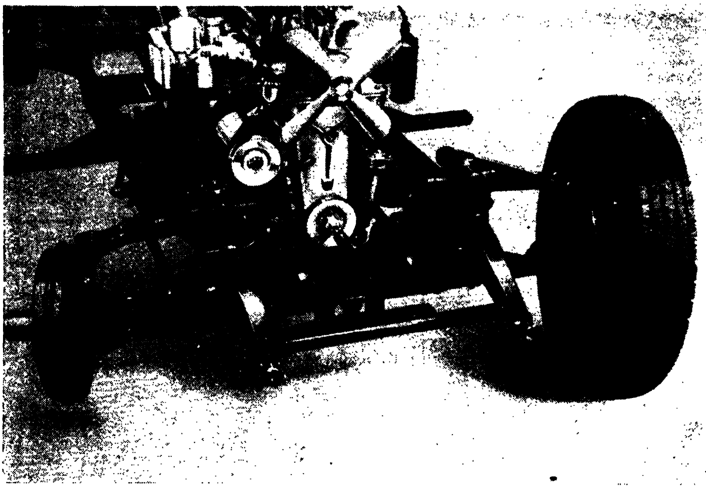

FIG. 26.

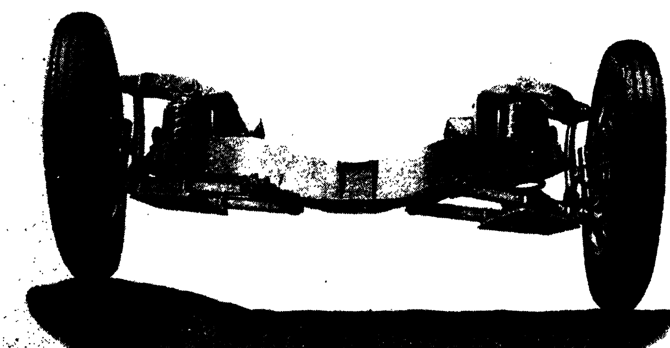

FIG. 27.

***Riding Comfort.*—Is dependent upon (*a*) the periodicity of the spring, and (*b*) the nature and extent of the damping applied to it. Periodicity depends on the amount of static deflection with a given load.**

Let t = seconds, l = deflection in ft.; then $t = \pi\sqrt{\frac{l}{32 \cdot 2}}$ from which Table X is calculated.

TABLE X.

PERIODICITY OF SPRINGS.

Deflection in Ins.	Complete Oscillations per Min.
1·5	153·0
2·0	132·7
2·5	119·5
3·0	108·3
3·5	100·0
4·0	94·1
4·5	88·8
5·0	84·0
5·5	80·0

The figures in this table are modified by the form of damping arrangement employed.

Front springs may have a range of 75–85 oscillations per min. and rear springs from 75–100, depending on the wheel base and track.

***Laminated Springs.*—Three types are in use: (A) the semi-elliptic; (B) the so-called cantilever; (C) the so-called quarter elliptic which is really the true cantilever, see fig 28.**

Let

W = load on spring in lbs.
L = length in ins.
δ = deflection due to W in ins.
R = W/δ, 'rate' in lbs per in. δ
f = stress in material lbs. per sq. in.
E = modulus of elasticity.
Z = modulus of section.
n = number of leaves.
t = thickness of leaves in ins.
b = breadth of leaves in ins.
M = bending moment.
I = moment of inertia of section.

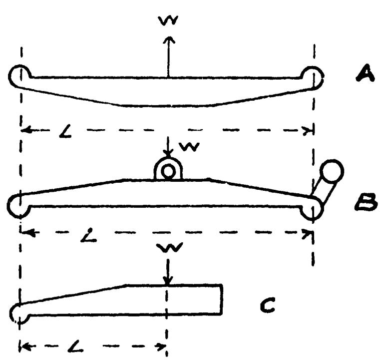

FIG. 28.

The modulus $E = 30 \times 10^6$, but owing to internal friction, irregularities of section, etc., a correction is needed; if 24×10^6 be taken for value of E, the results will conform to observed tests. Formulæ are given in the following table:—

TABLE XI.

LAMINATED SPRINGS. (See fig. 28.)

	Type.		
	A.	**B.**	**C.**
M	$WL/4$	$WL/2$	WL
I	$nbt^3/12$	$nbt^3/12$	$nbt^3/12$
Z	$nbt^2/6$	$nbt^2/6$	$nbt^2/6$
f	$3WL/2nbt^2$	$3WL/nbt^2$	$6WL/nbt^2$
δ	$WL^3/48EI$	$WL^3/24EI$	$WL^3/3EI$
δ	$\dfrac{WL^3}{96 \times 10^6 \times nbt^3}$	$\dfrac{WL^3}{48 \times 10^6 \times nbt^3}$	$\dfrac{WL^3}{6 \times 10^6 \times nbt^3}$

Semi-elliptic springs are frequently loaded unsymmetrically; in such a case BM = Wxy/L and $f = Wxy/Ls$; where x and y are the lengths of the two arms of the spring.

***Note.*—The stress f must never exceed 22 tons per sq. in. This is equivalent to limiting the energy stored in the spring relative to the weight of steel. The energy is the weight W, carried, multiplied by one-half the deflection in ft.; or**

$$E = \frac{W \times \delta}{2 \times 12}$$

A stress of 22 tons per sq. in. is equivalent to 3 ft.-lb. of energy per lb. of steel, and this must not be exceeded, irrespective of the quality of steel employed.

Spring calculations are complicated by the necessity of providing for the twisting of the axle due to braking, or the torque in driving, and these must be taken into consideration.

***Steel for Laminated Springs.*—The steel used is either a chrome-vanadium or a silico-manganese, for examples, see Table XII.**

TABLE XII.

PROPERTIES OF SPRING STEELS.

	Chrome Vanadium.	Silico Manganese.
Yield point .	184,800 lbs. per sq. in.	172,200
Ult. tensile .	194,900 lbs. per sq. in.	197,600
Red. area .	48 per cent.	36 per cent.
Elongation .	16 per cent. in 2 ins.	15 per cent. in 2 ins.
Brinell . .	450/455	4·55
C per cent. .	0·46	0·52
Mn ,, .	0·57	1·05
Si ,, .	0·17	1·95
Ni ,, .	0·15	—
Cr ,, .	1·40	0·05
Va ,, .	0·18	—

The foregoing is based on the assumption that the spring is strictly of rhomboidal proportions and that the initial curvature of each leaf is the arc of a concentric circle. In practice, mainly for appearance, increasing camber is given to the lower leaves to prevent separation of leaves on a rebound; the leaves are held together by a clip, rivet, or bolt, which puts initial stress into each leaf which increases as the shorter leaves are reached. This has the further bad effect of producing a localised stress in the leaf above where the lower leaf ends. To overcome this the end of the leaf is tapered both in breadth and thickness, but unless this is done with great intelligence it is ineffective.

The amount of extra curvature given to the lower leaves, known as 'nip,' should be a minimum. To check the rebound, additional leaves are frequently superposed above the top or master leaf, and the leaf next below it is preferably long enough at least partially to encircle the eye.

It is not necessary to weld the eye, and bushes are usually of rubber.

Good quality springs are frequently ground on the leaf surfaces after hardening, and sometimes interleaved with brass or zinc. With any laminated spring dust and mud should be excluded and continuous lubrication is imperative.

Helical Springs.—The stress conditions can be determined as follows:—

E_0 = transverse modulus of elasticity.
d = diameter of wire in ins.
R = mean radius of coil in ins.
n = number of free turns.
δ = deflection in ins.
W = load on spring in lbs.
W/δ = 'rate' per in. deflection.

then $W/\delta = E_0 d^4/64R^3 n$.

The value of E_0 is approx. 11,500,000; whence $W/\delta = 180{,}000 d^4/R^3 n$.

The maximum safe load = KD^3/R where K has a value of 10,000 to 12,000 lbs.

As in the case of laminated springs the periodicity is determined by the amount of deflection under static load.

Torsion-bar Spring.—Now coming into use as it lends itself to individual wheel springing. The bar is finished and ground to accurate dimensions the ends being left large and splined to engage the anchorage; one end being secured to the frame and the other to the wheel by means of links, the bar being thus subject to a twisting moment.

Let

T = twisting moment in lb. ins.;
R = radius of acting force in ins.;
W = tangential load;
d = dia. of bar in ins.;
f_0 = shearing stress lb./sq. in. at surface;
E_0 = transverse modulus of elasticity (11,500,000);
θ = degrees angle of twist at end of bar;
l = length of bar in ins.;

then $T = WR = \frac{\pi}{16} d^3 f_0$;

whence $f_0 = 16T/\pi d^3$; and $d = \sqrt[3]{16T/\pi f_0}$;

and $\theta = \frac{583 \cdot 61\, Tl}{E_0 d^4}$

The general question of suspension while mainly dependent on the springs, cannot be separated from the resilience of the tyres (a considerable matter since the introduction of large section low-pressure tyres) and the springs included in the term 'upholstery.' It is clear that the latter are of great importance, and may be of steel, sorbo rubber, or air cushions; hence the final oscillation period may be very different from that of the spring alone, and the resultant period is the one to consider. The vertical acceleration of passengers on the seats must not be great enough to lift them from the seats, hence they must at no time have an acceleration greater than that due to gravity. Generally speaking with a periodicity of 90 per min. at the springs the maximum vertical acceleration will probably not exceed this.

Frames.

The general principles of frame construction have undergone considerable modification in recent years. Formerly a considerable degree of general flexibility was deliberately aimed at, nowadays a maximum of rigidity is sought—particularly noticeable in passenger cars. With four independently sprung wheels a completely rigid frame would give best results. The universal employment of front-wheel brakes also profoundly effects the disposition of stresses in the frame. All types of frame are now heavily braced by structural diagonals; moreover, to secure the desired rigidity frames are of such a deep section that (as in the case of crankshafts) the frame structure is in the end subjected to very moderate specific stresses.

Car Weights.

Gross weight is the fully-laden weight of the complete car.

Tare weight is the unladen weight of the complete car including the body, but without the useful load of passengers or freight.

Chassis weight is the weight of the bare chassis without body or load, but includes oil, grease, water and fuel.

Front axle weight is the gross weight imposed on the ground by both front wheels and includes body and load.

Rear-axle weight is the gross weight imposed on the ground by both rear wheels including body and load.

Sprung weight is the total gross weight carried by the springs at either axle.

Unsprung weight is the weight of the axle, wheels, tyres, springs, brake drums and shoes, steering and brake rods., etc.

In calculating the frame stresses, the loads at each point of suspension of each unit must be taken, and the bending moment evaluated, taking account of the distributed load of the body and its fully laden contents. It is not necessary to calculate the shearing stresses as a rule, since these, for reasons already stated, are of very low specific value.

In the case of independent springing, and particularly when torsion-bar springs are used, the frame must be cross-membered at the spring anchorage to prevent buckling.

The following table gives the approximate weight of chassis parts for both passenger cars and commercial vehicles.

TABLE XIII.

APPROXIMATE PER CENT. WEIGHT OF CHASSIS COMPONENTS.

	Car.	Lorry.
Sprung weight:		
Radiator and water	4	5
Engine and gear box	37	27
Steering gear	1	2
Petrol tank and fuel	3	4
Frame	15	17
Total	60	55
Unsprung weight:		
Front axle, springs, wheels, tyres, brakes, steering levers, etc.	18	10
Rear axle, springs, wheels, tyres, brakes, etc.	22	35
Total	40	45
Total sprung and unsprung	100	100

For passenger cars the body weights are roughly as follows: body frame (steel), 14 per cent.; body framing complete with head fittings, 42 per cent.; steel panels, 10 per cent.; glass, mouldings, etc., 12 per cent.; trimming, 22 per cent. Total, 100 per cent.

For the whole car the chassis amounts to about 60 per cent.; body complete, 35 per cent.; and wings, valances, etc., 5 per cent. Total 100 per cent.

Dynamic Stressing.—The foregoing clearly applies to static loading only; dynamic stresses may often far exceed it, and concentration of load occurs as when striking obstructions, cornering, etc. When braking, there is always a transfer of load from rear to front axle. Thus if

w = weight transferred from rear to front axle;
W = weight supported by rear axle under static conditions;
μ = coefficient of friction between tyre and road;
h = height of centre of gravity in ft. above road;
L = wheel base in ft.

then $$w = \left(\frac{W \times \mu \times h}{L}\right)$$

This weight of course must be added to the static load supported normally by the front springs. It is thus seen that exact calculation of stresses is defeated by road conditions, hence a liberal margin of safety is required.

The stress in material should not exceed 20,000 lbs. per sq. in. where nickel alloy steel is used. A typical steel for hot pressed frames and cross-members would be 1 per cent. nickel-steel, yield point 68,000 lbs. per sq. in.; ultimate strength 94,000 lbs. per sq. in. Reduction of area 50 per cent. with 20 per cent. elongation.

It is to be noted that lack of rigidity at the front end of a frame is a fruitful contributory cause of 'wheel wobble,' due to the spring periodicity corresponding with that of the frame. By stiffening the latter and so raising the periodicity the trouble disappears.

Another change has taken place in the method of suspending the various units, which were formerly bolted solidly to the frame; great importance was then paid to three-point suspension to prevent distortion of *e.g.*, the engine, due to the flexion of the frame. All the components are now flexibly mounted on rubber cushions, the engine, for example, having a considerable elastic movement about its own principal axis.

This flexible mounting has not only prevented distortion in the components, but has, by insulating the noise producing elements, removed vibration and resonance from the frame, and also most of the remaining noise.

Modern technique in welding has enabled hollow box sections to be employed in frames which were formerly impracticable.

Very concentrated loading, such as occurs in a lorry fitted with a tipping body, requires special frame reinforcement at particular points. For these special calculations are necessary. The provision of a frame which will withstand modern speeds and the consequent road shocks, and will at the same time be relatively light is very largely a matter of good judgment by the designer.

Steering Gear.

The general lay-out of the modified Ackerman steering gear is well known, and the setting out of the linkage is most easily done by graphic methods; skill is required to effect the best all-round arrangement, which is a compromise between making the wheels track on wide or narrow lock. Satisfactory results can only be attained by experience.

The steering mechanism admits of wide variation in types, but takes one of five forms (1) The Nut and Screw, (2) the Worm and Sector, (3) the Cam and Lever, (4) Rack and Pinion, and (5) Re-circulating Ball.

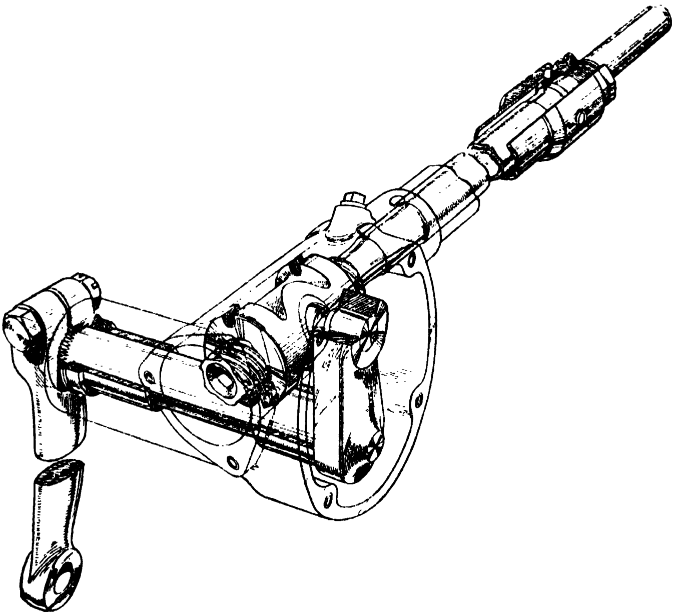

FIG. 29.

In all but the slowest running vehicles it is very desirable that the ratio of angular movement of the steering wheel to that of the first lever, should be differential, *i.e.*, as the lock increases so must the angular ratio or leverage, since on full lock great force is required to move the road wheels while a comparatively small force will suffice at the straight ahead position or zero lock. By making use of a toggle action it is possible to effect wide variation in the effective ratio for the two positions. With a plain worm and sector the angular ratio is constant at all points—largely to its disadvantage.

In certain designs of steering gear a variable ratio is provided, the ratio being at a minimum in the centre position and increasing as the wheel is turned in either direction.

An ordinary steering gear using the worm and nut is the Burman-Douglass, fig. 29. In this the sliding nut engages a spherical pin in a rocking arm; the differential motion referred to is present in a small degree (in one direction only) but the amount would seem to be negligible.

Fig. 30 illustrates the Marles double-roller type steering gear and fig. 31 a typical re-circulating ball type gear.

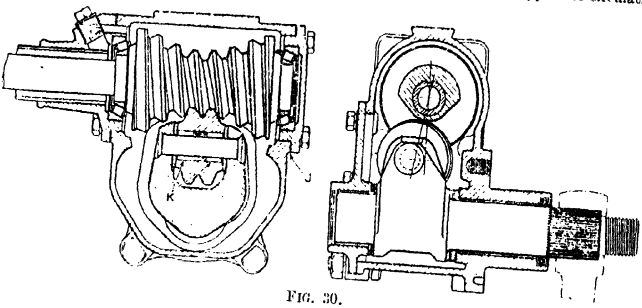

FIG. 30.

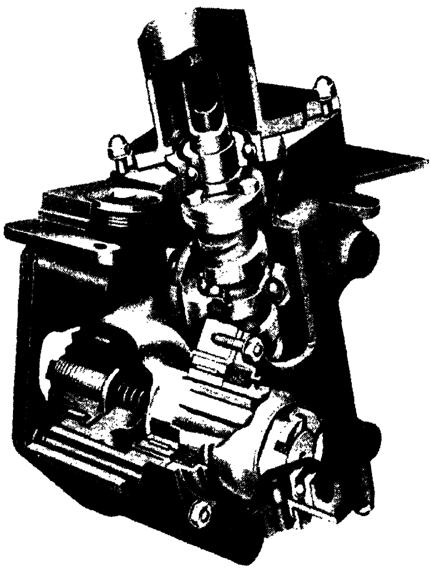

FIG. 31.

Brakes.

The function of the brake is to convert the kinetic energy of the vehicle into heat and dissipate this by radiation. The use of rubber tyres precludes the application of the brake to the wheel surface as is done in the case of railway wheels and those of horse-drawn vehicles, hence an independent brake drum is fitted to the side of the wheel. Owing to the large dimensions of the tyre, the brake drum cannot be much more than one-half the wheel diameter.

Brake drums are usually made of cast iron, alternatively they may be made from pressings or light alloy lined with cast iron; this material has the advantage of having a low coefficient of expansion, is less liable to score than alternative materials, and manufacture is relatively easy. Nickel and chromium are added with good results:—

Total carbon	**3·2**	**2·6**	**Manganese**	**0·8**	**0·5**
Combined carbon	**0·7**	**0·7**	**Nickel**	**—**	**1·0**
Silicon	**2·1**	**2·0**	**Chromium**	**0·35**	**0·45**
Phosphorus	**0·17**	**0·18**	**Sulphur**	**0·09**	**0·09**

the tensile strength of this is from 20 to 25 tons per sq. in.

Experience shows this to be by far the most satisfactory material.

The brake shoes are invariably faced with compressed asbestos fabric secured to the shoes with brass or aluminium rivets which has, when properly made, a coefficient of friction which lies between 0·3 and 0·4; the mean figure of 0·35 may be safely taken.

The wheel is kept revolving by a force equal to the weight on the ground × the coefficient of tyre friction applied at the effective radius of the tyre. Hence the braking force to overcome this can be expressed by the equation

$$P \times \mu_b \times d/2 = W \times \mu_r \times D/2.$$

where P = pressure on brake shoe; μ_b = coefficient of friction of brake lining; d = dia. of brake drum; W = the weight at the wheel tread; μ_r = road coefficient of friction; and D = the effective wheel diameter.

If $\mu_b = 0\cdot4$; $\mu_r = 0\cdot8$; and $D = 2d$, substituting,

$$P = \frac{W \times 0\cdot8 \times 2}{0\cdot4 \times 1} = 4W.$$

In this case the brake-shoe pressure is four times the vehicle weight.

If W = gross weight of vehicle the maximum braking effort or stopping force cannot exceed $W\mu_r$ when all the wheels are braked, and this is applied over the distance traversed before stopping = L ft.

The kinetic energy $E_k = Wv^2/2 \times 32\cdot2$ ft. lbs., and the potential energy $Ep = Wh$ ft. lbs., where v is the velocity in ft. per sec., and h is height fallen through during period of braking.

Hence $$L \times W\mu_r = E_k \pm Ep \text{ (on a gradient)};$$

so the stopping distance is

$$L = E_k(\pm Ep \text{ on a gradient})/W\mu_r.$$

this assumes a brake 100 per cent. efficient. It is thus seen that the shoe pressure may, and generally does, far exceed the gross weight of the vehicle.

If we take the last equation and substitute

$$L = E_k/W\mu_r$$

$$L = \frac{Wv^2}{64\cdot4 \times W\mu_r} \text{ and the W cancels out.}$$

Whence it follows that the weight of the vehicle has no effect upon its stopping distance, and a light car cannot be stopped in a shorter distance than a heavy one.

For any given deceleration the total braking force is given by the formula

$$P = W_f \times a/32\cdot2 \text{ lbs.}$$

where P = braking force; W_f = weight supported by braked wheels and a = desired deceleration. Here $P = p \times \mu_r$, where p = total shoe pressure and μ_b the coefficient of brake friction. The total pressure on the shoes for any desired deceleration is therefore

$$p = \frac{W_f \times a \times D}{32\cdot2 \times \mu_b \times d}$$

Where D and d are the respective diameters of wheel and brake drum.

This pressure is distributed over all the brake shoes, the combined area of which should be such that the unit pressure does not exceed 75 lbs. per sq. in. It can be shown that the total brake shoe area should be equal to W/15 sq. in.; where W = gross vehicle weight in lbs., and the brake drum is one-half the wheel diameter; this figure can seldom be attained in practice, but should be aimed at. It should be noted that the shoe should not cover much more than 100° of the drum surface or cooling is difficult.

***Stopping Distance.*—Assuming a tyre coefficient of friction of 0·6 the minimum stopping distances will be as follows:—**

Speed, m.p.h.	**10**	**20**	**30**	**40**	**50**	**60**
Distance, ft.	**5·55**	**22·25**	**50·0**	**88·8**	**138·5**	**200·0**

The brakes, however, are seldom in such condition that these minimum figures can be obtained in practice.

***Deceleration.*—This is expressed in the same terms as acceleration, and is directly proportional to the coefficient of tyre friction, thus**

$$\text{Maximum deceleration} = 32\cdot2 \times \mu_r \text{ ft./sec. per sec.}$$

(remembering that μ_r may be anything from 0·2 to 1·0) according to the state of the road, therefore the deceleration may vary 500 per cent., from 6·44 to 32·2 ft./sec. per sec.—a fact not always appreciated by drivers.

From the foregoing equations a car weighing 3,500 lbs., decelerating at 24 ft./sec. per sec. will require a total shoe pressure of 15,250 lbs., while an omnibus weighing 25,000 lbs. decelerating at 16 ft./sec. per sec. will require a total shoe pressure of 59,200 lbs. In both cases brakes on all wheels are assumed. Careful provision for forces of such magnitude is necessary. The pressures may be materially reduced by braking on surfaces running at higher speeds than the wheels, but both the area and heat dissipation of such brakes renders them of little use.

Legislation in Great Britain demands that there must be two independent means of operation, and one of them must be *direct*, and not assisted by any device, which, with modern weights and speeds, means that the *direct* system is of little use except for parking.

Servo Systems.—Practical considerations make it difficult to provide sufficient leverage to enable a driver to produce such forces as are needed, hence the use of various devices whereby mechanical assistance is given to the driver to produce the force required, and his muscular effort is so augmented that it only furnishes a small fraction of the power. Such systems are the Dewandre, in which the power is furnished by a large vacuum cylinder and piston, the vacuum being obtained from the suction of the engine when the throttle is closed; this system is mainly used for heavy commercial vehicles.

For cars, the systems in most general use are the hydraulic, of which the Lockheed is the best known; the Bendix, where the brake shoes are partially floating and the reaction of one shoe furnishes the force required to apply the other, and the Girling.

When an expanding brake is arranged with the two shoes resting on a fixed abutment and an expanding device diametrically opposite to the abutment, one shoe automatically increases its pressure as the result of wedging effect, when applied, and is called the leading shoe, whilst the other automatically decreases the pressure of its application and is called the trailing shoe. The leading shoe is the one in which the direction of rotation is from the expander towards the fixed abutment. Various devices have been produced with the object of causing the leading shoe to transmit some of its increment of pressure to the trailing shoe, and so increase the overall efficiency of the brake for the same pedal pressure.

Girling System.—Fig. 32 shows the arrangement of shoes and expanders assembled; in fig. 33, the hardened steel cone (1) actuated by the pull rod (2) causes the plungers (3) to move outwards through the interposed rollers (4). The plungers are in an oil-tight case which floats on the studs

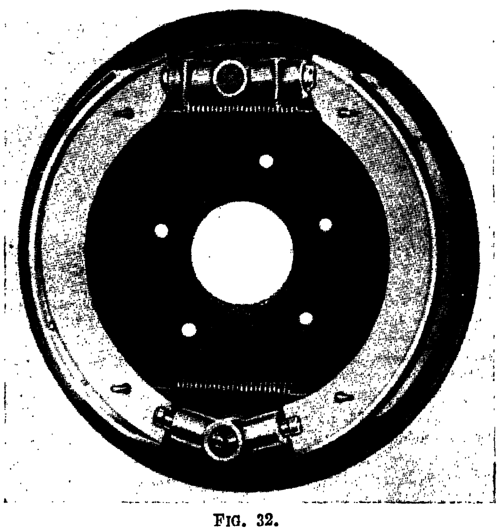

FIG. 32.

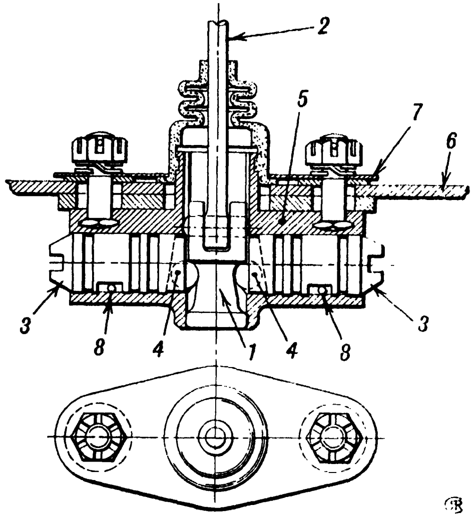

FIG. 33.

and spring washers (7), hence, the force is balanced between the shoes. Fig. 34 shows the adjustment at the heels of the shoes ; the cone (A) is forced by the screw between the plungers (C) which are thus extended carrying the shoes with them. From pull rod to shoe tip is a leverage of 6·33

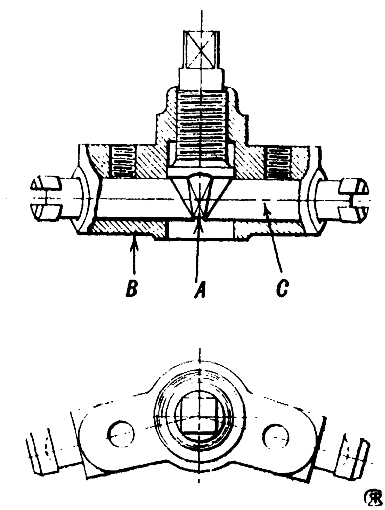

FIG. 34.

to 1. Fig. 35 shows the linkage arrangement. By means of floating levers the pedal movement is distributed equally between the eight shoes, all cross shafts are eliminated and the robust balance levers prevent any spring over which pedal movement has to be wasted.

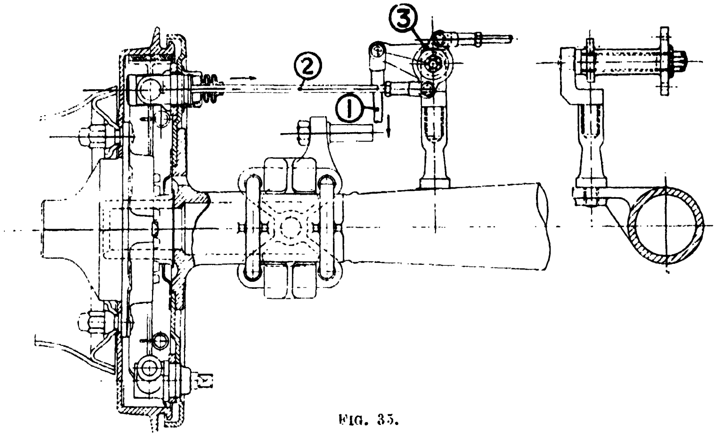

FIG. 35.

Fig. 36 illustrates the Girling two leading shoe arrangement in which, by means of bell-cranks and a connecting pushrod, the force applied by the expander is transmitted to the leading end of the second or trailing shoe, which then becomes a leading shoe being in full contact with the brake

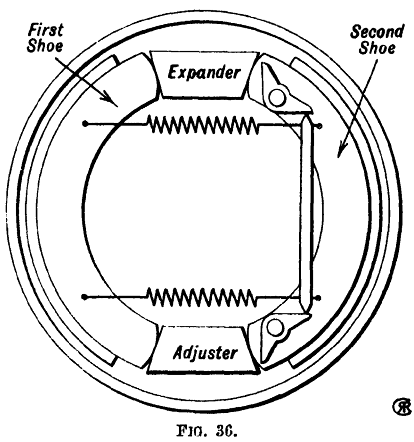

FIG. 36.

drum. Similar results are obtained in the Girling sliding shoe arrangement which, as the name implies, comprises a sliding second shoe, mounted on a steel carrier. The carrier and the standard fixed or leading shoe are operated in the normal Girling manner, when the brakes are applied the sliding shoe rotates until it comes into contact with the torque stop which is attached to the backing plate adjacent to the expander, thus becoming a leading shoe.

The Girling system is suitable for either mechanical or hydraulic operation ; the latest application, designed for use with cars having independent front suspension, being a combination of both, *i.e.* hydraulic operation for the front brakes and mechanical operation for the rear brakes.

Bendix Cowdrey System.—The operation of this sytem, as will be seen by reference to fig. 37, is similar to the Girling, balls being employed in the plunger or expander unit instead of rollers.

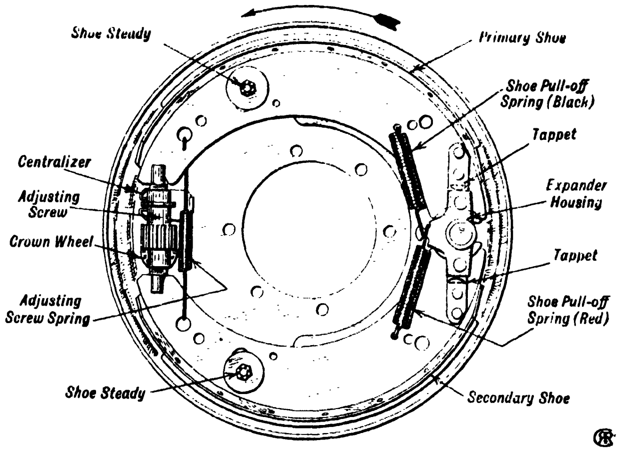

FIG. 37.

The adjuster unit, which is diametrically opposite to the expander, floats. When the operating plunger moves, the balls are pressed against the bevelled ends of the tappets, fig. 38. The bevels

are at slightly different angles so that the primary shoe moves out first; it is carried round slightly by the friction between the lining and the drum, and its torque is applied through the adjuster to the secondary shoe. This servo method of operating saves about *two-thirds* of the pedal pressure with corresponding reduction of stresses in mechanism.

Fig. 39 illustrates the adjusting means at the heel of the shoes. A compensated linkage is employed similar to that used on the Girling system. The Cowdrey system is suitable for either mechanical or hydraulic operation, and both these are employed according to the particular application.

Lockheed Hydraulic System.—In the Lockheed hydraulic system, the pressure exerted on the brake pedal is conveyed to the brake shoes by a column of special hydraulic fluid. The diagrammatic illustration, fig. 40, shows the Lockheed two leading shoe system, with two wheel cylinders placed between the front brake shoes and one wheel cylinder between the rear brake shoes. The master cylinder has a single piston, likewise the wheel cylinders, and all pistons are provided with rubber cups to maintain pressure and prevent loss of fluid.

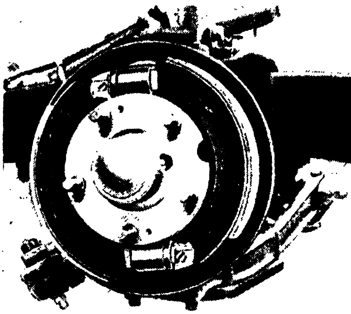

FIG. 41.

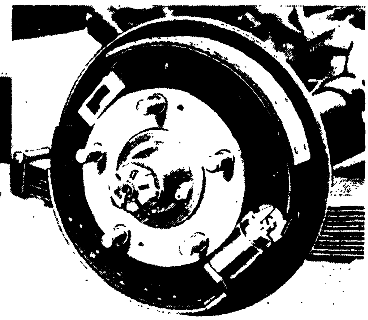

FIG. 42.

When the brake pedal is operated, the master cylinder piston applies a force to the fluid causing the single piston in each front wheel cylinder to come into contact with the leading tip of its respective brake shoe, while the trailing tip of the shoe finds a floating anchor by utilising the closed end of the actuating cylinder of the other shoe as its abutment. At the same time the rear wheel cylinder, which is free to slide in an elongated slot in the rear back plate between the tips of the leading and trailing shoes, operates on the tip of the leading shoe and this shoe abuts against a fixed anchor block at the bottom of the back plate, the web of the shoe being free to slide in a slot in the block. The trailing shoe is located in a similar manner between the anchor block and the closed end of the wheel cylinder, and is free to slide and therefore self-centering. The trailing shoe is operated by movement of the cylinder assembly as a result of the reaction of the leading shoe against the brake drum. Further effort on the pedal increases the force applied to the brake shoes.

Mechanical operation of the rear wheels is provided by means of a lever, which is connected to the handbrake lever through the necessary linkage, and the outer piston.

The front and rear brakes are shown in figs. 41 and 42 respectively.

Axles.

Both front and rear axles have essentially similar functions. Both are subjected to vertical and horizontal bending moments, and to torque. Front axles (generally) carry the steering mechanism, and rear axles (generally) the driving arrangements. Although very different in appearance, axles for independent wheel suspension have generally the same functions as conventional forms, and axles for front-wheel drive, or four-wheel steering are entirely special and **will not be considered. The axles of six-wheeled vehicles are special cases of suspension** rather **than of axle design.**

Normally front axles are of I section except the part between the spring seat and the wheel which alone is subject to torque. Generally the axle ends in a boss carrying the king pin to which the forked steering axle is fitted, this being known as the 'reversed Elliott' type.

There are at least four main types of rear axle housing in general use to-day, the built-up type, the pressed steel type, usually comprising two stampings welded together, the cast type, which is

really of composite construction, and the forged type. The pressed steel type is universal on the lighter cars and the forged steel type on the heavier commercial vehicles. The bevel or worm gears are supported, together with the differential gears, in a malleable-iron or light alloy casting which forms the cover for the axle.

In calculating stresses, the force causing a horizontal bending moment due to traction or braking cannot exceed μW which also limits the torsion. The vertical and horizontal bending moments can be combined into a common resultant.

If W = **the vertical bending moment;**
H = **the horizontal bending moment;**
T = **the twisting moment;**
M = **the combined moment;**

then $M = W + H + \sqrt{[(W + H)^2 + T^2]}$.

As, however, the static stresses (which alone can be evaluated) are much lower than stresses due to impact, very liberal allowance has to be made by a large factor of safety.

Front wheels are sometimes inclined outwards, but usually not more than 1°, and the king-pin is inclined in the opposite direction, pointing in fact to a point from $\frac{1}{2}$ in. to 1 in. inside the point of wheel contact. The king-pins are also given a rearward slope of 2 or 3° to ensure castor action of the wheel.

Both front and rear axles are very largely the product of proprietary manufacture, this being the case with all kinds of vehicles.

Lubrication.

The important consideration in selecting oil is viscosity at the normal running temperature, measured by a viscometer, the viscosity decreasing as the temperature is raised. The colour of the oil is no indication of its characteristics nor is its specific gravity.

If two surfaces are in contact and have relative movement there are three possible kinds of friction, all of which obey different laws.

(*a*) *Dry* friction, the surfaces being unlubricated and therefore in contact.

(*b*) *Greasy* friction, the surfaces being in contact, but lubricated.

(*c*) *Viscous* friction where the surfaces are completely separated by an oil film.

The latter is the normal condition and the only one to be considered. When a shaft rotates in a bearing it tends to climb up the side of the latter, and so assumes a position where the shaft axis is eccentric to that of the bearing and the oil is dragged round in a continuous stream at high velocity forming a wedging action which keeps the surfaces apart. There is a critical pressure-velocity figure where the oil film will break down, and since however smoothly the surfaces may be finished they consist microscopically of small projections which will penetrate the film, causing seizure. As this takes place the condition of *greasy* friction has occurred.

It is known that oils of animal or vegetable origin, *e.g.* sperm and castor oils, possess a condition of *oiliness* much more than mineral oils.

Hence, if the lubricant is defective in oiliness the friction at the metallic projections will be very high and heat is generated which decreases the general viscosity, ending in complete seizure. Oiliness will defer this condition. The heat is removed by, partly, conduction from the bearing surfaces, but mainly by oil running through the bearing and escaping at the sides. The advantage of forced lubrication being thus mainly due to the cooling effect of excess lubricant. An alternating load is less destructive than one unidirectional.

Again, Ricardo points out that a narrow bearing loses more oil through side leakage than a wide one, so is less efficient with natural lubrication, while with forced lubrication a narrow bearing can carry a heavier continuous load per sq. in. of projected area, because of the greater quantity of oil which can be passed through it ensuring better cooling. Again, at low speeds, the wedging action of the oil film is slow. It has been shown that even a bronze bearing may be crushed without destroying the oil film. Gudgeon pins are subject to the lowest rubbing velocity, but owing to the reciprocating motion, provided they are properly supported against deflection pressures up to 6,000 lbs. per sq. in., can be carried without forced lubrication.

***Types of Oils.*—These are either mineral oils, hydrocarbons of the paraffin series, or those of animal and vegetable origin. Since the latter possess greater oiliness it is usual to compound them with oil of mineral origin. They are seldom used pure on account of their cost.**

All oils tend to carbonise at high temperatures, and the resulting soot, with water vapour, causes thick sludge to form in the crankcase, which has little lubricating value, and tends to choke oil passages. Leaky pistons, allowing petrol to mix with the oil, reduce viscosity, hence the necessity for regular replenishment.

In engines of high performance the oil is circulated through a radiator for cooling it, and is also filtered to remove sludge and foreign matter.

Most if not all proprietary oils show consistent viscosity under working conditions, but those which lose an appreciable bulk under high temperatures are unsuitable, as are those whose constituents separate in use.

***Greases.*—For slow moving bearings greases are often used, *e.g.* spring eyes, etc., but there is some danger of grease solidifying unless very frequently renewed under high pressure, hence a thick oil applied from a grease gun has advantages.**

Chassis Lubrication.

ADVANTAGES OF OIL FOR LUBRICATION

(C. T. Myers.)

(1) Sustains as heavy a bearing as grease with less friction.

(2) Fed to one properly located point in a bearing will quickly spread over the entire surface.

(3) Will flow through a very small hole, and can be conducted a considerable distance by capillary attraction and surface tension.

(4) Carries much less dust than grease, can be filtered, and not so much exposed to dirt as grease, when in bulk or when being applied.

(5) Contains no inert matter to clog holes or channels.

(6) Engine oil can be used.

(7) Easier to apply automatically than grease.

(8) A flow of clean oil tends to clean a bearing, and bearings arranged for oil lubrication can be cleaned with petrol or paraffin.

(9) When oil is used on spring bolts, the seepage works down into the spring leaves, preventing rust.

LUBRICATION OF TRANSMISSION AND DIFFERENTIAL.

The following characteristics of the lubricant are necessary :—

(*a*) Must be of a character and consistency to coat, follow, cushion, and adequately lubricate the gear mesh.

(*b*) Must be capable of thorough distribution to any be[illegible] or plain bearing, and must have no corroding effect on the balls, rollers, [illegible]

(*c*) Should be of a body and character to minimise resistance and power loss due to the churning action of the gears. In the case of transmission, it should offer the minimum of resistance to the manual act of gear changing.

(*d*) Should be capable of carrying off the greatest amount of heat, and of exerting a washing action on the gear teeth and bearing surfaces.

(*e*) Should be a body to prevent leakage from the gear box or back axle under all normal operating conditions.

Electric Traction on Tramways.

The technical arrangements for electric tramways are practically standardised all over the world. Two 4-pole ventilated series or compound motors are used, usually with interpoles. The nominal rating of each motor is 30 to 60 h.p. with double-decked cars. The current transmission is effected by means of an overhead trolley-wire and rail return, collection being performed with a wheel trolley or sliding bow-collector. The voltage is most commonly 500 to 600, although a few American inter-urban roads have adopted a pressure of 1,200 volts. For control, a drum-controller or contactor is used, allowing of series-parallel and field-weakening methods for the regulation of the speed. Braking is by air or electric devices, the latter including rheostatic and magnetic track-brakes. Hand-controlled braking is used as a standby. For tramway sub-stations, rotary converters have replaced the older motor-generator sets, but mercury-vapour rectifiers are coming into use for modern installations (see Section XXVI (Vol. I), Electrical Engineering).

Tractive Resistance on Tramways.

The average pull required per ton of load to keep a car moving is 30 lbs. With exceptionally clean rails, as during a heavy rainfall, and with the rail grooves void of dirt, the pull may be as low as 20 lbs. per ton, or below this figure, approximating to the 10 or 12 lbs. of railway work. Again, a very dirty, clogged rail may demand more than the 30 lbs. Multiplying the pull by the speed in feet per minute gives the power in foot-pounds per minute, so that the horse-power is H.P. $= \frac{T \times W \times S}{33{,}000}$, where T is the pull per ton necessary, W is the load in tons, and S the speed in feet per minute. This rule gives the horse-power on the level. To find the power on a grade, the vertical rise of the car is found by dividing the speed of the car in feet per minute by the length of road in which there is a rise of 1 foot. The number of feet of vertical lift multiplied by the total weight in pounds gives the work done per minute against gravity, or $\frac{S \times W}{F}$, where W is the load, S is the speed, and F is the distance in which the road rises 1 foot. Thus on a 1 in 30 grade, F = 30. **The addition of the two results gives the total horse-power. Track resistance is increased at curves, also increased horse-power is required during acceleration. The latter depends not only on weight of car as a whole, but also on moment of inertia of rotating parts.**

RHEOSTATIC BRAKING.

Electric braking consisted first of simple rheostatic braking, the drag on the motor armatures, acting as generators, causing the retarding force necessary. Resistance is inserted at first to prevent excessive currents and retardation and too severe strains on the motor windings, etc. This resistance is gradually cut out as the controller handle moves over the braking notches.

Electro-magnetic braking was added later, the braking effect being then partly electrical and partly frictional.

One weak point of electric braking was that, should the car be stopped when going up an incline, there was a tendency to run back, and then the electric braking had no effect unless the reversing handle was moved into the backward position. Omission to do this caused a number of accidents. Many modern cars are equipped with air brakes.

Regenerative Braking Systems for Tramways.

An effective system of regenerative braking has the advantage of enabling an increase of schedule speed to be obtained economically. A number of methods have been developed. In one, the two motors of a car are connected permanently in series and compound wound, the shunt fields being permanently series-connected across line and earth. Speed regulation is obtained by control of the motor field currents. The series field turns are modified in strength by a diverter which is shunted across the series coils, the object being to utilise the series characteristics of the motors as much as possible when motoring and to reduce the reverse compound effect when regenerating. The system as applied to British conditions embodies the additonal complication of series-parallel control.

A SUMMARY OF THE BOARD OF TRADE REGULATIONS FOR ELECTRIC TRAMWAYS.

The following is a brief summary of the principal regulations affecting electric traction :—

When any rails on which cars run, or any conductors laid between or within 3 feet of such rails, form any part of a return, such part may be uninsulated. All other returns, or part of a return, shall be insulated, unless of such sectional area as will reduce the difference of potential between the ends of the uninsulated portion of the return below 7 volts.

Where any uninsulated conductor laid between or within 3 feet of the rails forms any part of a return, it shall be electrically connected to the rails, at distances apart not exceeding 100 feet, by means of copper strips having a sectional area of at least $\frac{1}{16}$ of a square inch, or by other means of equal conductivity.

All uninsulated returns shall be connected to the negative pole of the generator; the negative terminal of the generator shall be also connected through a current-indicator, mentioned below, to two separate earth connections, which shall be placed not less than 20 yards apart. This clause enacts that the two earth connections may be replaced by making one connection to a water-pipe of not less than 3 inches internal diameter, provided that permission be obtained from the owner of the water-pipe and the person supplying the water.

The earth connections referred to in this regulation shall be constructed, laid, and maintained so as to secure electrical contact with the general mass of earth, and so that an electro-motive force not exceeding 4 volts shall suffice to produce a current of at least 2 amperes from one earth connection to the other through the earth, and a test shall be made at least once in every month to ascertain whether this requirement is complied with.

When the return is partly or entirely uninsulated the company shall, in the construction and maintenance of the tramway, (a) so separate the uninsulated return from the general mass of earth and from any pipe in the vicinity, (b) so connect together the several lengths of the rails, (c) adopt such means for reducing the difference produced by the current between the potential

of the uninsulated return at any one point and the potential of the uninsulated return at any other point, and (*d*) so maintain the efficiency of the earth connections specified in the preceding regulations as to fulfil the following conditions, viz. :—

(i.) That the current passing from the earth connections through the indicator to the generator shall not at any time exceed either 2 *amperes per mile of single tramway line or 5 per cent. of the total current output of the station.*

(ii.) That if at any time and at any place a test be made by connecting a galvanometer or other current indicator to the uninsulated return and to any pipe in the vicinity, it shall always be possible to reverse the direction of any current indicated by interposing a battery of three Leclanché cells, connected in series, if the direction of the current is from the return to the pipe, or by interposing one Leclanché cell if the direction of the current is from the pipe to the return.

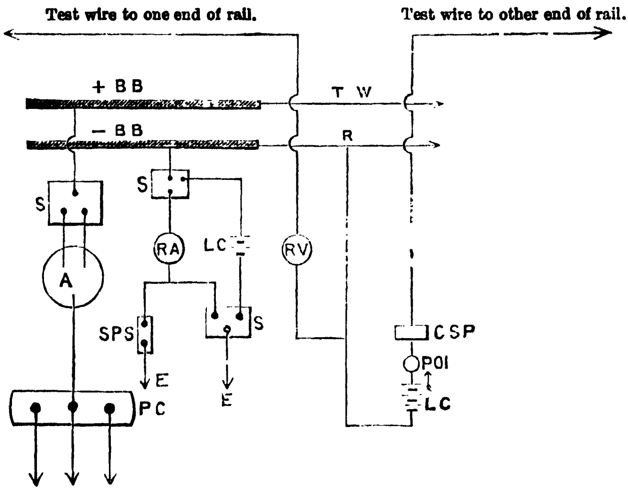

FIG. 43.—Diagram of Board of Trade Switchboard.

A, Ammeter reading $\frac{1}{10}$ – 3 and $\frac{1}{2}$ – 10 A.; B B, Bus bars; R, Return; T W, Trolley wire; S, Two-way switches; R A, Recording Ammeter 2 to 25 A; R V, Recording voltmeter 2 to 10 V.; L C, Leclanché cells; S P S, S.P. switch; E, Earth; P C, Three-way plug connections; P O I, P.O. indicator; C S P, Contact of sensitised paper.

In order to provide a continuous indication that the condition (i.) is complied with, the company shall place in a conspicuous position a suitable, properly connected, and correctly marked current indicator, and shall keep it connected during the whole time that the line is charged.

The owner of any such pipe may require the company to permit him at reasonable times and intervals to ascertain by test that the conditions specified (ii.) are complied with as regards his pipe.

When the return is partly or entirely uninsulated, *a continuous record shall be kept by the company of the difference of potential during the working of the tramway between the points of the uninsulated return farthest from and nearest to the generating station. If at any time such difference of potential exceeds the limit of 7 volts, the company shall take immediate steps to reduce it below that limit.*

The current density in the rails shall not exceed 9 amperes per square inch of the cross-sectional area.

The insulation of the line and of the return when insulated, and of all feeders and other conductors, shall be so maintained that the leakage current shall not exceed one-hundredth of an ampere per mile of tramway. The leakage current shall be ascertained daily before or after the hours of running when the line is fully charged. If at any time it should be found that the leakage current exceeds *one-half* of an ampere per mile of tramway, the leak shall be localised and removed as soon as practicable, and the running of the cars shall be stopped unless the leak is *localised and removed within 24 hours.*

The insulation resistance of all continuously insulated cables used for lines, for insulated returns, for feeders, or for other purposes, and laid below the surface of the ground, shall not be permitted to fall below the equivalent of 10 megohms for a length of one mile.

Trolley Buses.

Under certain traffic conditions where electric power is available, railless traction provides a valuable alternative to the motor omnibus and the electric tramway. Two overhead conductors are provided, as lead and return, and the vehicles carry trolley poles with under-running trolleys collecting the current from the conductors. These trolleys permit the vehicle to deviate at least 15 ft. from the centre-line on either side, so that they can pass other vehicles, and draw in to the kerb at stopping places. Railless tramcars compared with motor omnibuses have higher acceleration, lower working costs, longer life, and greater elasticity as regards the number of passengers carried, while they give a more reliable service and a greater annual mileage, and can climb hills with greater ease.

Present-day, single-deck trolley buses can accommodate up to 40 passengers. Double-deck, three-axle trolley buses can accommodate up to 70 passengers. The modern trend of design is to use all-metal bodywork instead of the composite construction body, and consequently, by reason of Ministry of Transport Regulations, low-voltage lighting has to be used. This may be provided by means of a small motor-generator set of approximately 1,600 watts output; or by a dynamo, belt-driven from the main motor. If it is required to manœuvre the bus when the overhead power supply is not available, special batteries are used. These are generally of the alkaline type, consisting of two 30-volt, 50-ampere-hour batteries; they are connected together in series for traction work and in parallel for lighting.

Where composite construction bodies are used, the lighting may be obtained from the overhead supply and the lamps are connected together in series. An arrangement is provided whereby if one lamp fails it short-circuits across its terminals, and consequently does not extinguish the other lights on the same circuit. A small auxiliary dynamo, either driven direct off the front end of the main motor, or belt-driven from the propeller shaft, provides the navigation and emergency lights.

The maximum speed of a trolley-bus depends upon the nature of the route, but is generally in the region of 35 m.p.h. The average speed of a single-deck trolley-bus is between 12 and 14 m.p.h., and the average speed of a double-deck, seventy-seater trolley-bus is 11½ m.p.h. The energy consumption of a two-axle, single-deck trolley-bus is 1·3 units per car-mile, and of a three-axle, seventy-seater trolley-bus 2·25–2·5 units per car-mile. The motor omnibus has an average speed of 10 m.p.h., and the fuel consumption of a Diesel-engined bus—fifty-six seater type—is 10–12 miles per gall. These figures, of course, depend upon the route and the nature of the service.

Trolley-Bus Motors and Controls.

Where single motors are preferred, the one-hour rating is of the order of 80 h.p., and these are now being built with a weight of 12 lb. per h.p. Double motors, each of half this rating, permit of series-parallel control and provide an economical half speed for running in traffic or fog. The double motor dispenses with the differential, by mounting one motor on each side of the chassis, and allows the bridge system to be used in the transition from series to parallel, thereby preventing change of torque. When series-wound motors are used, field control is resorted to in order to obtain improved starting conditions. Compound-wound motors are used where regeneration is required. The shunt field is employed to control the field strength, regeneration being obtained by increasing the excitation. This is sometimes done in conjunction with diversion of a portion of the series field.

Remote control is provided by a pedal-operated master controller. The contactor gear, which can be either electrically or pneumatically operated, is mounted either in the driver's cabin or on the chassis frame.

In order to save the mechanical brakes and also reduce the energy consumption, regenerative control in conjunction with rheostatic braking is extensively used. The vehicles regenerate down to 14–12 m.p.h., after which the rheostatic brake comes into operation, giving a maximum retardation in the region of 4 m.p.h. per second. Where buses are operating in very hilly districts, run back brakes can be fitted. These consist of a contactor which is normally held open by the current; should this fail or the bus start running backwards, the contactor closes and limits the bus speed to 2 m.p.h. Another safety device in the form of a coasting brake, which, by engaging a suitable control lever, limits the speed to 10–15 m.p.h. may be fitted. Deviation indicators, for driving in fog, indicate how far away from the overhead wires the bus may be. Leak alarms, showing when there is any chance of electric shock to the passengers, and dewirement indicators to warn the driver that the trolleys are off, may also be incorporated.

Electric-Battery Traction.

A secondary battery supplies d.c. driving motors. The scope of the vehicle is limited by the capacity of the battery and the need for frequent charging. Batteries are frequently used on trucks, on road vehicles and on shunting locomotives.

Industrial Electric Trucks.

For moving material about railway stations, factory premises, etc., electric battery trucks have been widely adopted, capable of carrying up to 5,000 lbs. and running at speeds up to 8 miles per hour; the net weight of the trucks is 1,600 to 2,500 lbs., and the mileage per charge 15 to 25 miles. In a railway warehouse 11 tractors and 600 trailers handled 130,000 tons per annum at an average cost of 15·1*d*. per ton. The loading platform can be fixed or made to lift, as required.

Charging Battery Vehicles.

The charging of vehicle batteries is nearly always controlled automatically, and does not involve the removal of the battery from the vehicle; a connection being taken from the charger to a socket on the vehicle. The charging rate is controlled automatically by the characteristic of the charging generator or rectifier and the battery, the result being that the current falls as the battery voltage rises on charge. The duration of the charge is usually controlled by the ampere-hour meter on the vehicle. This meter is set to run 10–15 per cent. slower on charge than on discharge, so as to allow for the overcharge required by the battery, and when the needle reaches full charge it trips out a circuit-breaker in the charging circuit.

Battery vehicles are well adapted for charging during the night hours, and specially low tariffs for this purpose are now offered in many districts. A standard Charging Plug and Socket is specified in B.S.I. Report, No. 74—1937.

Petrol-Electric Lorries.

In the petrol-electric vehicle the motive power is provided by a petrol engine, but the mechanical gear and clutch are replaced by a very flexible electric transmission. In a recent type of Stevens petrol-electric lorry of 3 tons capacity, the generator driven by the engine gives from 300 amperes at 80 volts to 230 amperes at 110 volts, and in addition to driving the vehicle it can be used to supply power for charging a battery or electric lighting, welding, etc. The electric motor is supplied through a special controller which gives forward and reverse connections with a wide range of speed variation, and when put in the neutral position enables the generator to supply electricity for external use. In the last case the generator can be given any desired characteristic—under, level, or over-compounded. A 3-ton waggon can supply three arc-welding equipments at 60 volts.

Oil-Electric Traction.

The Diesel engine operates most efficiently when developing a constant torque at a constant speed, *i.e.* a constant output. Thus, in order to utilise the Diesel engine to its full capacity, some device is required to convert the constant torque of the engine into the variable torque needed to haul the train. Instead of a mechanical gearbox, an electric transmission is frequently used for this purpose. This entails an electric generator and driving motors—the latter are usually direct-current traction motors.

Both constant-speed and variable-speed Diesel engines are used. Engines with critical speeds are included in the former class and various devices for controlling the power have been developed. In the Armstrong-Whitworth method of automatic constant-power control for constant-speed engines, it is claimed that, when desired by the driver, the engine output is kept within about $\pm$ 2½ per cent. of the correct value. Other well-known systems employ a generator with a characteristic designed to approach a hyperbolic curve, so that the product of terminal voltage and current is constant.

In the case of variable-speed engines, which can run at any speed between idling and full speed, the generator is designed to give a hyperbolic output curve. Here again several devices are in use to obtain the desired result.

In competition with the mechanical drive, the Diesel-electric drive is obtaining wide use in shunting locomotives, in motor-coaches, and in rail-cars. By fitting the 'dead man's' handle, one man only is required on the footplate. Diesel shunting is considered to be a necessary auxiliary to railway electrification, where there are objections to electrifying the sidings. Diesel locomotives have also received much publicity for driving high-speed trains.

Much of the earlier criticism regarding unreliability, noise and smell of Diesel locomotives and motor-coaches is no longer applicable, while improved facilities for maintenance and repair have added to the popularity of this form of traction.

TYPES OF AIRCRAFT—AERODYNAMICS—SCALE EFFECT AND DYNAMIC SIMILARITY—AIRSCREWS—PERFORMANCE—DESIGN.

The Aeroplane is commonly known as a 'Landplane' when used for land purposes, or a 'Seaplane' or flying-boat when used for maritime purposes. Machines of this type are initially able to leave the ground or water and subsequently maintain themselves in flight by virtue of their forward motion relative to the surrounding air.

An aeroplane consists essentially of five components:—

1. The main planes, by means of which the aeroplane is sustained in flight.

2. The fuselage or hull, in which the pilot, passengers, and/or other load, such as cargo, petrol, and oil, are carried.

3. The tail, which is rigidly attached to the rear of the fuselage or hull and comprises a tail plane and elevators in a horizontal plane, and fins and rudders in a vertical plane. This component is mainly responsible for the control of the aircraft.

4. The undercarriage, which, in the case of land planes, consists of a braced structure connected to the underside of the fuselage near its front end, supporting an axle carrying wheels, by the aid of which the machine leaves or alights on the ground.

In the case of twin- or multi-engined aeroplanes, this component may be in duplicate.

In getting off and landing, the tail is protected by a small tail wheel or skid attached to the rear end of the fuselage.

In Arctic regions, the wheels are replaced satisfactorily by long skids, while some aeroplanes are convertible into seaplanes by replacing the undercarriage structure by a similar one having two floats instead of wheels.

In the case of flying-boats, the hull serves the dual purpose of the fuselage and the undercarriage. Present-day hulls, when manufactured in duralumin, have a very important advantage over wooden hulls owing to the absence of water soakage, which in the latter hulls may amount to several cubic feet; this equivalent weight is thus available for useful load.

5. The engine, being the unit controlling the speed and height to which a machine may attain. In single-engined aeroplanes it is placed in the nose of the fuselage, so that the airscrew operates as a tractor; installations employing a pusher airscrew are rare.

When outboard engines are used, the mountings generally form part of the main plane structure.

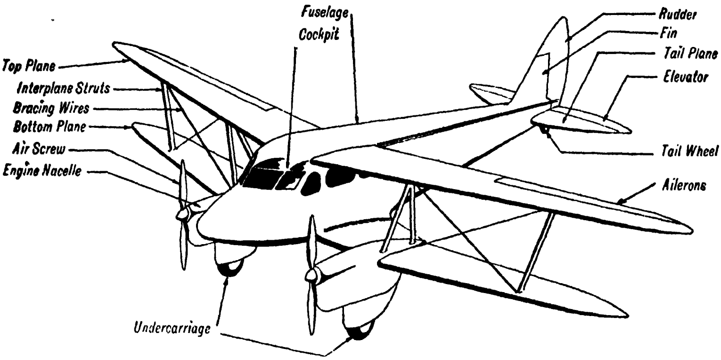

FIG. 1.—Main Components of a Small Biplane.

GEOMETRY OF PLANES.

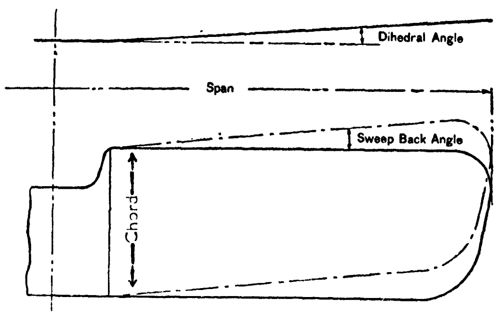

FIG. 2.

The several components are indicated in fig. 1, while the geometry of the planes is indicated in fig. 2.

AERODYNAMICS.

Wind Channels.

An essential instrument for aerodynamic research is the wind channel in which the forces and moments on a model suspended in an air stream are measured. But it is impossible to apply the data thus obtained to the full-scale machine or component (as distinct from a detail such as a wheel or strut) without certain corrections, known as 'scale effect.'

Two principal types of channel have been developed, the 'open' type and the 'closed circuit.' Most of those in use are of the latter type, in which the same air is caused by means of a fan to move along a closed circuit of rectangular plan form. The working portion occurs at one of the longer sides.

OPEN TYPE CHANNEL.

The open N.P.L. type channel is normally built of wood and supported on a braced steel structure, so that the horizontal centre line is well above the floor. The working portion of the channel is situated towards the end of the front portion of the channel which is fitted with a carefully shaped

intake. This part of the channel is generally square in section and about six diameters long. In order to further reduce any possible eddy motion which may have been set up at the intake, and to counteract the tendency of the fan to impart rotation to the air stream, a honeycomb is placed at each end of the channel.

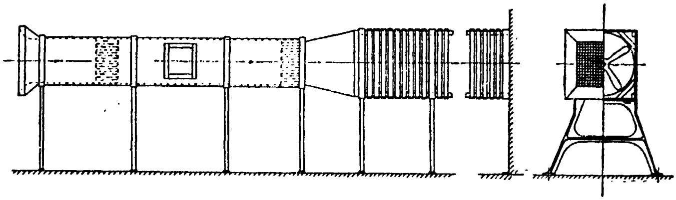

FIG. 3.—Modified N.P.L. Type, 2 ft. 6 ins. Wind Channel.

End View of Channel.

The end of the channel at the rear honeycomb is rigidly connected to a metal fan chamber, so constructed that in a distance of a few feet its section changes from that of the channel, viz. square or rectangular, to circular. The four-bladed fan is driven directly by a motor mounted on independent supports, so that no vibration from it shall reach and affect the air stream.

This type of wind channel, in which air enters at one end and is discharged through the diffuser at the other, must be installed in a large room free from obstacles which interfere with steady flow.

In the region of the working portion, glazed air-tight doors are fitted for convenient access and visibility.

CLOSED CIRCUIT CHANNEL.

This type of tunnel is one in which air is set in motion round a closed, or nearly closed, circuit. Diagrammatically, fig. 4 shows an arrangement in which a motor-driven fan is mounted near the intake and the air propelled round the tunnel to be discharged at the other end in the form of a jet. The latter is co-axial with the intake and the distance between the two ends of the tunnel forms the working portion.

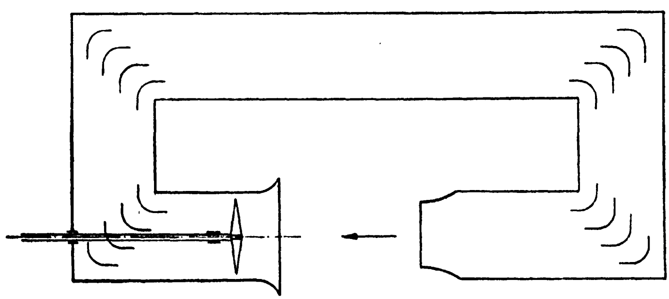

FIG. 4.

The air is helped round the four corners of the tunnel by a number of guide vanes. Power costs for this type is low since once the air is speeded up it is necessary only to maintain this *same* air in motion. Sometimes the working section is enclosed, but access to the models is not then as easy.

It has long been realised that with high-speed aircraft, special care must be taken in order to reduce the scale effect corrections which should be applied to results of model tests. The criterion being that Reynold's number $\frac{vl}{\nu}$ (where v is speed, l some linear dimension, usually the wing

chord, and ν the kinematic viscosity of the fluid medium) for the full-scale machine, and the model should be the same, suggests the possible courses :

(a) To increase the size of model and/or wind speed of test.

(b) To increase the wind speed and decrease the kinematic viscosity of the air by increasing its pressure, *i.e.* its density.

THE VARIABLE DENSITY CHANNEL.

Working on the lines indicated in (*b*), above, a wind channel was constructed in America in 1923 in which the model was tested in air at 20 atmospheres pressure. Some years later there was erected at the N.P.L. a similar channel to operate at 25 atmospheres pressure (fig. 5). Both channels were constructed in steel with hemispherical ends.

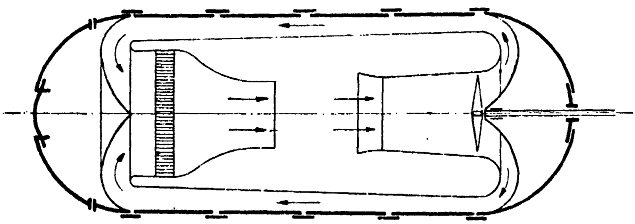

FIG. 5.

Comparative particulars are :—

	American.	N.P.L.
Jet diameter, ft. .	5	6
Pressure, atmospheres .	20	25
Wind velocity, ft./sec. .	70	90
Reynolds number	R	1.93 R
Normal h.p. of fan motor	250	400

DYNAMIC SIMILARITY AND SCALE EFFECT.

Flight tests and experiments on full-scale aircraft are an expensive matter ; in many instances the required information may be obtained from a test on a geometrically similar model in a wind channel.

It does not necessarily follow, however, that because the model and full-scale machine are geometrically similar, there will be similarity of flow of fluids past these bodies, nor similarity of motion of the latter. In other words, there may not be dynamic similarity. The whole of the utility and application of model test results to full-scale depends on the conditions of dynamic similarity being known and satisfied.

Generally the model test cannot be carried out so as to satisfy all the required conditions simultaneously, but as a rule one particular condition has a predominating effect on the motion concerned, and if this is fulfilled the model results may generally be applied to full-scale. Owing to the neglect of the secondary conditions there is frequently a discrepancy between the full-scale results as predicted from model experiment (depending, for instance, on the shape of the body concerned) and those obtained directly from full-scale flight tests. Due to this 'scale effect' a correction has to be applied to the model test figures to bring them into agreement with full-scale results.

The resistance to motion of that part of the hull of a ship or flying boat in contact with water is made up of two parts, viz. (*a*) skin friction (due to the viscosity of water), and (*b*) wave formation (due to the gravitational effect). At high speeds the resistance due to skin friction is relatively unimportant so that the wave-making resistance alone may be considered.

Froude's law of comparison demands that the corresponding speed on the water should be

$$v_m = v\sqrt{\frac{l_m}{l}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

both for model and full-scale hull.

COMPRESSIBILITY EFFECTS.

Whereas in the normal forms of wind tunnel the value of Reynold's Number (R) does not often exceed one million, it may in a variable density tunnel reach 5 or even 10 million. So that, although in actual flight at high speeds R may run as high as 20 million or more, it is commonly somewhat less: hence the variable density tunnel gives results which may in general be regarded as valid. The one serious difficulty to-day with tunnel work on models is that when the speeds become so high as to approach the velocity of sound the flow pattern changes substantially and this, with some uncertainty as to the effect of the tunnel walls, makes the interpretation of the results difficult. Wind tunnel tests are sometimes checked by wake measurements in free flight (in these tests a 'rake' of pressure tubes is used to measure the heads in the air wake behind the aircraft) and these have proved useful: but even such free flight tests, though avoiding the complication of tunnel constraints, are liable to fail when the velocity of sound is approached owing to the great spread of the air flow pattern. When the airspeed is 0·8 of the velocity of sound at any altitude, it is said to have a 'Mach Number' of 0·8, or M = 0·8. Hence in airflow at high speeds and high altitudes it is necessary to pay attention to the values of both R and M. High values of M are particularly liable to arise at altitude, because the velocity of sound falls with fall of temperature and its speed of 750 m.p.h. at sea level becomes only about 650 m.p.h. in the stratosphere (30,000 ft. and over). Nevertheless, despite the great increase in drag as values of M approach unity, modern fighter aircraft have reached such speeds.

At subsonic speeds (M less than unity), wind tunnel measurements can be relied upon to give results which, when the appropriate corrections are made, can be applied to full scale design. It is also possible to obtain useful design data from the little ultra-high speed tunnels used in artillery research in obtaining the ballistic coefficients for shells and rockets, even though the speeds are then well into the supersonic range. The difficult range of speed is the sonic (where M = 1) for it is then that the drag coefficient increases with great suddenness and the air flow pattern with it. A careful study is being made of this difficult region but far too little is at present known to enable the results of model tests to be interpreted as a reliable guide to aircraft constructors. The alternative procedure is to experiment with full-scale aircraft despite the risk to human life, or to employ pilotless aircraft with radio control. Although the full-scale experimentation has unfortunately led already to the loss of valuable lives, it has enabled the first flights into and through the 'sonic barrier,' as it is sometimes called, to be made by one or more intrepid pilots. The great engine thrust needed for the first penetration of the barrier by an aircraft was provided by boosting-rockets. Once through the barrier it is generally anticipated that the nature of the air forces to be encountered will be fairly readily predictable, with the result that the task of the aircraft designer will be eased.

It is likely that to meet military requirements, aircraft capable of flying at supersonic speeds will prove necessary. Hard as the sonic barrier may be to penetrate, it will be less difficult for small aircraft than for large ones. Had the barrier proved impenetrable, then once bombers and interceptor fighters had been pushed to the limit of their speed, there would have been no margin possessed by the interceptor to enable its task to be carried out, and the effectiveness of the defence against the bomber would have suffered gravely. As things are, however, there will not long hence be many interceptors capable of supersonic speed, whilst for some years, perhaps many years, bombers speeds will be limited to the subsonic. Hence fighters, with their margin of several hundreds of miles an hour of superior speed, will be at a great advantage, and the strength of the defence will gain greatly—much to the satisfaction of all peace-loving countries.

Aerofoils.

When the main planes of an aeroplane are considered apart from the rest of the machine they may be referred to as 'aerofoils,' and the shape of a main plane section given by a plane parallel to the plane of symmetry is spoken of as the 'aerofoil section.'

A typical section is shown in fig. 6.

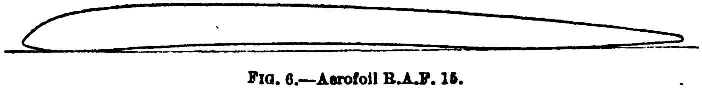

FIG. 6.—Aerofoil R.A.F. 15.

The upper and lower surfaces of an aerofoil are cambered, being arranged to meet in the front to form a nose or leading edge, while at the rear the aerofoil is finished off with a somewhat elongated trailing edge.

The chord of an aerofoil is generally defined as the length of the common tangent to the lower cambered surface cut off by projectors from the leading and trailing edges. In the case of a 'thick' aerofoil section in which the lower camber is convex like the upper, the chord may then be defined as the length of the line passing through the centre of curvature of the leading and trailing edges cut off by the extremities of the aerofoil.

Fig. 7 shows an aerofoil inclined at an angle of incidence α to the direction of the wind. The resultant force R acting on the aerofoil depends upon α, the wind speed V, and the area of the aerofoil S. Let the line of action of R cut the chord AB in C. The resultant force R may be resolved normal to and along the direction of flight giving a lift force L and a drag force D. The angle between the direction of the resultant force and the lift component is γ. The position of C is determined in the case of model experiments by the measurement of the moment M acting at the point A, the sign of M being reckoned positive when acting in a clockwise direction.

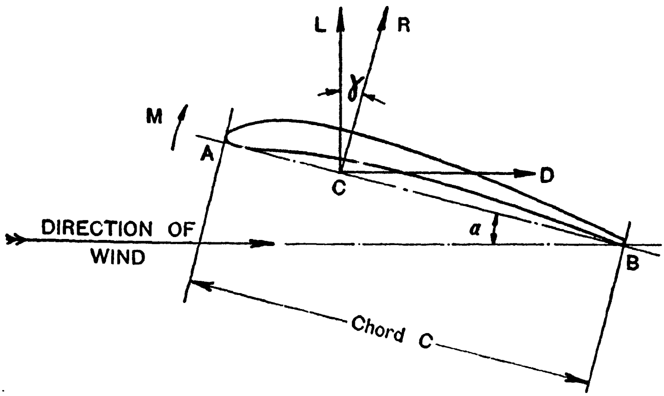

FIG. 7.—Forces Acting on an Aerofoil.

Provided that α is kept constant R, and therefore L and D, remain practically proportional to the area of the aerofoil, the square of the speed, and the density of the air. Under the same condition the ratio $\frac{AC}{AB}$ and γ remain practically constant. If ρ is the mass density * of air, the quantities $\frac{R}{\rho SV^2}$ and $\frac{AC}{AB} \cdot \gamma$ are non-dimensional and also practically independent of the linear dimensions of the model or wind speed during a given test.

The following definitions may now be made :—

$$\text{Lift coefficient } C_L = \frac{L}{\frac{1}{2}\rho SV^2} \qquad (2)$$

$$\text{Drag coefficient } C_D = \frac{D}{\frac{1}{2}\rho SV^2} \qquad (3)$$

$$\text{Moment coefficient } C_M = \frac{M}{\frac{1}{2}\rho ScV^2} \qquad (4)$$

Centre of pressure coefficient—

$$\text{or } \frac{AC}{AB} = -\frac{M}{c\,(L\cos\alpha + D\sin\alpha)} = -\frac{C_M}{C_L\cos\alpha + C_D\sin\alpha} = -\frac{C_M}{C_L} \text{ approx.} \qquad (5)$$

It is thus possible to express the aerodynamic characteristics of an aerofoil by plotting, as in figs. 8 and 9, the coefficients in equations (2) and (3) against the independent variable α, the angle of incidence. In experimental work α is given various values between $-5°$ and $+20°$, so that the whole flying range is more than covered.

* The mass density $= \frac{\text{weight density in lbs./ft.}^3}{g} = 0{\cdot}00238$ slug/ft.^{3} at ground level under standard conditions.

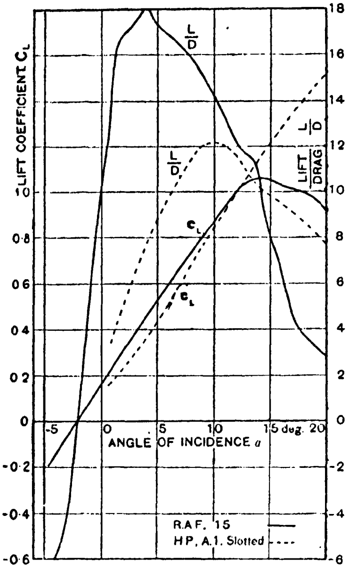

FIG. 8.

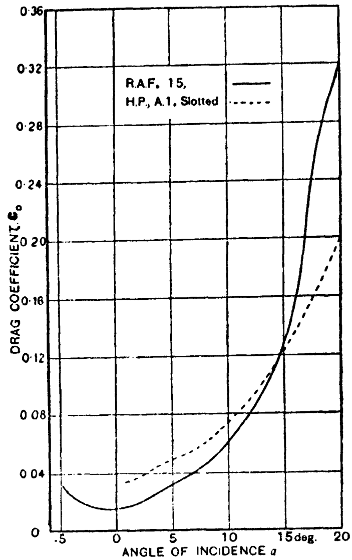

FIG. 9.

Flaps.

On aircraft with a high wing loading, it is necessary to fit some device that will limit the landing speed to a reasonable figure. The usual method is by the fitting of flaps to the aft underside surface of the wings. There are a large number of different designs of flap in use (some well-known types being shown in fig. 10), all of which depend for their action, on the large increase they give, when in the open position, to the maximum value of the lift coefficient.

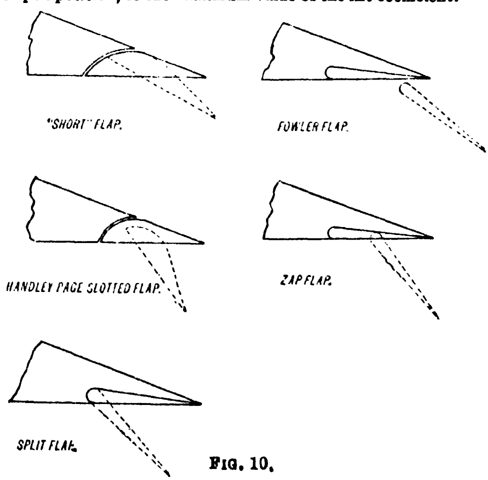

FIG. 10.

Slots may also be used to increase the maximum lift coefficient, but this involves a tall leggy undercarriage to enable the aircraft to land with the high angle of incidence required by the slotted wing.

Flaps have the further merit in increasing the drag, which for low drag machines, effects a very important reduction on the landing run.

By partially opening the flaps, the take-off may be improved by about 10–15 per cent.

EFFECT OF FLAPS.

Type of Flap.	Per cent. increase in C_D max.	Per cent. increase in C_D min.
Split flap . . .	35	14
Lap flap . . .	54	10
Fowler flap . . .	79	10

THE SLOTTED AEROFOIL.

The slotted aerofoil was produced simultaneously by Handley Page in this country, and Lachmann in Germany in 1919, both working independently. At that time the primary object was to produce an aerofoil having a high lift coefficient in order to reduce the landing speed of a given machine.

The main aerofoil, throughout its entire length, was made with an adjustable nose of streamline form called an auxiliary aerofoil, which could be moved to or away from the main aerofoil by a hand-operated link motion. With the slot closed the main aerofoil is of normal section. With the auxiliary aerofoil in its forward position the slot is said to be open.

Later it was found that good results were given if the auxiliary aerofoil were made of duralumin sheet, bent to suit the shape of the nose of the main aerofoil. Fig. 11 shows a leading edge slot of this type fully open. The main aerofoil section is the Handley-Page A.1, which is a slightly modified R.A.F. 15 shown in fig. 6, having increased camber to permit deeper spars being employed. It will be noticed that there is a rear slot provided between the back of the rear spar and the leading edge of the aileron. When the aileron is depressed the slot remains

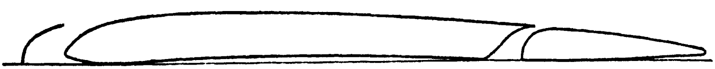

FIG. 11.—Aerofoil H.P., A.1 (Modified R.A.F. 15).

open and it is found that the effect of this is to reduce the angle of incidence required for take-off or landing from an excessive figure above 20°, to one in the region of 18°. With the front slot open and the aileron at 0°, the results of wind-channel tests (for which k_D and α have been corrected for channel restraint) are shown compared with those for a standard R.A.F. 15 section in figs. 8 and 9. It will be seen that an increase in lift coefficient of nearly 100 per cent. is obtained, but at the expense of an increased angle of incidence. The model used for these observations was 36-in. span by 6-in. chord (6·4 ins. with slot open), and the experiments were performed in a channel 4 ft. × 4 ft. at a wind speed of 44 ft./sec.* It is clear, therefore, that by the use of a leading edge slot extending the whole main plane span, a greatly increased speed range is possible.

Factors affecting the Aerodynamic Qualities of an Aerofoil.

Quite apart from its geometrical properties, the results of tests on an aerofoil lose much of their value unless certain data are specified. The model chord, aspect ratio, and wind speed should be quoted, as these quantities have been shown to have a considerable effect on the characteristics. Experiments at the N.P.L. have in the past been undertaken to ascertain the extent of the variations involved when an aerofoil of given section is tested as a monoplane.

These tests were carried out with models of the same chord, but different spans. Both C_L and $\frac{L}{D}$ were found to be affected. The maximum valve of C_L increases with the aspect ratio, as does the gradient of the curve for which C_L is plotted against α. This effect is still in evidence for aspect ratios well in excess of 10 or 12, but it is most serious for low values up to about 5, becoming less important as the aspect ratio is increased above this amount.

* *Flight*, January 28, 1926. 'Tests on Slotted Aerofoil.' F. Handley Page.

The $\frac{L}{D}$ variation is very large for values of α above 2° or 3°; below this region the effect is, however, small. For a particular model, by changing the aspect ratio from 4 to 6 it was possible to obtain a 20 per cent. increase in the value of $\frac{L}{D}$. Hence large aspect ratios appear to be desirable from an aerodynamic point of view, but as a rule structural considerations limit the aspect ratio to a figure between 5 and 6.

Distribution of Pressure over the Chord of an Aerofoil.

In order to determine the manner in which the pressure varies over the chord of an aerofoil on both upper and lower surfaces, a special model is prepared, and measurements made of the fluid pressure at various places. The model is preferably made of metal, and the surface drilled deep

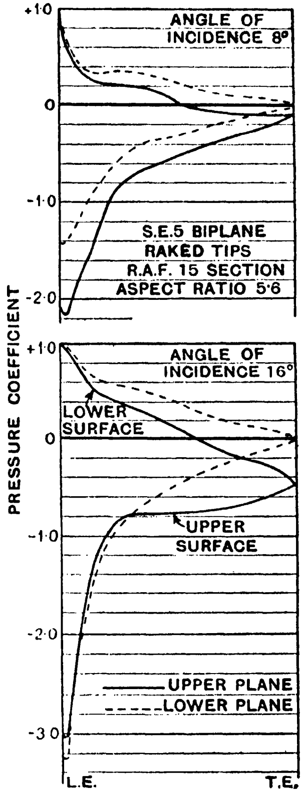

FIG. 12.—Distribution of Load over Chords of Biplane. (R. and M. 355.)

enough at the desired places, so that all the holes are connected to a common tube, which is finally connected to a Chattock gauge. The holes are filled with plasticene, and one opened at a time, so that the local pressure may be taken. It has been shown that the size of the hole is unimportant; generally it is $\frac{1}{32}$ in. diameter. In this way the distribution of pressure over any chord may be obtained. Except for a region near the tips, the pressure distribution across the chord for the whole length of plane (of constant chord) is indicated in fig. 12 for two angles of incidence. This refers

to experiments on R.A.F. 15 biplane of 6-in. chord, the results of which are given in R. and M. 355. Generally there is a suction on the upper surface and a smaller pressure on the lower surface. Both the positive and negative pressures reach their greatest values near the leading edge where the change in pressure is very rapid. At the point on the nose normal to the air stream, the pressure is known to be $\frac{1}{2}\rho V^2$ lbs. per sq. ft. In fig. 12 the coefficient of $\frac{\rho V^2}{2}$ is plotted for each point, and it is clearly shown that near the nose of the upper surface of the aerofoil the pressure rapidly falls to a local value of approximately $-3\cdot0\rho V^2$.

Distribution of Pressure over the Span of an Aerofoil.

The investigation described in the previous paragraph was extended in order to find out how the intensity of load per foot-run of span varied over the whole of the top and bottom planes. For angles of incidence of 8° and 16° the results are exhibited in fig. 13, in which, for convenience, the ordinates are coefficients which represent the normal force per foot-run of span per foot-chord divided by $\frac{\rho V^2}{2}$.

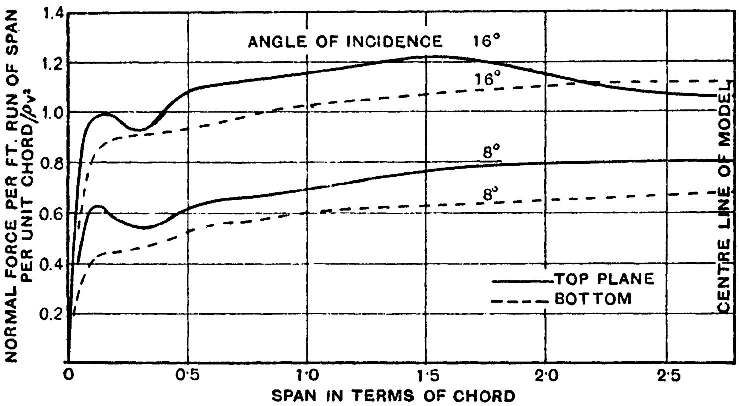

FIG. 13.—Variation of Normal Force along Span. (R. and M. 355.)

As would be expected, the normal force on the bottom plane is generally less than that for the top plane, while, with the exception of a temporary rise near the tips, there is a general falling off in loading as the tip is approached.

Low Drag Wings.

The airflow over a wing surface tends to be smooth and 'laminar' over and just behind the leading edge but to become eddying and 'turbulent' thereafter. The drag from laminar flow is much less than that from turbulent, so that any delay in the transition from the one to the other is a gain. It is hard, however, to attain in practice, and hard to preserve when attained, as the transition is affected by any waviness in form, or even by roughness due to the presence of sand or dirt on the wing surfaces. But since the drag would, in some cases, be reduced by 50 per cent. if the flow could be made laminar throughout, it will be seen that the inducement is great. Efforts have been made to preserve laminar flow by air suctions in the after part of the wing, but there is much work to be done before they can be shown to produce a good balance-sheet, in which the saving in the power required for propulsion is greater than the power used to produce the necessary suctions. It seems likely that jet-propelled aircraft will lend themselves more readily than their predecessors to this development, and if they do the speeds attained by such craft will be higher than even they are at present. Although drag coefficients rise greatly as M approaches unity, they fall again thereafter. It is only at the 'barrier' itself that they reach formidable heights. Gun projectiles and rockets have, of course, long since penetrated the barrier, but it is difficult to do so with aircraft.

The Aerofoil Theory.

The flow of air past an object is a three-dimensional one. Consequently the results in the case of an aerofoil of infinite span, for instance, would not be the same as for one of finite span.

In the case of a finite aerofoil the type of flow associated with the lift is known to be of the form shown in fig. 14. It will be seen that above the aerofoil, where the pressure is low, the

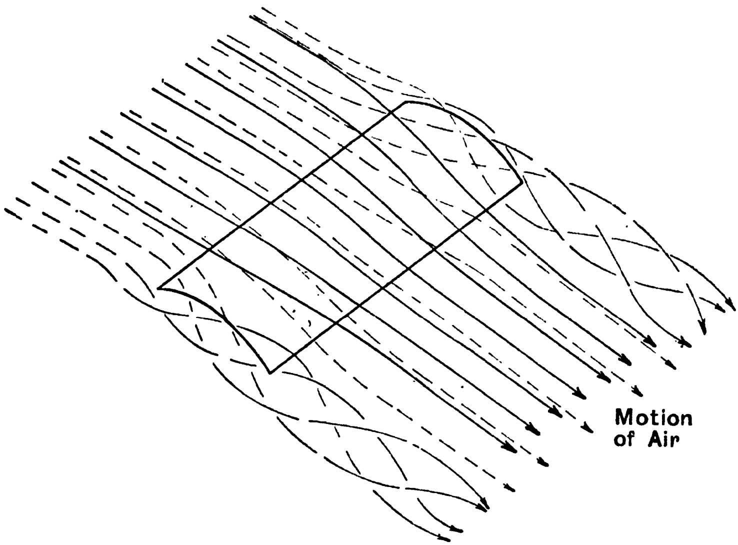

FIG. 14.

streamlines tend to converge towards the centre; while those underneath, in the high pressure region, tend to flow outwards. At places where these streamlines leave the aerofoil, trailing vortices are formed. In the conventional infinite aerofoil these trailing vortices of course do not exist. In general there will be a downward velocity or down wash of air over the whole span of the wing (fig. 15) and a corresponding upwash outside the limits of the wing tips. This

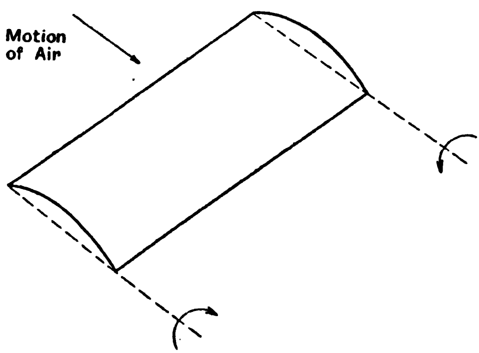

FIG 15.

downward velocity is known as the induced velocity, w, which is small compared with the air velocity V (fig. 16). The very small component induced velocity in a direction parallel to the

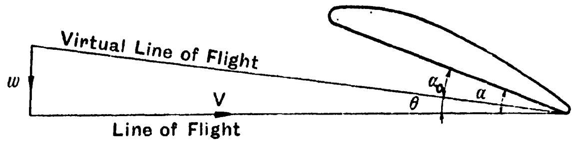

FIG. 16.

chord is neglected. The effect of the induced velocity is to reduce the angle of incidence α to an effective angle α_0 given by

$$\alpha_0 = \alpha - \theta \text{ where } \theta = \tan^{-1}\frac{w}{V}$$

Corresponding to motion along the virtual line of flight inclined at θ to the free stream (fig. 17) let C_{L_0} and C_{D_0} be the lift and drag coefficients. A component of the lift increases the drag, for

$$C_L = C_{L_0} \operatorname{Cos}\theta - C_{D_0} \operatorname{Sin}\theta$$

$$\text{and } C_D = C_{D_0} \operatorname{Cos}\theta + C_{L_0} \operatorname{Sin}\theta$$

but θ is small and $\operatorname{Sin}\theta = \theta$ radians. So that in the limit we may write

$$C_L = C_{L_0}$$

$$C_D = C_{D_0} + C_{L_0}\theta = C_{D_0} + C_L\theta$$

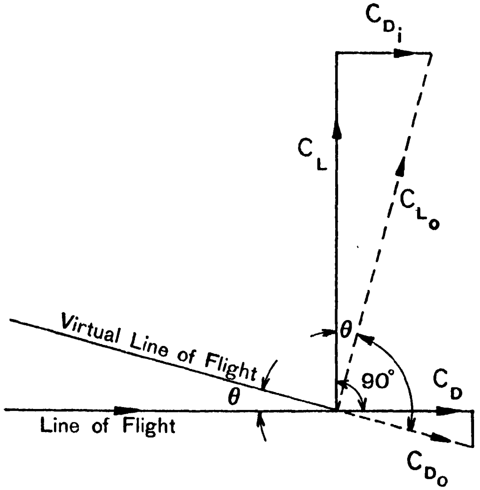

FIG. 17.

Induced Drag.—The term $C_L\,\theta$ is the induced drag coefficient C_{D_i}, and is so named since it is due to the induced velocity of the trailing vortices.

The Total Drag Coefficient **C_D for a monoplane aerofoil is the sum of the profile drag coefficient C_{D_0} and induced drag coefficient C_{D_i};**

thus: $$C_D = C_{D_0} + C_{D_i} \text{ where } C_{D_i} = C_L\,\theta_i$$

The Value of **C_{D_i}.—By making certain assumptions, including the type of aerodynamic loading, the value of the induced velocity may be calculated for a given monoplane or biplane.**

Assuming an elliptical distribution of lift over the span of a monoplane (*cf.* fig. 17) the mathematical treatment shows that w is constant at all positions along the span and that

$$\theta = \frac{C_L}{\pi A} \text{ radians}$$

where A = aspect ratio.

The relation between three dimensional and two dimensional flow for a given lift coefficient C_L may now be expressed as follows:—

$$a = a_0 + \frac{C_L}{\pi A}$$

$$C_L = C_{L_0}$$

$$C_D = C_{D_0} + \frac{C_L^2}{\pi A}$$

The latter equation shows that for a given lift coefficient C_L the induced drag depends upon the aspect ratio only. Further, the greater the aspect ratio, the smaller is the value of the induced drag, which becomes zero when A is infinite, corresponding to two dimensional flow.

By observing C_D and calculating C_{D_i} it is found that below the critical angle of incidence C_{D_0} is tolerably constant.

THE AIRSCREW.

A typical airscrew is shown in fig. 18. The shape of the blade changes continually along its length, but at all cross sections the resemblance to an aerofoil is maintained, except that near the boss it becomes more or less streamline.

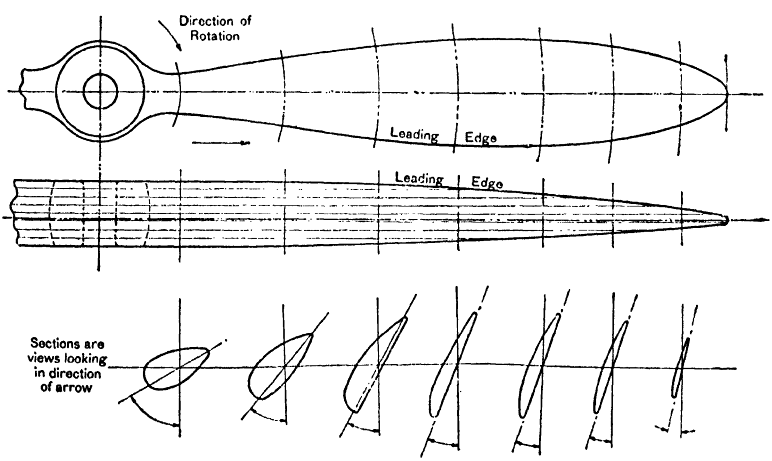

FIG. 18.—Typical Wooden Airscrew showing Laminations.

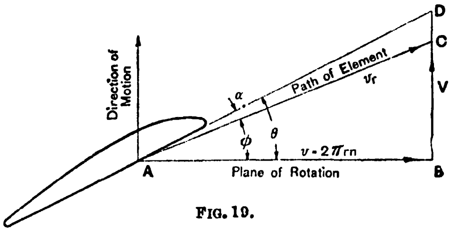

FIG. 19.

Consider an element of the blade as in fig. 19, and let

V = velocity of translation of element, *i.e.* forward velocity of aircraft;
n = rotational airscrew speed;
r = radial distance of element from axis of rotation;
a = angle of attack (or incidence) of blade element to helical path;
ϕ = angle between direction of relative wind at blade element, *i.e.*, the plane of rotation;
θ = blade angle of element, *i.e.*, the angle between chord of element and plane of rotation.

so that $\theta = \alpha + \phi$

The triangle ABC is development of helical path of element, in which AB represents linear velocity ωr or $2\pi rn$ in the plane of rotation; BC represents V; and AC, the path of the element, represents the relative wind velocity v_r.

Thus $$\tan \phi = \frac{V}{2\pi rn}, \quad \text{or,} \quad 2\pi rn \tan \phi = V.$$

Now an airscrew is designed for a definite value of V corresponding to race or climb conditions, hence in a given airscrew $2\pi rn \tan \phi$ is constant at all points along the blade, and hence $\tan \phi$ varies inversely as r, and each element describes a helix of the same pitch.

SLIP.

The analogy of a nut working on a bolt breaks down in the case of an airscrew for two reasons, viz.:

(*a*) For a given rotational engine speed the aeroplane, and therefore the airscrew, may have different translational speeds: and

(*b*) As the air passes the plane of the airscrew it receives an additional backward velocity and the airscrew is said to slip and the stream of air behind the airscrew is called the slip stream.

PITCH.

Considering the airscrew as a whole the term 'pitch' requires careful definition. Two pitches are in use.

(i) *The Geometrical Pitch.*—Suppose in a certain airscrew each blade element had no angle of attack as in fig. 20. In unit time each element moves forward V feet, but travels along its path

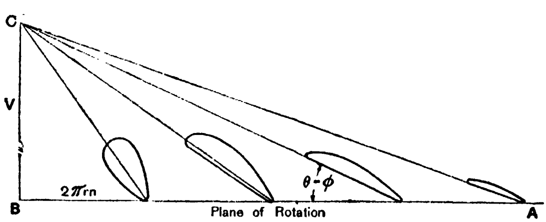

FIG. 20.

in the plane of rotation a distance $2\pi rn$. In these circumstances the advance BC of the airscrew per revolution is called the 'Geometrical Pitch' P_g and the airscrew is said to have a constant pitch.

Usually, however, airscrews are made with varying angles of attack α along the blade (fig. 19), thus the geometrical pitch of each element varies, and the airscrew cannot be said to have a geometrical pitch.

In such a case the geometrical pitch of an element situated at two-thirds radius from the axis is called the 'Geometrical Mean Pitch' for the airscrew, *i.e.*,

$$BD = P_g = 2\pi . \tfrac{1}{3}D \tan \theta = 2\cdot 1\ D \tan \theta,$$

where D = airscrew diameter.

(ii) *The Experimental Mean Pitch.*—Apart from other factors the thrust of an airscrew depends upon its rotational and translational speeds, n and V.

For any airscrew, at certain corresponding values of n and V the slip-stream entirely disappears, the air in the vicinity of the airscrew remaining practically undisturbed so that the thrust falls to zero. The value of $\frac{V}{n}$, or the advance per revolution when the airscrew thrust is zero, is called the 'Experimental Mean Pitch' P.

Under working conditions when the airscrew is developing thrust at speeds V_1 and n_1 the slip is given by

$$\frac{V_1}{n} + \text{slip} = P$$

Airscrew Characteristics.

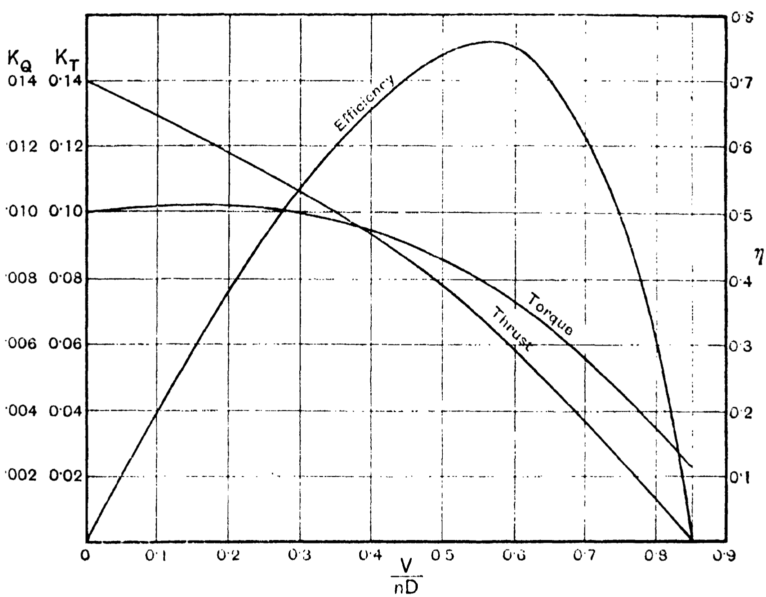

FIG. 21.—Airscrew Characteristic Curves.

The thrust T and torque Q of an airscrew are shown in Part D to depend upon ρ, V, n, and some linear dimension, generally taken to be the diameter D.

Provided that $\frac{V}{nD}$ (the advance per revolution as a fraction of the diameter) is constant, T is practically proportional to the mass density ρ, the square of the rotational speed n, and the fourth power of the airscrew diameter D.

∴ We may put

$$\text{Thrust coefficient } k_T = \frac{T}{\rho n^2 D^4} \quad . \quad . \quad . \quad . \quad . \quad (6)$$

similarly,

$$\text{Torque coefficient } k_Q = \frac{Q}{\rho n^2 D^5} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where k_T and k_Q are both non-dimensional, varying only with the value of $\frac{V}{nD}$ provided that the tip speed does not approach the velocity of sound.

Hence, in the same way that C_L and C_D depend upon the angle of incidence α for an aerofoil, so k_T and k_Q depend upon $\frac{V}{nD}$ for an airscrew. The complete performance of an airscrew may therefore be expressed in terms of these quantities by plotting experimental results.

A typical set of characteristic curves is shown in fig. 21.

The efficiency curve is obtained from the known values of k_T and k_Q from the relation

$$\eta = \frac{1}{2\pi} \cdot \frac{V}{nD} \cdot \frac{k_T}{k_Q} \cdot = \frac{1}{2\pi} \cdot \frac{k_T}{k_Q} \cdot J. . \quad . \quad . \quad . \quad . \quad (8)$$

where

$$J = \frac{V}{nD}.$$

It is seen that the thrust is maximum when the airscrew has no translational speed V, falling off to zero at a certain value of J. This value corresponds to the experimental mean pitch P as a fraction of D.

The torque remains tolerably constant, first increasing slightly then falling off to a low value when the thrust is zero.

The efficiency is zero when $V = 0$ and also when $T = 0$.

The working range of this airscrew corresponds to values of J between 0·40 and 0·65, the maximum efficiency being reached when J is between these values. Except in special cases the value of J at top speed does not exceed unity.

Airscrew Theories.

A number of theories have been put forward by means of which expressions for thrust, torque and efficiency may be obtained. Among the most important are :—

(a) The Froude momentum theory.
(b) The application of Bernouilli's theorem
(c) The simple aerofoil theory.
(d) The inflow theory.

The Froude Momentum Theory.

In propounding this theory Froude supposed the actual airscrew replaced by an ideal one consisting of an imaginary disc in whose plane an instantaneous change of pressure occurred under working conditions.

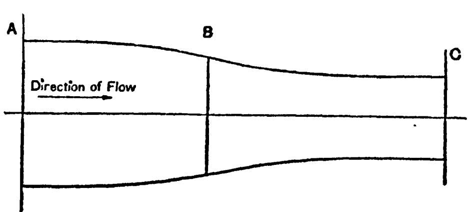

Fig. 22.

Regarding the airscrew as stationary, the ingoing and outgoing streams are indicated in fig. 22. On the upstream face of the disc there is a region of negative pressure which causes motion, and on the downstream face the pressure instantaneously changes to a positive value which increases the pressure of air in the outgoing stream or slip-stream.

Assuming frictionless streamline flow, and considering sections A and C sufficiently removed from the disc B such that the streamlines are parallel, tabulate the quantities concerned :—

Section.	Velocity.	Cross-sectional Area of Stream.	Pressure.
A	V_1	A_1	p_1
B	V_0	$A_0 = \frac{\pi}{4}D^2$	—
C	V_2	$A_2 = KA_0$	p_1

The outgoing stream contracts, making the slip stream velocity V_2 greater than V_1.

Thus

$$V_2 = V_1(1 + b), \quad \ldots \ldots \quad (9)$$

where b is the outflow factor.

Neglecting losses, it may be shown that,

$$V_0 = V_1\left(1 + \frac{b}{2}\right)$$

$$= V_1(1 + a_1) \quad \ldots \ldots \quad (10)$$

where a_1 is the inflow factor

Hence in the ideal airscrew, half the added or slip stream velocity is imparted to the air immediately in front of the airscrew.

THRUST.

Since the thrust is given by the rate of change of momentum of the air stream, it may be deduced that,

$$T = \rho KA_0(1 + b \quad bV_1^2 \quad \ldots \ldots \quad (11)$$

where T is the thrust.

EFFICIENCY.

The ideal efficiency may be given as,

$$\eta_f = \frac{\text{work got out per sec.}}{\text{work got out per sec.} + \text{added kinetic energy of slip stream}}$$

from which

$$\eta_f = \frac{1}{1 + \frac{b}{2}} = \frac{2}{2 + b} = \frac{1}{1 + a_1}$$

which is known as the ideal or Froude efficiency. Generally the actual efficiency is between 80 per cent. and 85 per cent. of this ideal value.

THE APPLICATION OF BERNOUILLI'S THEOREM.

A consideration of the instantaneous pressure difference at the plane of the airscrew leads to a result identical with equation 12, so that in the ideal airscrew the theoretical inflow factor a_1 is half the outflow factor b. In the inflow theory it is assumed that under all conditions $a_1 = \lambda b$.

Actually λ is less than ½ being more nearly ⅓.

The Bernouilli and momentum theories may be combined to give results which agree fairly well with practice, so far as thrust is concerned.

The Simple Aerofoil Theory.

Considering the airscrew as made up of independent aerofoil elements moving along helical paths forms the basis of this theory proposed by Froude and subsequently developed by Lanchester and Drzewiecki.

Axial inflow as indicated in the momentum theory is neglected, the velocity of air relative to the airscrew and immediately in front of its plane being taken as V, the translational speed of the aircraft.

FORCES ACTING ON BLADE ELEMENT.

Fig. 23 shows the forces acting on an element of blade at radius r from the axis and substituting V for U and ϕ for ϕ_1, the diagram is applicable to the present case.

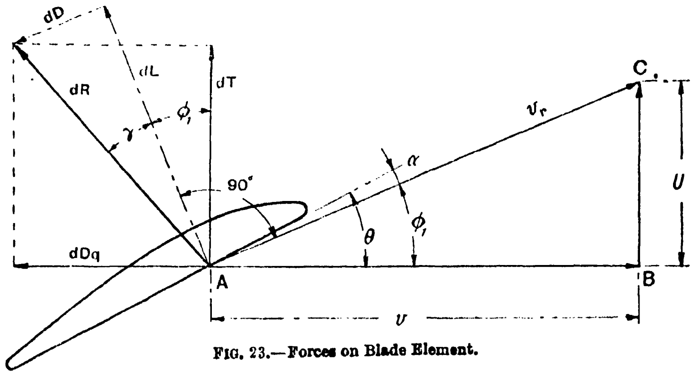

FIG. 23.—Forces on Blade Element.

We have, treating the element as an aerofoil,

dR = Resultant force on element
dL = Lift " " "
dD = Drag " " "

where,
dL and dD act normal to and along OA respectively.

The direction of dL is in advance of dR by angle γ such that

$$\gamma = \tan^{-1}\frac{C_D}{C_L}$$

dT = thrust on element, *i.e.*, the axial component of dR,
dD_q = transverse component acting at radius r from axis of rotation
dQ = torque reaction on element,

then

$$dT = dR\cos(\phi + \gamma) \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$
$$dD_q = dR\sin(\phi + \gamma)$$
$$dQ = r\,dR\sin(\phi + \gamma) \quad . \quad . \quad . \quad . \quad . \quad . \quad (13)$$

EFFICIENCY OF WHOLE AIRSCREW.

The efficiency of the whole airscrew is given by:

$$\eta = \frac{\text{work done by airscrew}}{\text{work done by engine}}$$

which reduces to

$$\eta = \frac{\tan\phi}{\tan(\phi + \gamma)} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (14)$$

On this basis, the efficiency of the element is maximum when $\phi = 45° - \frac{\gamma}{2}$.

Since $\frac{\gamma}{2}$ is small, this means that the maximum efficiency occurs when the rotational and translational speeds of the element are approximately equal.

The efficiency of the whole airscrew may be taken to be that of an element situated at a distance from the axis of about two-thirds tip radius. Thus, if an element so situated is working under the above condition, the airscrew would be working approximately at its maximum efficiency.

The Inflow Theory.

The simple theory, which was the first to be applied to design, generally gave efficiencies which were in excess of those obtained in practice. This led to the adoption of the inflow theory which allowed for the fact that the air immediately in front of the airscrew has a velocity greater than that of translation of the airscrew.

The axial inflow factor a_1 may be obtained experimentally for any given model or it may be calculated.

There is experimental evidence that in addition to axial inflow, a rotational inflow also exists, acting towards the boss. This is, however, small and is generally neglected.

Helix Angle of Blade Element.

Fig. 23 shows the forces acting on an element of blade, as already described, but in arriving at the helix angle ϕ_1, the velocity of the air passing the airscrew disc is now given by

$$U = V(1 + a_1)$$

and

$$\tan \phi_1 = \frac{U}{\omega r} = \frac{V(1 + a_1)}{2\pi r n}.$$

Efficiency of Blade Element.

The efficiency of the element now becomes

$$\eta_a = \frac{1}{1 + a_1} \cdot \frac{\tan \phi_1}{\tan(\phi_1 + \gamma)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (15)$$

Thus the actual efficiency is the product of the Froude and Drzewiecki efficiencies except that U and not V is used in calculating ϕ_1.

The Total Thrust and Torque per Blade.

For any element of blade having chord c, treating the element as an aerofoil, the resultant force dR on it is $dR = c_L \rho c\, dr\, v_r^2 \sec \gamma$,

and

$$\text{Total thrust/blade } T_b = \int_0^R pc \sec \gamma \cos(\phi_1 + \gamma)\, dr \quad . \quad . \quad . \quad (16)$$

$$\text{Total torque/blade } Q_b = \int_0^R pc\, r \sec \gamma \sin(\phi_1 + \gamma)\, dr \quad . \quad . \quad (17)$$

where

p = pressure/ft.² or air loading of blade $= C_L \dfrac{\rho v_r^2}{2}$.

In an analysis, the integrals in (16) and (17) are evaluated graphically. For this purpose about six sections or elements of blade are considered, approximately corresponding in position with those shown in fig. 18 and the thrust and torque grading for each element, viz.,

$$pc \sec \gamma \cos(\phi_1 + \gamma) \text{ and } pc\, r \sec \gamma \sin(\phi_1 + \gamma),$$

calculated, assuming $\sec \gamma$ to be unity. These are plotted on a base representing the blade radius, so that the area under each curve represents T_b and Q_b respectively.

The efficiency of the whole blade is,

$$\eta_b = \frac{V}{\omega} \cdot \frac{T_b}{Q_b}.$$

The efficiency of a well-designed airscrew is in the region of 80 per cent.

Diameter of Airscrew Required.

It is generally necessary to fix the diameter of an airscrew and determine the necessary blade widths to absorb the available torque by the use of equations (16) and (17).

In order to avoid a trial and error process as far as possible, a preliminary determination of the required diameter may be obtained by formulæ proposed by Watts.* These are given below :—

Two-bladed airscrews

$$P = 1 \cdot 11 \times 10^{-10} D^4 n^3 V \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (18)$$

Four-bladed airscrews

$$P = 2 \cdot 30 \times 10^{-10} D^4 n^3 V \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (19)$$

where

P = h.p. absorbed ; n = r.p.m. ;
D = required diameter in ft. ; V = translational speed in m.p.h.

Note that here V is an estimated speed which will, among other things, depend on the efficiency of the airscrew when designed. In view of this there is every justification for looking upon the first airscrew for a particular case as experimental, making any necessary modifications after the initial trials have been completed.

In a particular design the diameter may be restricted to one smaller than that given by the equations above, for reasons of, say, ground clearance.

---

* *Screw Propellers for Aircraft.* H. C. Watts.

Horse-Power Absorbed.

The engine power curve, supplied by the engine manufacturers, gives the power to be absorbed at stated engine revolutions. The corresponding airscrew revolutions are known from the gear ratio of the engine, and at this speed the airscrew torque must be such as to absorb the power developed.

Thus, if

b = number of blades; P = horse-power absorbed.

$$P = \frac{2\pi\, Q_b\, n.b.}{33{,}000} \qquad \qquad (20)$$

where Q_b is the torque absorbed per blade as given in equation (17).

In design, the unknown maximum blade width c is determined from equation (20) and the remaining chords at specified sections are immediately known from the plan form adopted.

Rotational Speed.

In order that it may develop maximum power, the engine, and therefore the airscrew, must be run at or near a certain rotational speed. For a given flight or translational speed, the airscrew must have its maximum efficiency when the engine is running at that rotational speed. It follows that every combination of engine and aircraft will require its own particular airscrew.

Neglecting inflow, the maximum efficiency of a blade element at radius r from the boss occurs when $\phi = 45°$ approximately.

From fig. 19, $\tan \phi = \dfrac{V}{2\pi\, rn} = 1$ when $\phi = 45°$.

This means that for the element, $\dfrac{V}{nd} = \pi$ for best results. In any case the whole blade cannot work under this condition of maximum efficiency, and in practice it is not possible to cause the airscrew to rotate slow enough to give a value of π for the pitch diameter ratio.

On the other hand, in order to obtain a light airscrew for a given diameter, the blade widths must be small and the rotational speed high.

For conditions of maximum efficiency, airscrews operate, as a rule, at a value of J between 0·6 and unity.

The question is one of compromise, but, other things being equal, a slow-running airscrew has a greater efficiency than a high-speed one. It is also much less noisy.

Number of Blades.

Airscrews are made with either two, three, or four blades.

The choice of the number of blades usually rests with the designer. The advantages of two- and four-bladed airscrews are given below :—

Two-bladed airscrew—
- Weighs very much less than the corresponding four-bladed airscrew.
- Easy to transport.
- Easier to manufacture than four-bladed airscrew.
- Stronger at boss " " "
- Cheaper " " "

Four-bladed airscrew—
- Smaller diameter than corresponding two-bladed airscrew, which may be an advantage when clearances are important. Better balancing effect so that engine tends to run better and without vibration. Generally somewhat more efficient than two-bladed airscrew.

Manufacture.

Airscrews are made in either wood or metal, the materials being American walnut, Honduras mahogany, duralumin, or steel.

A very great disadvantage of wooden airscrews is that in tropical countries the blade warps and consequently its efficiency seriously falls.

Metal airscrews do not give this trouble.

Metal Airscrews.

Metal airscrews are manufactured from light alloy (generally duralumin) or mild steel.

There are very definite advantages in the use of metal airscrews, among which are :—

(a) Damage to blades by rain and hail is very rare.

(b) They withstand large and rapid changes in temperature and variations in atmospheric conditions generally, whereas the blades of wooden airscrews twist in tropical countries, causing a falling off in efficiency.

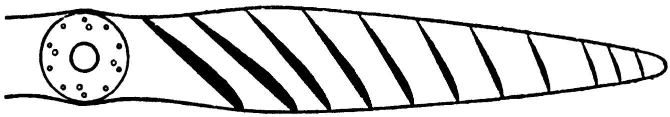

FIG. 21.

(c) As the blade tip sections can be made quite thin, as indicated in fig. 21, very high tip speeds may be employed, such as occur in high speed or racing aircraft.

ADVANTAGES.

Particular advantages of this type of airscrew are :—

(a) After preliminary trials the blades may be adjusted to suit the aircraft and engine speeds. The blades may also be altered to suit any subsequent change in these speeds.

(b) The single forging avoids joints in the blade just where a joint is least desired. The extra complication of blade attachment fittings are also avoided.

(c) In cases of accident these airscrews bend where wooden ones would break. Damaged duralumin airscrews are frequently corrected and put into service again.

(d) Bent blades may be straightened up to 5° without thermal treatment.

BLADE STRESSES.

Cases have been known of airscrews working satisfactorily at a stress of 27,500 lbs./in.², corresponding with a factor of safety of 2.

The Variable Pitch Airscrew.

The usual design condition for a fixed-pitch airscrew is for maximum efficiency at top speed and maximum horse-power. This condition, however, is not consistent with high efficiency during take-off and climb for the following reasons. The pitch of an airscrew designed for top speed is such that the angle between the incidence wind (the vector sum of the rotational velocity of the airscrew and the forward speed of the aircraft) and the nose-tail line of the airscrew blade section is that corresponding to maximum efficiency of the section. During climb and take-off, when the forward speed of the aircraft is considerably less than that at top speed, this angle will be greater than that required for maximum efficiency and may be so great as to stall the section. Moreover the torque coefficient for a given pitch increases with decreasing forward speed, thereby preventing the engine developing its full horse-power by reducing the engine r.p.m.

The Variable Pitch Airscrew surmounts this difficulty by enabling the pitch or inclination of the blades to be reduced for take-off and climb.

There are two main classes of Variable Pitch Airscrews :—

(1) Those whose pitch can be adjusted to fine pitch only on the ground (automatically taking up the coarse or top speed pitch in the air). These are called Adjustable Pitch Airscrews.

(2) The true Variable Pitch Airscrew, whose pitch can be adjusted in the air. The usual methods for adjustment are one or combinations of the following.

(a) Automatic control.—Usually brought about by the engine r.p.m. or the aerodynamic forces on the blades.

(b) Controlled pitch.—This may be achieved by some mechanism operated manually by the pilot, an electric motor, hydraulic pressure or by centrifugal forces.

Pitch variation is sometimes so considerable in range as to enable the pitch to be set at a negative angle, in which case the airscrew can be usefully employed as a brake when landing ; though as there is then no slip-stream effect on the tail surfaces much greater attention has to be paid by the pilot to directional control.

Contra-rotation airscrews are sometimes paired on a common axis; there are then no troublesome gyroscopic couples on turning to port or starboard, and this greatly assists the pilots control during manœuvre. They also remove any overturning tendency when opening the engine throttle on starting.

Thrust and Torque of Airscrews.

Expressions for the thrust and torque of an airscrew as given below show that its performance depends upon the value of J $\left(i.e. \frac{V}{nD}\right)$ at which it is working.

Consider first the case of airscrews whose tips speeds are less than 800 ft./sec. Then the effect of compressibility of the air may be neglected, although it is then on the point of becoming important.

STATIC AIRSCREW.

Consider a static airscrew, *i.e.*, one which rotates in a fixed plane and has no forward motion.

If the thrust T depends only upon airscrew diameter D, rotational speed n, mass density ρ, then

$$T = k_T \rho n^2 D^4 \quad . \quad . \quad . \quad . \quad . \quad . \quad (21)$$

where k_T is a constant called the thrust coefficient.

Similarly the torque,

$$Q = k_Q \rho n^2 D^5 \quad . \quad . \quad . \quad . \quad . \quad . \quad (22)$$

where k_Q is a constant called the torque coefficient.

MOVING AIRSCREW.

Let the airscrew be moving with translational velocity V. If the thrust now depends only upon V, D, n, and p,

$$T = \rho n^2 D^4 f_1\left(\frac{V}{nD}\right)$$

or

$$T = \rho n^2 D^4 f_1(J) \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

where J is non-dimensional.

Similarly

$$Q = \rho n^2 D^5 f_2(J) \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

Equations (23) and (24) show both T and Q to be dependent on J. In a given airscrew, D is fixed so that T and Q depend upon $\frac{V}{n}$. If then $\frac{V}{n}$ be kept constant $f_1(J)$ and $f_2(J)$ are also constant, so that we have

$$f_1(J) = k_T = \frac{\text{Thrust}}{\rho n^2 D^4} \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

$$f_2(J) = k_Q = \frac{\text{Torque}}{\rho n^2 D^5} \quad . \quad . \quad . \quad . \quad . \quad . \quad (26)$$

HIGH-SPEED AIRSCREWS.

From experiments on high-speed *static* airscrews, it appears that when the tip speed of such approaches the velocity of sound (in air) the airflow undergoes changes, until, if the tip speed be increased, the outflow ceases, and the slip-stream disappears when the velocity of sound is reached; the airscrew then appears to operate as a centrifugal fan. With high-speed airscrews this is serious for the phenomenon is associated with a falling off of the thrust.

It seems reasonable to suppose that at such high speeds the compressibility of the air plays an important part.

Considering compressibility effects only, if v_s is the velocity of sound in air, the resistance to motion takes the form

$$R = \rho l^2 v^2 f\left(\frac{v}{v_s}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (27)$$

and the effect of compressibility depends upon the velocity v as a fraction of the velocity of sound v_s in the undisturbed fluid. The relative importance of this may be obtained by applying Bernouilli's equation to a compressible fluid and assuming adiabatic transformation.

Let δp = increase in pressure at a stagnation point in the body.
v = velocity of undisturbed stream.
ρ = mass density where speed is v.

Then, if $\gamma = \frac{7}{5}$,

$$\delta p = \tfrac{1}{2}\rho v^2 \left[1 + \tfrac{1}{4}\left(\frac{v}{v_s}\right)^2 + \tfrac{1}{40}\left(\frac{v}{v_s}\right)^4 + \ . \ . \ .\right] = \tfrac{1}{2}\lambda\rho v^2. \quad . \quad . \quad . \quad (28)$$

Since the series in equation (38) rapidly converges, the effect of compressibility may be neglected so long as $\tfrac{1}{4}\left(\frac{v}{v_s}\right)^2$ is small compared with unity.

The following table gives the approximate values of λ for the whole range of values of V from zero to v_s.

V *ft./sec.*	0	200	400	600	800	1,000
λ	1·000	1·008	1·033	1·077	1·149	1·224

When V = 220 ft./sec. (150 m.p.h.), λ = 1·01, so that the neglect of compressibility at this speed would introduce an error of 1 per cent. On the other hand, it is clear that for velocities of 800 ft./sec. and over the effect of compressibility can no longer be disregarded.

PERFORMANCE.

In the estimation of aeroplane performance, two important quantities are involved, viz. horse-power required, and horse-power available. Both of these are usually required for all attitudes of the aeroplane over the flying range for a stated series of altitudes.

On the one hand, the horse-power required is calculated from the known or estimated drag coefficients of the various components and the aerodynamic characteristics of the main planes; on the other hand the horse-power available is a quantity which is not obtained without considerable calculation. Apart from the characteristics of the airscrew itself, its performance also depends on the particular combination of engine and aeroplane.

Account has to be taken of (*a*) the variation of engine power consequent upon the decrease in density, pressure, and temperature, with altitude; (*b*) the changing value of J under which the airscrew operates with varying attitudes of flight; (*c*) the continual change of atmospheric conditions from day to day and place to place.

The Standard Atmosphere.

In order to afford a basis of comparison of full scale tests, an International Standard Atmosphere has been defined * which corresponds with the average conditions in Western Europe.

It is assumed that:

(i) The air is dry and its chemical composition the same at all altitudes, by volume being 78·03 per cent. nitrogen, 20·99 per cent. oxygen, 0·94 per cent. argon, and 0·04 per cent. carbon dioxide.

(ii) The temperature at mean sea-level is 15° C., and the barometric height reduced to 0° C. is 760 mm.

(iii) The weight of air under these conditions is 1·2257 kg./m.^{3} (0·07656 lbs./ft.^{3}). The value of 'g' is taken to be uniform at 980·62 cms./sec.^{2} (32·17 ft./sec.^{2}). The mass density ρ_0 of air at mean sea-level is therefore 0·00238 slug/ft.^{3}

(iv) For any altitude Z metres above mean sea-level up to a limit of 11,000 metres, *i.e.* to the bottom of the Stratosphere, the temperature (°C.) varies thus:—

$$\theta_z = 15 - 0\cdot0065Z \quad . \quad . \quad . \quad . \quad . \quad . \quad (29)$$

(v) Above 11,000 metres θ is constant and equal to $-$ 56·5° C.

(vi) It follows that for any altitude Z less than 11,000 metres, where the barometric pressure is p_z and specific weight a_z and specific mass ρ_z, these quantities are connected by the equations:—

$$\frac{p_z}{p_0} = \left(\frac{T_z}{T_0}\right)^{5\cdot256} = \left(\frac{288 - 0\cdot0065Z}{288}\right)^{5\cdot256} \quad . \quad . \quad . \quad . \quad . \quad . \quad (30)$$

and

$$\frac{\rho}{\rho_0} = \frac{a_z}{a_0} = \left(\frac{T_z}{T_0}\right)^{4\cdot256} = \left(\frac{288 - 0\cdot0065Z}{288}\right)^{4\cdot256} \quad . \quad . \quad . \quad . \quad . \quad (31)$$

(vii) For altitudes above 11,000 metres the relations are:—

$$\log_{10}\frac{p_1}{p_z} = \log_{10}\frac{\rho_1}{\rho_z} = \log_{10}\frac{a_1}{a_z} = \frac{Z - 11,000}{14,600} \quad . \quad . \quad . \quad . \quad (32)$$

where suffix 1 refers to conditions at Z = 11,000 metres.

Table I. shows the approximate values of relative density and pressure and temperature for various heights as given by equations (30) and (31). For convenience, altitudes in feet have been tabulated.

* Air Publication 1173.

TABLE I.

International Standard Atmosphere.

Height, feet.	Relative Density $\frac{\rho}{\rho_0} = (\sigma)$	Relative Pressure $\frac{p}{p_0}$	Temperature. °C.
0	1·00	1·00	15·0
1,000	0·98	0·97	12·5

80,000	0·03	0·025	− 55·0

The Variation of Piston Engine Power with Altitude.

It has been found by H. L. Stevens (R. and M. 960), that the variation in power is approximately proportional to $\left(\frac{p}{p_0}\right)^{1 \cdot 05}$.

For a given r.p.m., therefore, the b.h.p. in a standard atmosphere at mean sea-level (generally referred to as ground-level) must be multiplied by a horse-power factor $f(h)$ in order to obtain the corresponding b.h.p. at altitude h.

In symbolic form

$$(\text{b.h.p.})_h = \text{Std. b.h.p.} \times f(h) \quad . \quad . \quad . \quad . \quad (33)$$

the r.p.m. being the same in each case;
where

$$f(h) = \left(\frac{p}{p_0}\right)^{1 \cdot 05}. \quad . \quad . \quad . \quad . \quad (34)$$

Horse-Power Required.

The amount of labour involved in the calculation of the horse-power required depends, as in the case of the horse-power available, upon the data available and the degree of accuracy required. The value of the result depends upon a fairly accurate knowledge of the resistance of the several parts or components as deduced from model tests. Fortunately, for most components the resistance is proportional to the square of the velocity over a very large range, but in the case of elongated aerodynamic bodies such as a fuselage or flying-boat hull, where skin friction effects are important, the index of V is less than two. Unless due care is taken serious errors in the estimated resistance may arise. It is found, however, that if the resistance of such bodies is known for a speed approximately mid-way over the flying range of speeds, the error at the extreme speeds in applying the V_1^2 law is small.

RESISTANCES OF COMPONENTS.

The following list gives the resistances of various details or components at 100 m.p.h. at ground-level which may be used in the absence of other data. In all cases the resistance may be assumed to vary as the square of the speed.

Fuselage (good streamline) when $\alpha = 0°$	**2·6 lbs./sq. ft., projected area.**
„ (two cockpits and nose radiator) wheren $\alpha = 0°$	**8·0 „ „ „ „**
Tail plane and elevators	**0·75 lbs./sq. ft. of plan area.**
Fins and rudders	**0·60 lbs./sq. ft. of side area.**
Wheel, 800 × 150 mm.	**13·5 lbs. with shield to tyre.**
Struts, fineness ratios 2·5 to 5·0	**2·3 lbs./sq. ft. projected area.**

Add 0·4 lbs. for each end.

SIMPLE METHOD OF CALCULATION.

In an approximate method of calculating the horse-power required ($HP._R$) the following assumptions are usually made :—

(i) The tail load may be ignored.

(ii) The variation in resistance of components due to changes of α may be neglected.

(iii) The line of thrust passes through the C.G.

(iv) The obliquity of the line of thrust may be neglected.

(v) The airscrew slip-stream diameter is $0 \cdot 8$ D.

(vi) The resistance of parts in the slip-stream is increased by 25 per cent. for any speed of flight (i.e., the slip-stream velocity is always $\sqrt{1 \cdot 25}\, V$).

In view of condition (iii) the method outlined below cannot be applied to flying boats without modification.

The total resistance is composed of two parts (*a*) that due to main planes; (*b*) that due to remainder.

For the former,
in steady flight,

$$L = W \quad \text{. . . . .} \quad (35)$$

$$D = \frac{W}{L/D} = \frac{W}{\delta} \quad \text{. . . . .} \quad (36)$$

Let V_1 = flight speed in m.p.h.

then $V_{m.p.h.} = 1 \cdot 465\, V_{ft./sec.}$ and $(V_{m.p.h.})^2 = 2 \cdot 15\, (V_{ft./sec.})^2$

and
$$V_1^2 = \frac{W}{2 \cdot 15\, C_L \frac{\rho S}{2}} \quad \text{. . . . .} \quad (37)$$

For the latter,
if R_1 = resistance of parts outside slip-stream at 100 m.p.h.
R_2 = „ „ inside „ „ „ „
R = total resistance at 100 m.p.h.

then
$$R = R_1 + 1 \cdot 25\, R_2 \quad \text{. . . . .} \quad (38)$$

For a single-engined tractor, R_2 includes the fuselage, part of tail unit and undercarriage. Hence, using equations (36) and (38).

At any speed V_2, the total drag of the aeroplane is given by

$$D_W + D_B = \frac{W}{\delta} + R\left(\frac{V_1}{100}\right)^2 \quad \text{. . . . . .} \quad (39)$$

But for steady flight, using equation (3),

$$T = \frac{W}{\delta} + \frac{R}{10^4}\left(\frac{W}{2 \cdot 15 C_L \frac{\rho S}{2}}\right) = \frac{W}{\delta} + D^1 \quad \text{. . . . . .} \quad (40)$$

Finally,
$$H.P._R = \frac{V_1 T}{375} \quad \text{. . . . . . .} \quad (41)$$

Draw up Table II. for equal increments of C_L up to $C_{L\,max.}$ and plot the results as in fig. 25.

TABLE II.—ESTIMATION OF H.P. REQUIRED.

C_L	$\delta = \frac{L}{D}$	$\frac{W}{\delta}$	D^1	T	V_1	$H.P._R$

Deductions from Performance Curves.

Flight at Altitude.

In order to obtain the horse-power required $H.P._R$ for altitudes other than ground-level it is not necessary to go over a similar set of calculations.

If $H.P._R$ and V refer to ground conditions, then at altitude h where the relative density is σ the corresponding powers $H.P^1._R$ and speeds V^1 are given by

$$H.P.^1_R = \frac{H.P._R}{\sqrt{\sigma}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (42)$$

$$V^1 = \frac{V}{\sqrt{\sigma}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (43)$$

Thus all the powers and speeds in Table II. are divided by the appropriate $\sqrt{\sigma}$ to obtain the corresponding figures at any desired altitude.

Range of Flight Speeds.

In fig. 25, the curves of $H.P._A$ and $H.P._R$ both relate to the same height, viz., ground-level. The extreme flight speeds are given at the points of intersection of these curves. At A the stalling speed is obtained whilst at B the maximum flight speed is revealed.

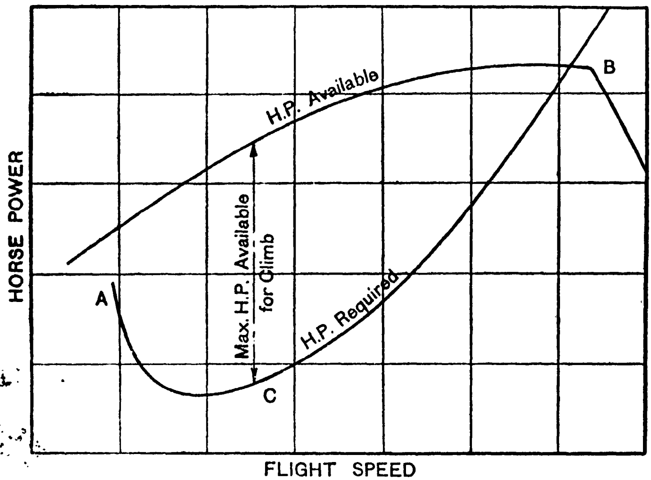

Fig. 25.—Aeroplane Performance Curves.

Rate of Climb.

The vertical intercept between the two curves corresponding with a certain flight speed V, represents the H.P. available for climb. The best climbing speed occurs when the forward speed is adjusted (by operating the elevator) to that at C where the h.p. available for climb is maximum.

It will be seen that the rate of climb r (or vertical velocity of ascent) will vary with the forward speed, in fact

$$r = \frac{(H.P._A - H.P._R)\,33{,}000}{W} \text{ ft./min.} \quad . \quad . \quad (44)$$

At the extreme speeds r is zero.

DESIGN.

Materials.

In Table III. is a list giving the mechanical properties of most of the materials used on aircraft construction.

STEEL.

This may be used in the form of bar, forging, casting, seamless tubing or sheet. The number of alloy steels in use on aircraft construction is very extensive and in the choice of the correct specification for any particular duty considerable experience is necessary. For instance, where the steel is to be welded one of the special welding steels may be used with advantage and where parts are liable to be exposed to corrosion stainless steel is advisable.

A fitting designed to transmit large loads should always be made from high tensile steel to keep the weight of the fitting down. Whether steel or duralumin is used in the construction of the primary structure of an aeroplane is usually a matter of preference, though it is usual for a tubular frame to be made from high tensile steel and a stressed skin structure or monocoque from duralumin.

DURALUMIN.

This is an aluminium alloy and in strength is the equal of mild steel though more susceptible to corrosion.

To minimise this, machined fittings in duralumin should be anodically treated. Fittings made from flat sheet should employ Alclad which is duralumin sheet protected on either face by a thin layer of aluminium.

In the use of duralumin, continuous care has to be taken to ensure that its remarkable properties are not impaired by bad handling and treatment.

MAGNESIUM ALLOY CASTINGS.

This metal has already established itself as a very economical material (from the weight point of view) for non-structural parts such as instrument mountings, subsidiary control mountings, etc.

WELDING.

The advantages of welding over riveting are briefly :—

1. Quickness.
2. Cheapness.
3. Ease of repairs.
4. Simpler design.
5 Structure more homogeneous.

The two main methods of welding are :—

(*a*) The oxy-acetylene welding process.
(*b*) The electrical resistance process of spot, seam and arc welding.

Oxy-Acetylene Welding.

Where heat-treatment after welding is impossible (local reheat-treatment being prohibited) it is advisable to use the low carbon, the carbon manganese and the chromium molybdenum steels, using a welding wire to DTD82A. Stainless steels are difficult to weld satisfactorily. Aluminium sheet (Spec. L. 4) as used for cowling, fairing and tanks can be easily welded using a flux to Spec. DTD119 and a welding wire of the same material.

In the gas welding of anodically treated parts (as in repair work) the protective coating should be thoroughly removed before welding.

In welding aluminium casting a welding wire of aluminium with 8–9 per cent. silicon is advised.

The welding of duralumin has not yet become a satisfactory process.

Magnesium alloys can be welded with a flux and wire similar to those used for aluminium.

Electric Seam Welding.

In this process a continuous but fluctuating current of low voltage forms a series of spot welds. It has been successfully applied to the welding together of high tensile steel strip (Spec. 54A) and proved itself at least equal to a riveted joint.

Spot Welding.

This process consists in passing through the sheets to be welded together a low voltage current, The water-cooled electrodes apply mechanical pressure during the passage of the current.

Strength of Spot Welds.

Material: M.S. Strength per spot weld in lbs.

Gauge.	Single Shear.	Double Shear.
22	1,100	1,600
20	1,600	2,300
18	1,900	2,750
16	2,400	3,400
14	3,400	4,200
12	3,900	5,600
10	5,800	8,400

Material: Light Alloy. Strength per spot weld in lbs.

Gauge.	Single Shear.	Double Shear.
26	170	310
24	240	390
22	340	530
20	420	950
18	460	950

BENDING OF ALUMINIUM ALLOY SHEET.

The following bend radii should be adhered to:—

Condition.	Inside Bend Radii.	
	22 G. and Less.	More than 22 G.
Fully annealed	$\frac{1}{2}t$	$1t$
Finally heat-treated within one hour after quenching . .	$1\frac{1}{2}t$	$2t$
Finally heat-treated and aged .	$2\frac{1}{2}t$	$3t$

CASTINGS.

Should not be used where failure of any one casting could cause the structure to fail or the control of the aircraft to be lost.

Castings used in primary parts of the structure should be radiologically examined or, if that is not practicable, proof-loaded.

RIVETS.

Some of the many types of rivets used in aircraft construction are shown in fig. 26.

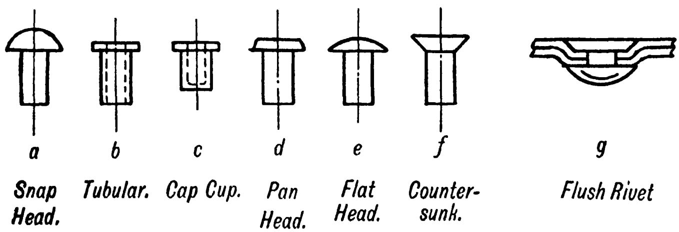

FIG. 26.

A riveted joint may fail in any of the following ways :—

(1) Failure in shear of rivet.
(2) ,, bearing of rivet.
(3) ,, tension of plate.
(4) ,, bearing of plate.

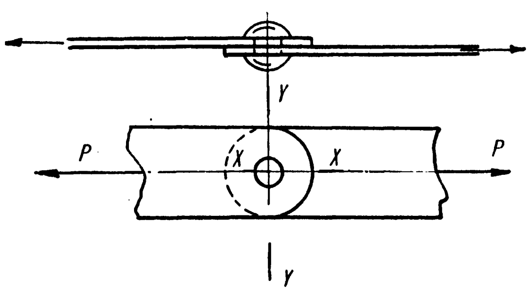

FIG. 27.

The strength of the riveted joint shown in fig. 27 is the least of the values given by the following formula :—

f_t = tensile strength of plate in lbs./in.
f_B = bearing ,, ,, ,, ,,
f_s = shear ,, rivet ,, ,,
f_B' = bearing ,, ,, ,, ,,

Bursting across XX	$T = \frac{5}{4} at f_t$ lbs. (empirical).
Tearing „ YY	$T = 2bt f_t$ „
Bearing in plate	$T = dt f_B$ „
Shear of rivet	$T = \left(\frac{\pi d^2}{4}\right) f_s$ lbs.
Bearing in rivet	$T = dt f_B'$ lbs.

GROUPS OF RIVETS.

FIG. 28.

When two strips are connected together as shown in fig. 28 by a long row of rivets, it is important to remember that the loads on the end rivets are greater than the loads on the centre rivets due to the stretch in the plates.

GROUPS OF RIVETS ECCENTRICALLY LOADED.

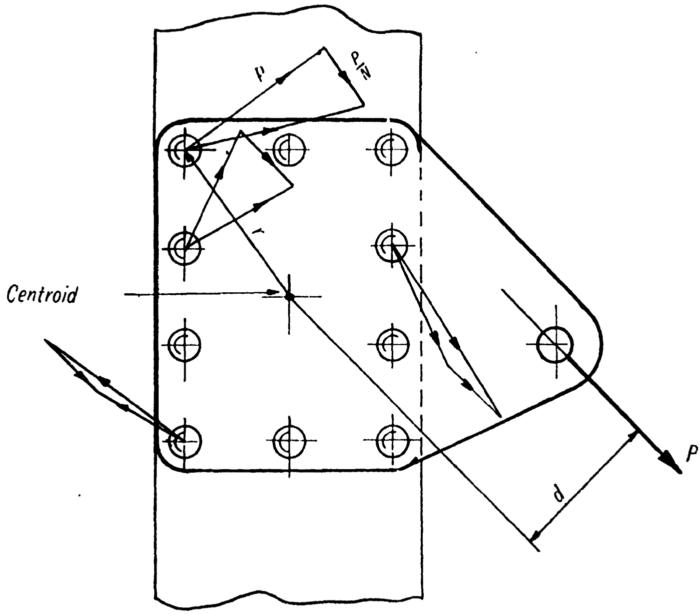

FIG. 29.

When a group of rivets (fig. 29) has to resist an offset load, the load on each rivet can be considered as being the vector sum of the direct load $\frac{P}{N}$ and the moment Pd. To find the loads on the rivets proceed as follows.

(1) Find the centroid of the rivets (work on rivet areas if all of the same material as is usually the case—if materials are different the areas should be adjusted in proportion to the bearing or shearing strengths of the various rivets).

(2) For each rivet calculate (area of rivet $\times$ r^2) and find total for all the rivets ($= \Sigma Ar^2$).

Then the load p on any one rivet X due to the offset load and acting in a direction normal to the radius r,

$$p = \frac{Pd \times \text{area of rivet } A \times r}{\Sigma Ar^2}$$

Then total load on rivet X = vector sum of $\frac{F}{N}$ and p.

Where $\frac{P}{N}$ acts in the direction of P.

Notes on Riveted Joints for Aircraft.

Never use rivets in tension.

Width of material round a rivet should not be less than $1\frac{1}{2}$ $\times$ diameter of rivet.

Rivet centres should not be less than 3 $\times$ diameter of rivet.

Solid rivets in double shear can only develop about $1\frac{1}{2}$ $\times$ single shear strength of rivet.

The strength of a group of rivets can be accurately determined by experiment only.

For riveting thin plates hollow rivets are easier to rivet and have bearing strengths more nearly equal to their shearing strengths than solid rivets.

The riveting of a long row of rivets causes a considerable stretch in the material.

Wiring Lugs and Sockets.

Let f_t = tensile strength of lug in lbs./in.^{2}

f_B = bearing strength of lug or pin (whichever is the less) in lbs./in.^{2}

f_s = shear strength of pin in lbs./in.^{2}

Then referring to fig. 30—

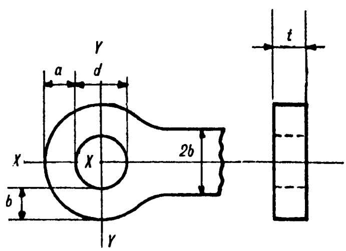

FIG. 30.

$$\text{Strength across XX} = \frac{5}{4} at f_t \text{ lbs.}$$

$$\text{,, ,, YY} = 2bt f_t \text{ lbs.}$$

$$\text{,, in bearing} = dt f_B \text{ lbs.}$$

$$\text{,, in shear} = 2\left(\frac{\pi d^2}{4}\right) f_s \text{ lbs.}$$

For a correctly designed lug these values should be approximately equal.

In order that the full bearing and shear strengths of the joint may be developed it is important that the thread finishes outside the lug.

It has been found that a large bearing stress will cause a considerable reduction in the shear strength of the pin. (See Air Publication 970, chapter VIII, section IV.) The maximum permissible bearing stress f_B that may be used depends upon the type of load to be taken. If the load is an alternating one, such as may occur on an engine mounting, it should be kept low. It is frequently advisable to bush lugs with H.T.S. bushes to prevent the development of slackness and of acilitate its remedy should it occur under working conditions.

STRUTS.

P = Load applied to strut in lbs.
A = Cross-sectional area in ins.^{2}
l = Length of strut in ins.
p = Ultimate strength of material in lbs./in.^{2}
E = Modulus of elasticity in lbs./in.^{2}
I = 2nd moment of area.
k = Radius of gyration of section in ins.
h = Distance of farthest fibre from the N.A.
a = Constant determined by experiment.

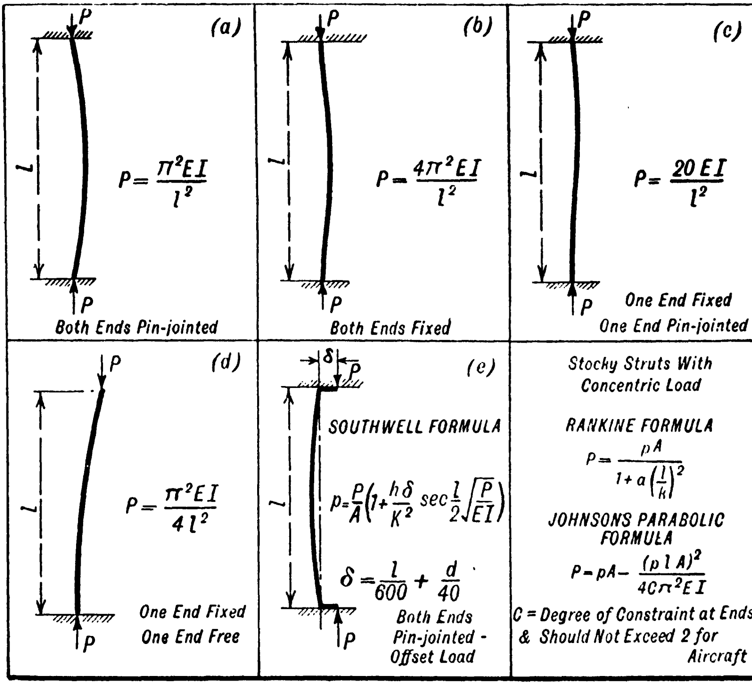

FIG. 31.

For long slender struts with concentric loading the well-known Euler formula may be used (fig. 31) to determine the maximum load that may be applied to the strut without failure. The value of the load thus found is such, that if one, but very slightly in excess of it be applied to the strut and the strut then deflected a small amount, then the deflection will continue to increase until the strut breaks. Though the strut finally breaks through the stress exceeding the maximum tensile or compressive stress that the material will stand, it is important to understand that the collapse in its initial stages is due to instability. The stress at which the strut fails in buckling $\left(\frac{\text{Euler load}}{\text{area of cross section}}\right)$ may be considerably less than the maximum stress the material will stand as a small block, but for very short, stocky struts it will approach the latter value. It is therefore important to check the Euler stress to find if it exceeds the ultimate strength of the material.

The Euler formula applies only to closed sections.

The strength of open sections, as struts (such as channels and angles), can be accurately found only by test.

In using the Euler formula for aeroplane struts it is unwise, owing to the deflection of the adjacent structure, to count on having fixed ends.

Short stocky struts with concentric loading can be designed either to the Johnson Parabolic formula or the Rankine formula.

Struts with Offset Loads.—In practice it is inevitable that there should be an eccentricity between the applied load and the neutral axis of the strut. The eccentricity will in general be the sum of the following :—

(*a*) Initial bow in tube.
(*b*) Offset end fittings.
(*c*) Bore of tube eccentric with outside.
(*d*) Offset load.

Various formula have been evolved to make allowance for this, the most well known, perhaps, being the Southwell formula. This equation is best solved by trial and error or by means of method described in Air Publication 970.

Many curves, however, are in existence giving the strength of struts of various diameters and thickness and materials that obviate the necessity for laborious calculation.

BEAM-COLUMNS.

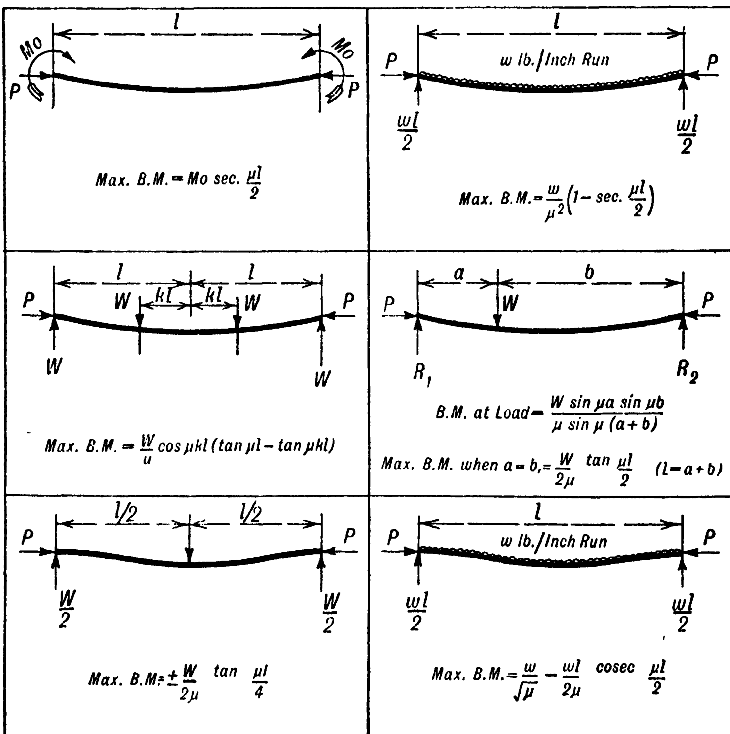
P = End load in lbs.

$\mu = \sqrt{\dfrac{P}{EI}}$.

I = 2nd moment at area in in.^{4}

E = Modulus of elasticity in lbs./in.^{2}

Max. B.M. in lbs./ins. when lengths are in inches and loads are in pounds



The Max. Stress is given by $p = \dfrac{P}{A} + \dfrac{\text{Max. B.M.}}{Z}$ where Z is the modulus of the section.

FIG. 32.

A beam-column can be defined either as a strut with a side load or a beam with an end load. In fig. 32 are given the formula for the more simple conditions of loading. For the stressing of continuous beams on three or more supports, with end loads, the reader is advised to consult Air Publication 970 or 'Aeroplane Structures' by Pippard and Pritchard.

Beams.

The elementary formulæ for beams on two supports are given on p. 424.

When a beam is continuous and carried on more than two supports, the theorem of three moments has to be used for determining the reactions at the supports and the bending moment diagram.

Theorem of three moments for a uniform load and rigid supports.—For a beam as in fig. 33 we have

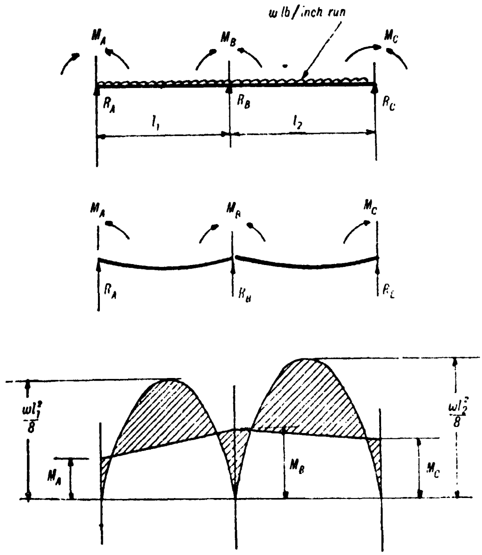


FIG. 33.

$$M_A l_1 + 2M_B(l_1 + l_2) + M_C l_2 = \frac{w}{4}(l_1^3 + l_2^3).$$

If there are more than three supports the above equation is applied successively to the adjacent pairs of spans and solved together.

For three supports there are three unknowns and one equation.

For N supports there are N unknowns and (N−2) equations.

The value of the bending moments at each end of the beam are known by the end conditions. For example, in fig. 36 as there is no overhang and the joints A and C are pinjoints $M_A = M_C = 0$.

The reactions at the supports (fig. 33) :—

$$R_B = \frac{wl_1}{2} + \frac{wl_2}{2} + \frac{(M_B - M_A)}{l_1} + \frac{(M_B - M_C)}{l_2}$$

$$R_A = \frac{wl_1}{2} + \frac{(M_A - M_B)}{l_1} \text{ and } R_C = \frac{wl_2}{2} + \frac{(M_C - M_B)}{l_2}$$

To draw the bending moment diagram, draw the diagram for each span of the beam as though it were pin-jointed at each support. Then superimpose the bending moment diagram for the fixing moments. The shaded portion of the diagram is the resultant bending moment diagram.

The above equations apply only to a beam with a uniform load. For any other system of loading the following should be used.

$$\frac{6A_1x_1}{l_1} + \frac{6A_2x_2}{l_2} + M_A l_1 + 2M_B(l_1 + l_2) + M_C l_2 + 6EI\left(\frac{y_a}{l_1} + \frac{y_c}{l_2}\right) = 0$$

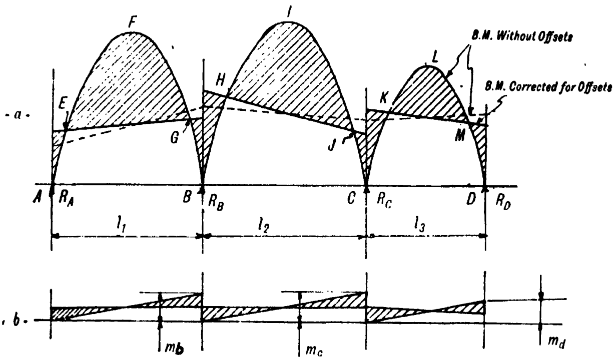

FIG. 34.

where in fig. 34 A_1 = area AEFGB (bending moment diag. of a simply supported beam between A and B).

A_2 = area BHIJC.

x_1 = Distance of centroid of AEFGB from A.

x_2 = " " " BHIJC from C.

y_a = vertical distance of B below A after loading.

y_b = " " " C " "

assuming A, B and C to be collinear before loading.

The reactions at the supports are the sum of the reactions for simply supported beams and reactions due to the end moments.

OFFSET MOMENTS.

Offset bend moments are introduced in the manner indicated in fig. 35.

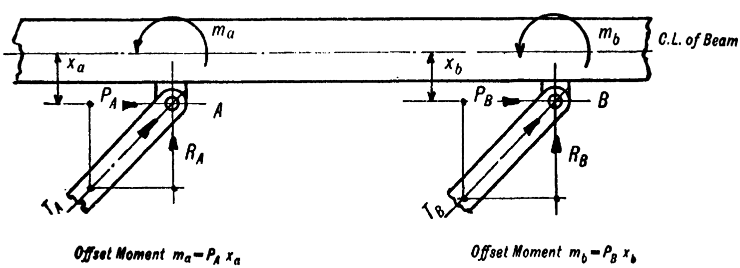

FIG. 35.

To find the bending moment diagram for a continuous beam with offset moments, first find the bending moment diagram, neglecting the offsets. Calculate the offset moments m_a, m_b,

m_0, etc., and apply the theorem of three moments to determine the bending moment diagram due to them acting alone.
This gives

$$M'_A l_1 + 2M'_B(l_1 + l_2) + M'_C l_2 = m_a l_1 + 2m_b l_2$$

where M_A', M_B', etc., are the bending moments at the supports due to the offsets.

From the end conditions and the repeated application of this formula the bending moment diagram for the offsets can be drawn (fig. 36b). This diagram should then be superimposed on the bending moment diagram drawn for no offsets (fig. 36a).

Generalised Theorem of Three Moments.

The form of the simple theorem of three moments as applied to continuous beams has been extended by Berry to allow for effects of compressive or tensile end loads in the various bays, such as occur in aeroplane spars.

Spar with Compressive End Loads.

If the supports remain collinear, we have, for two adjacent bays :—

$$\frac{M_{AR}l_1}{E_1I_1} f(\theta_1) + \frac{2M_{BL}l_1}{E_1I_1} \phi(\theta_1) + \frac{2M_{BR}l_2}{E_2I_2} \phi(\theta_2) + \frac{M_{CL}l_2}{E_2I_2} f(\theta_2) + \frac{w_1l_1^3}{4E_1I_1} \psi(\theta_1) + \frac{w_2l_2^3}{4E_2I_2} \psi(\theta_2) = 0;$$

where

$$f(\theta) = \frac{6(2\theta \operatorname{Cosec} 2\theta - 1)}{(2\theta)^2}; \qquad \phi(\theta) = \frac{3(1 - 2\theta \operatorname{Cot} 2\theta)}{(2\theta)^2}$$

$$\psi(\theta) = \frac{3(\tan \theta - \theta)}{\theta^3}; \qquad (2\theta)^2 = \pi^2 \frac{P}{P_e}.$$

P_e = Euler load for span in plane of bending.

Spar with Tensile End Loads.

For two adjacent bays we have :—

$$\frac{M_{AR}l_1}{E_1I_1} F(\theta_1) + \frac{2M_{BL}l_1}{E_1I_1} \Phi(\theta_1) + \frac{2M_{BR}l_2}{E_2I_2} \Phi(\theta_2) + \frac{M_{CL}l_2}{E_2I_2} F(\theta_2) + \frac{w_1l_1^3}{4E_1I_1} \Psi(\theta_1) + \frac{w_2l_2^3}{4E_2I_2} \Psi(\theta_2) = 0.$$

where

$$F(\theta) = \frac{6(1 - 2\theta \operatorname{Cosech} 2\theta)}{(2\theta)^2} \qquad \Phi(\theta) = \frac{3(2\theta \operatorname{Coth} 2\theta - 1)}{(2\theta)^2}$$

$$\Psi(\theta) = \frac{3(\theta - \tanh \theta)}{\theta^3}.$$

Spar with Compressive and Tensile End Loads in Adjacent Bays.

In this case the relevant terms for each bay are selected from the two general equations given above, so that the equation for two such bays will contain both trigonometrical and hyperbolic terms.

Values of the Functions.

The above functions have been calculated by Berry for various values of θ and are to be found in Air Publication 970 (H.M.S.O.).

Stressed Skin or Monocoque Construction.

A stressed skin structure consists of a thin sheet metal shell stiffened and strengthened by transverse and longitudinal members attached (usually by rivets but sometimes by welding) to the inside surface of the skin. The transverse members are called hoops, frames or bulkheads and the longitudinal members stringers (or longerons). The functions of the bulkheads are to prevent distortion of the monocoque, stabilise the longitudinals and to distribute over the monocoque skin any concentrated loads (such as those imposed by the landing gear, wing attachments, tail unit, etc.).

Stringers are necessary to increase the longitudinal compressive strength of the monocoque.

For the stressing of thin sheet metal structures there is no method approaching in simplicity and accuracy the well-known methods for determining the loads in the members of a tubular

structure. This is mainly due to the difficulty in calculating the loads at which local buckling or elastic instability of the thin sheet will occur.

However, a considerable amount of research has been carried out on problems of a simple but fundamental nature, and below is given a very brief summary of some of the results. It cannot be too strongly emphasised that in a last resort actual tests are the only satisfactory source of correct and reliable data. Even in the laboratory experimental results may differ by as much as 100 per cent., so in practice where the conditions of loading are still more uncertain, it is possible that greater differences than this may occur.

Thin-Walled Cylindrical Tube in Compression.

If the tube has a large l/k it will fail by buckling (fig. 36) (*i.e.* as a strut). If its l/k is small it will fail by local buckling or wrinkling. The tube should be stressed for both cases.

$$p \text{ (wrinkling stress in lbs./in.}^2) = 0 \cdot 18 \frac{Et}{r};$$

$$p \text{ (Euler or buckling stress in lbs./in.}^2) = \left(\frac{\pi k}{l}\right)^2 E;$$

where

E = Mod. of elasticity in lbs./in.²

k = Rad. of gyration of tube in ins. = $0 \cdot 7r$.

Flat Corrugated Sheet in Compression.

Where the compressive loads in a flat sheet are considerable it is sometimes expedient to replace a large number of closely spaced stringers by a corrugated sheet (fig. 37). Box spars are usually built this way.

A conservative estimate of the maximum wrinkling stress is given by the formula

$$p = 0 \cdot 12 \frac{Et}{r} \text{ lbs./in.}^2$$

The corrugations should also be stressed by the strut formula

$$p = C\left(\frac{\pi k}{l}\right)^2 E \text{ lbs./in.}^2$$

where C = fixing moment coefficient which should normally be taken as $1 \cdot 0$ but may be increased to a maximum of $1 \cdot 5$ under very favourable conditions.

k = the rad. of gyration must be calculated for the particular corrugation used.

Corrugated Thin Walled Tube in Compression.

The strength of a thin metal tube (fig. 38) may be greatly increased by corrugations, when the critical stress is due to wrinkling or elastic instability.

$$p \text{ (wrinkling stress in lbs./in.}^2) = 0 \cdot 12 \frac{Et}{r}.$$

$$p \text{ (Euler or buckling stress)} = \left(\frac{\pi k}{l}\right)^2 E$$

k = Rad. of gyration of tube = $0 \cdot 7R$ (not $\cdot 7r$).

r = Rad. of corrugation.

Thin Walled Circular Tube in Torsion.

The maximum shear stress that a thin metal tube (fig. 39) will withstand when in torsion without the development of local wrinkling is given by

$$f = \frac{CEt}{R} \text{ lbs./in.}^2$$

where $C = 0 \cdot 06$ to $0 \cdot 07$

Owing to the fact that shear wrinkles can develop in relatively small areas of unsupported surface, the presence of stringers and bulkheads does not affect to any marked extent the above formula.

For normal shear failure $p = \dfrac{T}{2\pi r^2 t}$ lbs./in.²

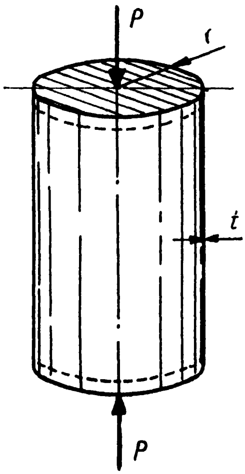

FIG. 36.

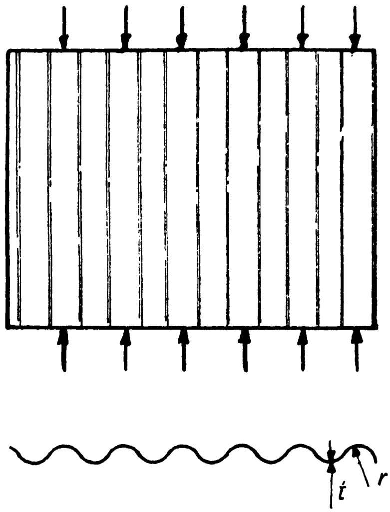

FIG. 37.

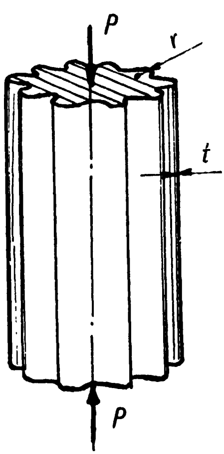

FIG. 38.

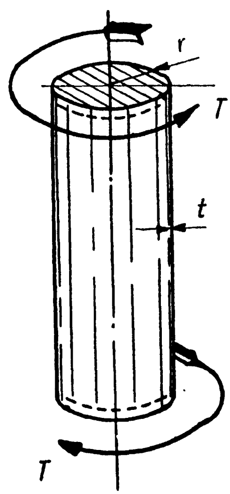

FIG. 39.

THIN WALLED CIRCULAR TUBE IN BEND (WITHOUT SHEAR).

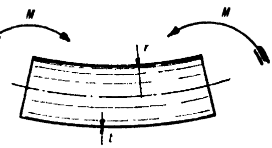

FIG. 40.

The compressive stress at which local wrinkling occurs for the case in fig. 40 is given by the formula

$$p = 0\cdot20\,\frac{Et}{r}\ \text{lbs./in.}^2$$

If tube is corrugated on the compression side this stress may be increased to

$$p = 0\cdot12\,\frac{Et}{r}\ \text{where now } r = \text{rad. of corrugations.}$$

BULKHEADS.

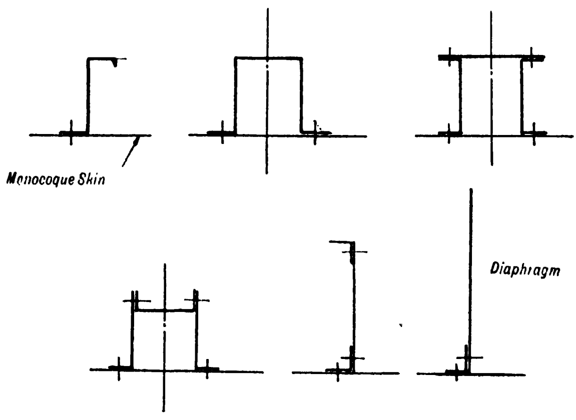

FIG. 41.

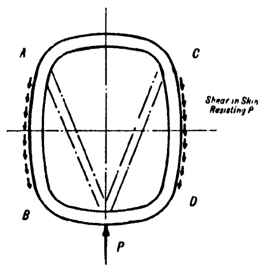

FIG. 42.

Fig. 41 shows a few typical bulkhead sections. The functions of a bulkhead have already been briefly referred to. When a concentrated load P is applied to a bulkhead (see fig. 42) it

is resisted by the shearing force in the skin between the points A and B and C and D, where the rivets connecting the bulkhead to the skin must be adequate to transmit the load from the bulkhead to the skin. If there are no reinforcing struts (shown chain-dotted) the bulkhead between B and D must be capable of transmitting the bending moment due to P.

STRINGERS.

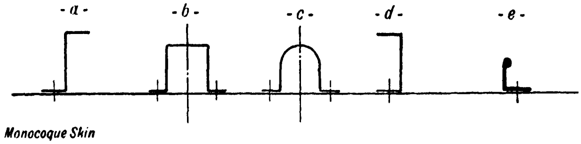

FIG. 43.

Fig. 43 shows a few typical stringer sections. The sections (*b*) and (*c*) are more efficient as struts than the other sections, whose free edges are liable to be unstable. In the choice of a stringer, of which a considerable length may be required per machine, the problems of manufacture and erection should be considered as well as those of strength and stiffness.

The failure of a stringer-skin combination may arise from any of the following causes:—

(1) Failure as a strut.
(2) Failure due to wrinkling of stringer.
(3) Failure due to wrinkling of skin.
(4) Failure due to twisting of stringer.

It should be noted that as the stringer is more likely to collapse as a strut towards the centre of the machine than outwardly (owing to the support given by the skin in the latter direction), it is perhaps desirable to offset the load on the stringer towards the centre of the machine away from the neutral axis of the stringer (see fig. 44).

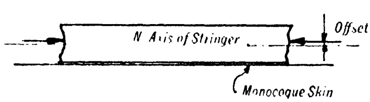

FIG. 44.

It is important to remember that the wrinkling of the skin may cause the premature failure of the stringer and *vice versa*.

The strength of the closed sections in compression, such as (*b*) and (*c*), can be calculated by the Euler formula, but the strength of the other open sections can be accurately determined only by experiment.

One method in estimating the strength of a stringer skin combination is to estimate the maximum stress permissible in either acting alone, and then multiply the lesser of these by the sum of their area.

HOLES IN A MONOCOQUE SKIN.

Holes in a monocoque should be so stiffened that the distortion with the hole is no greater than without it. Lack of rigidity may cause the development of high stresses in other parts of the structure.

The Torsion of Thin Sections.

WRINKLING STRESS.

When a thin-walled section is in torsion (fig. 45) the shear per unit length of section is constant. (This is implied in the formula $f = \frac{T}{2tA}$ where f = shear stress/in.^{2}, T = torsion, t = thickness of section, and A = area enclosed by outside contour of section.)

The value of the shear stress at which local wrinkling occurs is given by

$$f = 0{\cdot}06\,\frac{Et}{R}\ \text{lbs./in.}^2$$

where R is the argest radius of curvature of the section.

ANGULAR TWIST.

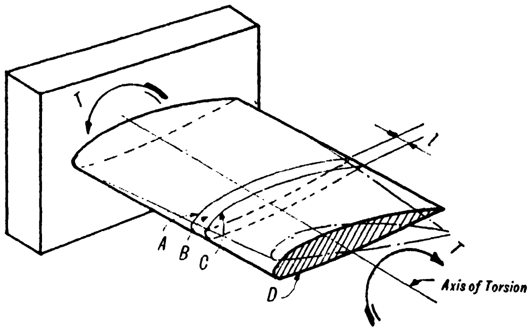

FIG. 45.

To determine the angular deflection about the flexural axis of the section shown in fig. 45 under the action of a continuously applied torque (continuous but varying along the length of the section), first divide the section into a number of comparatively short sections such as AC.

Then the angular twist of AC due to the torque applied between B and C is given by the formula:

$$\Delta\theta = \frac{TCl}{4A^2tN} \text{ radians}$$

where T = torque applied between B and C in lbs. ins.;
C = periphery of section in ins.
= AC in ins.;
A = area enclosed by contour of section in ins.^{2};
t = thickness of section in ins.;
N = shear modulus in lbs./in^2.

The total angular twist of the whole section is given by $\theta = \Delta\theta_1 + \Delta\theta_2 + \Delta\theta_3 +$ etc.
$= \Sigma\Delta\theta$ radians.

TORSION COMBINED WITH AXIAL COMPRESSION.

Let f_t = maximum permissible shear stress } From wrinkling formula above.
p_a = ,, ,, comp. ,,
f = stress due to torsion
p = ,, ,, ,, compression.

Then $\frac{p}{f_t - f} = \frac{p_a}{f_t}$ (conservative values).

Having determined f for a given torsion we can calculate the maximum compressive load that may be applied with it, or *vice versa*.

DEEP BEAMS WITH THIN WEBS (TENSION FIELD THEORY).

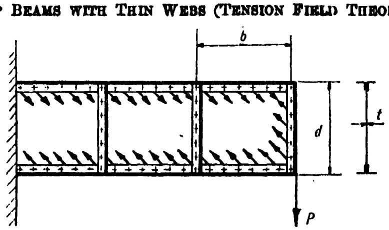

FIG. 46.

In this theory the web is assumed to be incapable of withstanding compression (fig. 46).

Wager, to whom the theory is due, gives the following formula :—

Let f = shear stress in lbs./in.^{2}

F = total vertical shear at section considered in lbs.

Then maximum tensile stress in web $= 2f = \dfrac{2F}{dt}$ lbs./in.^{2}

and is inclined at slightly less than 45° to the flanges.

VERTICAL LOAD ON STIFFENER.

$$P = \frac{Fb}{d} \text{ lbs.}$$

Note that the web being in tension prevents the stiffener failing through buckling as a strut.

FLANGE MEMBERS.

Due to the tension field in the web there is a tendency for the flanges to sag between the stiffeners.

$$\text{Load in flanges} = \frac{BM}{d} + \frac{F}{2} \text{ lbs.}$$

RIVETS CONNECTING FLANGES TO WEBS.

$$\text{Load per rivet} = 1{\cdot}35\frac{Fp}{d}$$

where p = pitch of rivets in ins.

F = vertical shear at section in lbs.

RIVETS THROUGH JOINT IN WEB.

$$\text{Load per rivet} = 1{\cdot}5\frac{Fp}{d}$$

where p = pitch of rivets.

CRITERION FOR A TENSION FIELD WEB.

To determine which of the two types of web are more economical the index figure $\dfrac{\sqrt{F}}{d}$ can be used.

If $\dfrac{\sqrt{F}}{d} < 8{\cdot}32$ a tension field web is demanded, but if $> 12{\cdot}5$ a shear-resistant web is in order. At values intermediate between these the more economical type of design can be determined only by more actual comparison of the two types of beam.

DEEP BEAMS WITH NON-BUCKLING WEBS.

The shear stress which produces wrinkling of the web is—

$$f = \frac{f^2}{3{\cdot}6\,CE}\left(\frac{b}{t}\right)^2 \text{ lbs./in.}^2$$

= ultimate shear stress in lbs./in.^{2}

If b/t is $> 1{\cdot}35\left(\dfrac{CE}{f}\right)^{\frac{1}{2}}$

the shear stress which produces wrinkling of the web is—

$$\frac{0{\cdot}9\,CE}{(b/t)^2} \text{ lbs./in.}^2$$

STIFFENERS FOR NON-BUCKLING WEB.

Intermediate stiffeners must be used when $b > 60t$. The size of these stiffeners can be fixed by the Wagner Equation.

$$\text{Second moment of area of stiffener} = \frac{2{\cdot}3}{t}\,C\left(\frac{Fd}{33E}\right)^{\frac{4}{3}} \text{ ins.}^4$$

where C = distance between centre of stiffener rivets in ins.

FRAMES.

Let L = number of links in structure.

N = number of joints (or nodes).

Then if the structure is to be rigid we have as the minimum number of links possible, the following equations.

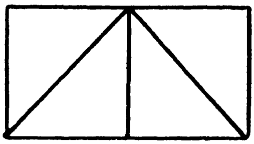

FIG. 47.

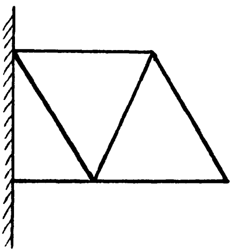

FIG. 48.

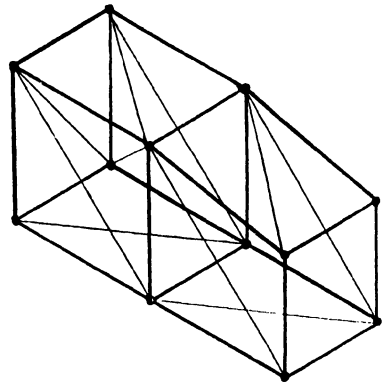

FIG. 49.

Plane Frame (fig. 47), L = 3N − 3.

Plane Frame attached to a solid support (fig. 48), L = 2N.

Space Frame (fig. 49), L = 3N − 6.

Space Frame attached to a solid support, L = 3N.

If a structure has fewer links than required by the above equations the structure is definitely incomplete; but, on the other hand, if the number of links satisfies or even more than satisfies the same equations, it does not necessarily follow that the structure is complete (since one part of a structure may have more links than necessary and another part less).

Structures that have fewer links than is required are called incomplete or deficient.

Structures that are just stiff with the minimum number of links are called determinate.

Structures that have more links than necessary for rigidity are called redundant or indeterminate.

Plane frames should be stressed by the usual method of drawing the force diagram.

Space frames can be stressed by Southwell's method of tension coefficients (see 'Aeroplane Structures' by Pippard and Pritchard).

Redundant frames can be stressed by the application of the Principle of Least Work or Castigliano's Theorems.

Particulars of Various Aeroplanes.

Particulars of various types of aeroplanes are given in Table IV., pp. 433-439.

Throughout this section free use has been made of Reports of the Aeronautical Research Committee for which thanks are due to the Controller of H.M. Stationery Office from whom permission has been obtained.

SECTION XXXI

PART II

AERO ENGINES

Aero engines are internal combustion engines of either the piston or turbine type. The piston engine, both air and liquid cooled, with spark ignition has been the most widely used type to date. Its rival over a long period of years has been the compression ignition engine, but where high power and light weight are required—as they very commonly are—the spark ignition type has always led. The struggle is not yet over but its importance has become less with the rapid advance in recent years of the internal combustion turbine engine (see p. 448). The piston type of aero engine is not likely to survive for powers exceeding 4,000 h.p. and some experts incline to put the figure lower than that.

Because of the conditions of flight, the aero engine has differed from other I.C. engines by reason of the demands for: (1) great power in a single unit; (2) small volume and low head resistance; (3) low weight; (4) great reliability; (5) high power output for a short time at take-off; (6) high percentage of power at high altitude and therefore low air pressure and temperature. Designers have been able to satisfy these conflicting demands to a remarkable degree. Engines developing 3,500 h.p. from 24 cylinders are available.

Piston Engines.

The cylinders of piston engines are arranged either *radially* or *in line*. The *radial* arrangement used only for *air-cooled* types, may have 3, 5, 7, 9, 14 or 18 cylinders with powers ranging from 50 to over 2,000 h.p. Up to 9 cylinders the engine consists of one row but the 14- and 18-cylinder engines consist of two rows with the rear row staggered behind the front row for better cooling.

The radial arrangement is not used for *liquid cooled* engines, these being always in *in-line* banks of up to 6 with the axis of the bank parallel to the direction of flight to reduce head resistance to a minimum. The bank may be arranged with the cylinders vertical and above the crankcase, in which case it is referred to as an *upright* engine, or they may be under the crankcase, an *inverted* engine. This type has the advantage of greater visibility for the pilot. Other ways of arranging the banks are in a 'vee' (usually 60°, upright or inverted) an 'H' (with two crankshafts), a 'double vee' (also with two crankshafts, included angle 150°), or an 'X.'

The *in-line* bank of cylinders may also be used for *air-cooled* engines with either 4 or 6 cylinders per bank. There may be either one, two or four banks arranged in the upright, inverted, inverted 'vee,' 'H,' or opposed flat systems.

Mechanical Efficiency.

Direct determination of mechanical efficiency by the simultaneous measurement of both the indicated and the brake horse-power is not practicable. Accurate phasing is so extremely difficult that any attempt to obtain the indicated mean effective pressure from the card is in practice quite impossible.

The following method is therefore employed: an accurate measurement of the total losses, both friction and pumping losses, is obtained when motoring the engine immediately firing has ceased so that temperature and other conditions are approximately identical to the conditions when the engine is running under its own power. This figure for the losses is then added to the observed brake horse-power of the engine and the sum quoted as the indicated horse-power. The figure obtained for i.h.p. is then used for the determination of the mechanical efficiency of the engine.

The mechanical efficiency of a radia engine is higher than that of an in-line (or vee) type engine as shown in Table I.

TABLE I.—MECHANICAL EFFICIENCY.

Type of Engine.	Mechanical Efficiency.
	Per Cent.
Radial direct drive, normally aspirated	92·0
Radial, geared, normally aspirated	89·5
Radial, geared, fully supercharged	83·0
Vee, direct drive, normally aspirated	89·5
Vee, geared, normally aspirated	87·0
Vee, geared, fully supercharged	80·5

The total losses of an engine may be divided into (*a*) frictional losses, (*b*) pumping losses; typical figures being given in Table II, the losses being expressed as the equivalent brake mean effective pressure.

TABLE II.—SUB-DIVISION OF TOTAL LOSSES.

Engine Speed. R.P.M.	Pumping Loss. Lb. per Sq. In.	Piston Friction. Lb. per Sq. In.	Bearing Friction and Auxiliaries. Lb. per Sq. In.	Total Loss. Lb. per Sq. In.
1,000	2·5	5·5	1·0	9
1,500	4·0	8·5	1·5	14
2,000	5·0	12·0	2·0	19

Thermal Efficiency.

Strictly, thermal efficiency means the efficiency with which the heat actually generated by combustion in the cylinder is converted into mechanical work.

For practical purposes, however, thermal efficiency is taken as the ratio of the heat equivalent of the work done by the engine to the heat supplied or, expressed in another way, as the equivalent of the inverse of the fuel consumption per horse-power. This definition has been standardised in the report of the Heat Engines Trials Committee of the Institution of Civil Engineers wherein the brake thermal efficiency is defined as follows :—

$$\text{Brake thermal efficiency} = \frac{100 \times \text{B.H.P.} \times 2{,}546}{(\text{Calorific value (gross) of the fuel} \times \text{fuel consumption lb. hr.})}$$

The Committee adopted the higher (or gross) calorific value of the fuel as a figure to be used in all calculations, since the gross value is a direct experimental determination whereas the lower (or net) value is the gross value less a quite arbitrary deduction.

The effect of using the gross value on the figure of thermal efficiency is given in the report as follows :—

	Thermal Efficiency.	
	On Net Value.	On Gross Value.
	Per Cent.	Per Cent.
Internal combustion engine	35	32

The calorific values and latent heat of various fuels are given in Table III.

TABLE III.

Fuel.	Specific Gravity at 15° C.	Gross Calorific Value.		Latent Heat of Evaporation. B.Th.U. Lb.
		B.Th.U. Lb.	B.Th.U. Imp. Gal.	
Aviation gasoline	0·704–0·782	19,500–20,100	142,000–152,250	140
Motor benzole .	0·880	18,250	157,000	168
Methyl alcohol .	0·829	9,900	82,100	500
Ethyl alcohol .	0·798	11,800	94,500	406

Standard aviation gasoline to Air Ministry Specification D.T.D. 224 has an average gross calorific value of 20,000 B.Th.U. lb. (net value 18,750 B.Th.U. lb.) and a modern aircraft engine at normal power and speed having a fuel consumption of 0·55 lb. b.h.p. hr. gives a brake thermal efficiency of 22·5 per cent. (or reckoned on the net value of the fuel 24·7 per cent.).

The Ideal Air Cycle.

The efficiencies of the standard engine using air as the working agent and following the ideal constant volume cycle are given in Table IV and the theoretical limits for the thermal efficiency and i.m.e.p. in Table V. These efficiencies are usually used when comparing the efficiencies obtained on test of actual engines.

TABLE IV.—AIR STANDARD EFFICIENCY.

(*Engines of High Output*—H. R. Ricardo.)

The Influence of Compression Ratio in Piston Engine Combustion.

The thermal efficiency is greatly affected by the compression ratio and as a general rule the highest ratio that can be satisfactorily employed should always be used.

The quantity of residual gas left in the clearance space diminishes as the ratio is increased. Since the presence of exhaust gas in the cylinder reduces the rate of combustion, a reduction of the amount left in the clearance space has the effect of increasing the combustion rate. The reduction of the quantity of hot exhaust gas also reduces the rise in compression temperature with increase of compression ratio. The temperature of the residual gas may be taken as 850° C. and the temperature at the end of compression at different ratios after allowing for the proportion of residual exhaust gas, considering the swept volume of the cylinder to be 1 cu. ft., are given in Table VI.

TABLE VI.

Compression Ratio.	Volume Residual Gas at 850° C. Cu. Ft.	Vol. at N.T.P. Cu. Ft.	Vol. of Charge. N.T.P.	Temp. of Mixture before Compression. °C.	Max. Temp. of Compression. °C.

(*Internal Combustion Engine*—D. R. Pye.)

The effect of compression ratio on power, maximum pressure, thermal efficiency and heat to cooling water is shown in fig. 1.

THE TURBINE ENGINE.

As the burning gases in the piston engine are employed to rotate an airscrew so as to produce a large diameter air jet, the dynamic reaction from which propels the aircraft, it is natural to ask whether the burning gases could not produce a suitable jet for this purpose without requiring the intervention of an airscrew. That question has been asked—and answered, largely by the efforts of Sir F. Whittle. The burnt gases from the combustion chamber, with or without an admixture of air, can provide a jet which, though much smaller and much faster than that from an airscrew, will give the necessary thrust for propulsion, and continue to do so at air speeds so high as to embarrass any airscrew, by reason of the latter's grave loss of efficiency when the speed of sound is approached.

For metallurgical reasons there is at present a rather low temperature limit to the cycle of operations, and this leads to the fuel economy of jet-propulsion units being low at speeds of less than 400 m.p.h.; but when the speed rises to 600 m.p.h. the rate of fuel consumption becomes less than that of the piston engine. Greater economy at lower speeds is obtainable by taking much more power out of the turbine than is needed to drive the air compressor, and using the balance to add an airscrew jet to the now reduced one from the exhaust. It must be remembered that the power required by the air compressor is usually far more than the net power produced by the unit, but that since this power flows in a closed circuit the only loss is that due to mechanical inefficiency. Close study of mechanical details is therefore amply repaid.

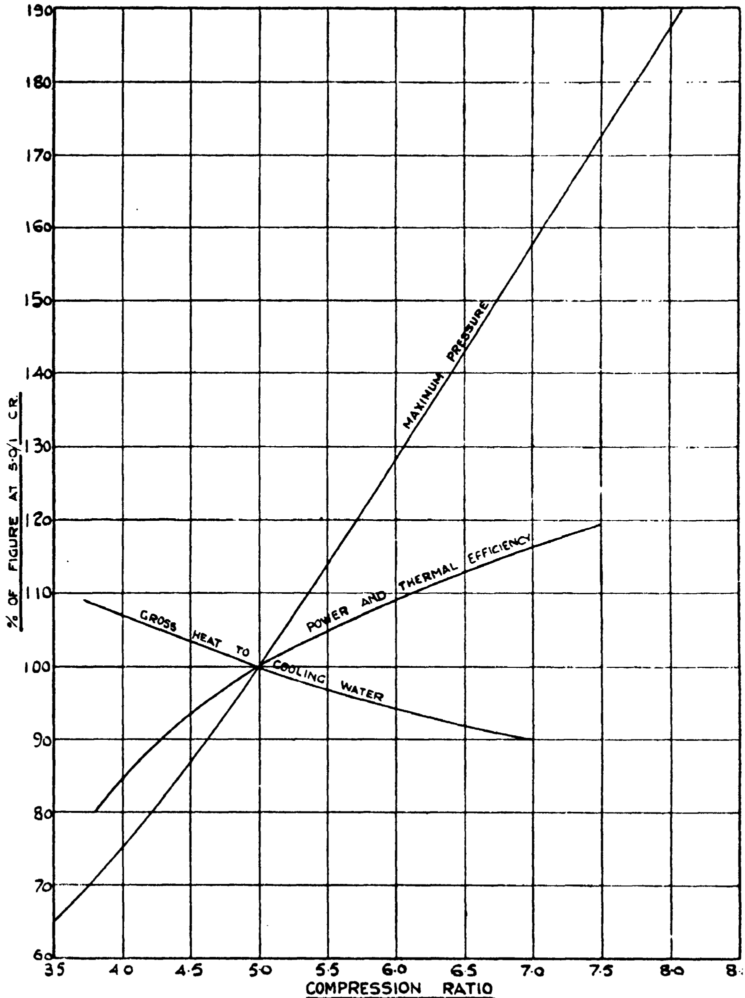
One of the unsolved problems is whether the centrifugal compressor or the axial compressor is the better. Both are in use. The former is easier to design and build but, as the latter leads to a less overall diameter and therefore to lower head resistance, it is likely to be preferred.

The turbine engine normally works on the constant-pressure-cycle, just as the normal piston-engine operates on the constant-volume-cycle, and it might be thought that the same ideal thermal efficiency formula could hardly apply to both. As it happens, however, the same formula does apply to both and is that given in Table IV on p. 447; moreover, the efficiency so calculated is identical with the ratio of the temperature rise on compression to the final compression temperature, a useful result readily applied to the turbine engine, and showing directly the great importance of as high a compression ratio as can safely be allowed.

At present this ratio is limited by metallurgical considerations in turbine and combustion chamber design, consequently the thermal efficiency is lower than that of a piston engine and the fuel consumption higher. The turbine is, however, less affected by high altitudes, and in the jet type has no airscrew to suffer from the effect of an approach to sonic speeds. Hence for very high speed and high altitude work the turbo-jet combination is highly efficient. An intermediate type is the turbine applied to an airscrew drive, and this may become popular for civil transport types owing to the combination of reasonable economy with a welcome freedom from vibration and bothersome noise.

A curious type of which more may be heard in the future is the Ram-Jet Engine (or 'athodyd'). This makes use of the principle that at exceedingly high air speeds the intake air is so effectively

EFFECT OF COMPRESSION RATIO ON POWER, THERMAL EFFICIENCY, MAXIMUM PRESSURE AND HEAT FLOW TO COOLING WATER OF PISTON ENGINES.



(H. R. Ricardo.)

FIG. 1.

compressed by being 'brought to rest' relatively to the aircraft that no mechanical compressor (or turbine for driving it) is needed and the engine consists solely of a combustion chamber and an exhaust jet. It is simple and cheap, and may well prove useful in certain small pilotless aircraft of military type. It is simpler even than the rudimentary flap-type impulse engines fitted to the 'flying bombs' of the 1939–45 war.

Volumetric Efficiency.

There are two ways of considering the volumetric efficiency of a piston engine:—

(a) The ratio of the volume swept by the piston to the volume of mixture drawn in per stroke in the pressure and temperature of the surrounding air;

(b) The ratio of the mixture drawn in per stroke to the quantity that would be contained in the swept volume of the cylinder at N.T.P.

Neglecting the effect of the exhaust gas in the clearance space by definition (b) above

$$\text{Volumetric efficiency} = \frac{273}{\text{Temp. °C. absolute of the induction charge}}$$

In theoretical calculations this definition should always be used, but for practical engine tests the Heat Engine Trials Committee have standardised definition (a) and the volumetric efficiency is calculated as follows:—

$$\left.\begin{matrix}\text{Volumetric}\\ \text{efficiency}\end{matrix}\right\} = \frac{\text{Vol. of inlet air per min. at the temp. and pressure of the engine air intake}}{\text{Total swept vol. of all the power cylinders per min. during the power stroke.}}$$

In addition to the limitations imposed by valve area, valve timing, compression ratio, engine speed and the form of induction system, the volumetric efficiency is dependent on variable factors such as cylinder temperature, latent heat of evaporation of the fuel, mixture strength, and the heat received by the mixture from the induction system. It is therefore difficult to give an average figure, but for a normally aspirated engine the volumetric efficiency should lie between 75 per cent. and 85 per cent.

The *Adiabatic Efficiency* of a blower is the ratio of the power theoretically required for the adiabatic compression of a given weight of air between specified pressure limits to the power input to the air during compression, assuming that no frictional losses occur.

M = Weight of air lb. minute.
J = Joule's equivalent (1,400 ft. lb. per centigrade heat unit).
C_p = Specific heat of air at constant pressure (0·238).
γ = The ratio of the specific heats of air (1·41).
T_1 = Absolute temperature of air (° C.) at intake.
T_2 = " " " " " " delivery.
P_1 = " pressure of air at intake.
P_2 = " " " " " delivery.

$$\frac{J \times C_p}{33{,}000} = 0{\cdot}0101 \quad \frac{\gamma - 1}{\gamma} = 0{\cdot}291$$

Power for Adiabatic Compression.

$$\text{Adiabatic H.P.} = \frac{M \times J \times C_p \times T_1\left[\left(\frac{P_2}{P_1}\right)^{\frac{\gamma-1}{\gamma}} - 1\right]}{33{,}000}$$

Detonation.

Ricardo defines detonation thus: 'The phenomenon of detonation appears to be the setting up in the cylinder of an explosion wave. This occurs when the rapidity of combustion of that portion of the working fluid first ignited is such that, by its expansion, it compresses before it the unburnt portion beyond a certain rate. When the rate of temperature rise due to compression by the burning portion of the charge exceeds that at which it can get rid of its heat by conduction, convection, etc., by a certain margin, the remaining portion ignites spontaneously and nearly simultaneously throughout its whole bulk, thus setting up an explosion wave which strikes the walls of the cylinder with a hammer-like blow.'

Detonation should not be confused with 'pre-ignition,' which is a premature explosion of the charge caused by an excessively hot spot in the cylinder such as a glowing piece of carbon deposit. Detonation is affected by the maximum flame temperature, the compression pressure and the proportion of diluent exhaust gas left behind in the cylinder.

KESTREL XVI (FULLY SUPERCHARGED PISTON ENGINE). ENGINE POWER AT CONSTANT R.P.M. AT ALTITUDES.

FIG. 2.

Aviation Fuel.

Aviation fuel can be divided into two classes: volatile and non-volatile. The former class comprises the petrols and the latter the Diesel oils. Both are composed of a complex mixture of hydrocarbons. Petrol is a distillate of crude petroleum boiling between 140° and 400° F. containing three series of hydrocarbons; paraffins, naphthenes and aromatics. Aromatics are the most desirable, naphthenes next, while the paraffins are worst. Resistance to detonation is the most important characteristic of fuel. An average aviation fuel distilled from petroleum would contain about 50 per cent. paraffins, 30 aromatics and 20 naphthenes. As well as from petroleum, aviation fuel can also be made from coal.

The constant search for methods of improving fuel economy and increasing the power of engines has called for higher compression ratios and greater boost pressures, these in turn necessitating higher resistance to detonation. The 'octane number' of a fuel is a measure of its resistance to detonation and is defined as 'the percentage by volume of iso-octane (2, 2, 4 tri-methyl pentane) in a mixture of iso-octane and normal heptane which matches the fuel in anti-detonation value when tested by the standard C.F.R. Motor Method.'

The demand for high octane fuels has been more than the ordinary distillation products of petroleum could satisfy in quality and it has been found that fuels above 87 octane could best be made by breaking down the petroleum molecule into gaseous hydrocarbons, rebuilding them into high anti-detonation fuels and adding tetra ethyl lead. Experimental work had established the fact that the addition of this substance in small quantities greatly raised the resistance to detonation. The gaseous hydrocarbons may come from gas wells, oil wells, the distillation of crude, or the 'cracking' processes. Fuels may be developed by blending with base gasoline, or using catalytically-cracked or hydrogenated gasoline. Fuels of 90 octane can be made by adding T.E.L. to certain types of aviation base gasoline, but fuel of higher octane must include a blending agent such as iso-pentane or iso-octane. The use of leaded fuels is now almost universal for aero engines, the only ones which do not call for it being some of the smaller engines of about 100 h.p. which are designed to run on first quality unleaded motor spirit of about 70 or 74 octane.

The oil industry has become chemically a most complicated affair in the last ten years and aviation fuel has advanced a long way from being just a distillation product of petroleum. Alkylation is an important modern development. The following are extracts from a paper published in 1941 by H. R. Tate of the Standard Oil Development Company:

'The research laboratories of the oil industry have found that the branched-chain paraffins—iso-paraffins—more nearly approach the ideal aviation fuel than any type of hydrocarbons occurring in crude oil or capable of being synthesised in large volumes from refinery raw materials. The iso-paraffins in the aviation gasoline boiling range are characterised by high calorific value, high clear octane numbers, good lead susceptibility, excellent chemical stability, and freedom from gum deposition in storage or in the induction system of aircraft engines. The classic example of iso-paraffins is iso-octane, the primary reference standard for octane ratings. Blends of technical iso-octane and straight-run or hydrogenated gasolines in the form of 100 octane fuels have been produced in increasing quantities. In 1937 approximately 170,000 barrels of 100 octane aviation gasoline were produced and it is estimated that by the end of 1940, the yearly production of such fuels containing iso-octane will reach 4 or 5 million barrels.

'Oil technologists were not content with the cold and hot sulphuric acid and other polymerisation processes for making technical iso-octane . . . Research was therefore directed toward the coupling of the olefin with an iso-paraffin to produce a branched chain, saturated paraffinic compound. Previous work had shown the possibility of this direct coupling—alkylation—by means of metallic halide catalysts, but the catalyst costs were too high. The research staffs . . . worked out processes whereby the coupling . . . was effected by the catalytic action of sulphuric acid. The alkylation process is a commercially-proven method. . . . Nineteen commercial plants are in operation in U.S.A. . . . The total output is approximately 6,800,000 barrels per year of aviation alkylate.

'Present indications are that 100 octane is not the ceiling for high-output engines. Fuels of over 100 octane can readily be made from butene alkylates plus moderate concentrations of T.E.L. The 300° F. end-point butene alkylates with 3 c.c. T.E.L. per U.S. gal. have octane numbers well over 100 (one example being equivalent to iso-octane plus 0·52 c.c. T.E.L. per U.S. gal.).'

A typical 100 octane fuel made from butene alkyate blending agent and a 74 octane straight-run gasoline shows end points of 105° and 270° F. The amount of alkylate required varies from 50 to 70 per cent. depending on the octane rating of the base. (The octane rating used in U.S.A. is determined by the A.S.T.M. method or the Army method. In the above extracts from the paper, the rating is A.S.T.M.)

During the year 1939, before the outbreak of war, 87 octane fuel (DTD 230) was the standard for British military engines in combat aircraft, but some squadrons were operating experimentally with 100 octane. During 1940 the Merlin-engined Spitfire and Hurricane fighters used 100 octane exclusively. As the war went on, bombers started to use it for take-off and, though no official statement has been made, it is likely that more and more extensive use was made of it for continuous operation.

TABLE VIII.

Fuel Specification.	Octane No. C.F.R. British Air Ministry Method.	Engine Output. B.H.P. Litre.	Engine Weight. Lb. B.H.P.	Fuel Consumption. Lb. B.H.P. Hr.
D.T.D. 134	73	20·5	1·76	0·55
D.T.D. 224	77	22·7	1·58	0·53
D.T.D. 230	87	28·0	1·29	0·49
—	100	35·0	1·05	0·45

A usual fuel for air transport use is 87 octane, though it is likely that higher quality will be used in increasing proportion in the immediate future.

Fuel quality affects power very much. By changing from 87 to 100 octane fuel, the take-off power of the Merlin X was raised by 20 per cent. On a Merlin II the B.M.E.P. of 165 lb./sq.in. with 87 octane could be raised to 205 with 100 octane.

Ethyl Fluid.

Tetra Ethyl Lead $Pb(C_2H_5)_4$ has the following characteristics:—

Specific gravity at 20° C.	1·659
Boiling point	200° C. (with decomposition)
Freezing point	− 156° C.

The ethyl fluid at present used for aviation purposes is known as '1.T.Mix' and is coloured blue. It has the following composition:—

Tetra ethyl lead $Pb(C_2H_5)_4$	61·42 per cent. by weight.
Ethylene dibromide	35·68 „ „ „ „
Dye	0·17 „ „ „ „
Kerosene and impurities	Balance
Specific gravity of fluid at 20° C.	1·755

The proportion of T.E.L. in ethyl fluid, by volume, is 65·5 per cent.

Ethyl fluid is completely soluble in petrol and will not separate out under any normal storage conditions. Some idea of the value of tetra ethyl lead in suppressing detonation will be gathered from the fact that the addition of the first cubic centimeter (1·0 c.c.) to a gallon (4,545 c.c.) of petrol can increase the anti-knock value of that petrol by as much as 15 octane numbers, the actual amount depending on the characteristics of the particular petrol. The maximum allowable concentration of lead in any fuel for commercial purposes is limited to 3·6 c.c. per Imperial gallon although for military or other government purposes this limit is raised to 7 c.c. Imperial gallon. The addition of lead to petrol does not sensibly alter any of the characteristics of the spirit and the lead has no effect until combustion commences.

In quoting the concentrations in a petrol it is always the amount of tetra ethyl lead that is given and not the amount of fluid, since it is the lead that is the active anti-knock agent. Although tetra ethyl lead is poisonous, in its diluted state in petrol there is no danger whatever, and fuels containing lead up to the maximum permitted concentration can be handled in the same manner as ordinary petrols.

Fuel of High Flash Point.

Research has been directed towards developing a fuel of high flash point in order to reduce fire risk after accident. This has been loosely called 'safety fuel.' Such fuels have been produced with boiling points in the 300° to 425° F. range and flash points of 110° or 115° F. The heating value and anti-detonating qualities approximate to those of normal fuels; octane ratings up to and greater than 100 have been attained in them. High flash fuels may be of the aromatic type or branched-chain paraffins.

Vapour Lock at High Altitude.

Boiling of the petrol with the formation of vapour lock in the fuel system is one of the problems which high altitude flight brings in its train. Reduction of the atmospheric pressure at altitude

allows the fuel to vaporise at much lower temperatures than at sea-level pressures. To combat this it is necessary to use a fuel with a low vapour pressure, increase the pressure within the fuel tank, or keep the temperature of the fuel low. The first method is not promising as an auxiliary fuel of high vapour pressure would be required for starting and also because high octane fuels with low vapour pressure are not readily available.

The pressure inside the tank could be increased by applying a supercharge pressure or by 'self-supercharging.' This consists in closing the tank vent just after the fuel has started to boil and so generating a pressure which prevents it boiling at any higher altitude. With a fast-climbing fighter, the tankful of fuel does not cool as quickly as the aeroplane climbs, and this is very conducive to vapour lock. If no other steps are taken to prevent vapour lock, it may be necessary to cool the tank contents on the ground but so far this has not been attempted.

With a fuel of 7 lb./sq. in. Reid vapour pressure if the aeroplane left the ground at 38° C. and the fuel did not cool, boiling would start just below 20,000 ft. With a supercharge pressure on the tank of 4 lb./sq. in., boiling could be prevented up to 40,000 ft.

Cold Corrosion.

When engines are stored subsequent to running on leaded fuels, serious corrosion of the stee cylinders has, in certain circumstances, been found to occur. This corrosion varies with the absolute humidity of the atmosphere, and is therefore much more prevalent under tropical conditions.

A large number of compounds have been tested as inhibitors of this corrosion by the Ethyl Gasoline Corporation, and the following mixture, known as E.G. 174, has been found to be effective in all conditions:—

	Per Cent.
Commercial triethanolamine	5
Aluminium stearate	10
Normal butanol	10 to 12
Lard oil (3½–7½ per cent. free acidity as oleic acid)	Balance

The mixture is somewhat difficult to manufacture as it tends to be unstable and throws down solids unless manufactured with care. It can be obtained commercially.

High Temperature Liquid Cooling.

The outlet temperature of a normal water-cooled engine is limited by the boiling point of water, and when flying at about 5,000 feet this means a limitation to about 80° C. The rate of heat dissipation depends on the temperature difference between this outlet temperature and the temperature of the surrounding air. A comparatively small temperature difference means that a large radiator has to be used which imposes a substantial 'cooling drag' and anything that can be done to increase the value of the temperature difference will obviously reduce this drag since the necessary dissipation of the waste heat will be obtained from a smaller radiator.

In order to increase the temperature difference, high boiling-point liquids are now being used, and of these ethylene glycol is the most important. The characteristics of this liquid are given in Table IX.

TABLE IX.

ETHYLENE GLYCOL $C_2H_4(OH)_2$.

Density at 25° C.	1·11
,, ,, 100° C.	1·05
Viscosity at 25° C.	17·0
,, ,, 100° C.	0·020
Specific heat	0·675
Boiling point °C.	178
Freezing point ° C.	−17
Flash point ° C.	124
Latent heat at 100° C. . . .	240

The heat transfer coefficient of water is approximately 4·7 times that of ethylene glycol.

With the use of glycol in the engine jackets the actual metal temperatures increase not only due to the higher liquid temperatures employed, but also due to the relatively poor heat transfer

of glycol compared to water and to the much lower evaporative effect which, when water is in use, serves to safeguard any 'hotspots' in the cylinder or head. The use of glycol therefore introduces serious difficulties in engine design and the greatest care must be taken to provide adequate liquid flows and velocities if cracking and distortion of the engine structure are to be avoided. It is usual to limit the outlet temperature of the glycol to not more than 120° C. to 130° C., since experience has shown that an appreciable margin between the maximum temperature reached by the liquid and its boiling point must be maintained if trouble with hotspots in the engine is to be avoided.

The increase in the temperature difference, however, in a glycol cooled system does permit a much smaller radiator being used with an appreciable increase in aircraft performance, particularly at high flying speeds.

Evaporative Cooling.

In evaporatively cooled systems the circulating water is introduced into the cylinder jackets at the boiling point at any altitude, boiling being prevented by maintaining a pressure in the jackets and also by ensuring that the rate of circulation is kept high. The steam separator is at atmospheric pressure, and from here the water is returned to the engine and the steam led to the condenser where its latent heat is dissipated and the condensate returned to the cylinder An engine, the Rolls Royce Kestrel, has passed an official type test evaporatively cooled, and certain types of aircraft installation flew successfully in the 1930 decade.

On older types of machines of comparatively low wing loading, sufficient surface is available for the condensers and, therefore, almost dragless cooling is achieved, but the general performance of these machines is so low by modern standards that the complete elimination of cooling drag effects comparatively little improvement. In modern high performance aircraft the surface available for cooling is not only very limited but also very difficult to reach from the engine which involves serious complications in the system. Since there is almost no reduction of cooling drag if the steam is condensed in a conventional honeycomb radiator the evaporative cooling system cannot be considered promising for modern high performance aircraft, and no engines employing this system are at present in use in this country.

Pressure Cooling.

Pressure water cooling is a later way of obtaining a small radiator surface through the use of a high temperature coolant in the liquid form, the boiling point of water being raised by subjecting it to pressure. Water is a better coolant than glycol because : (1) Its viscosity is lower, its latent and specific heats are higher and its heat-transfer coefficient greater ; (2) it has less tendency to 'creep' through joints ; (3) it is more easily obtainable in an emergency than glycol.

A 30 per cent. solution of glycol is recommended so that freezing does not occur on the ground or during a glide with engine off. A pressure-cooled system is similar in all respects to a water-cooled system with the addition of a spring-loaded double-acting relief valve instead of a vent on the header tank. With an open vent the drop in boiling point with a 30 per cent. solution from sea level to 12,000 ft. is 12·5° C. but with a relief valve set to 15 lb./sq. in. above atmospheric the drop is only 6·5° C. At 25 lb./sq. in. it is 5° C. A pressure-cooled system is affected by altitude changes to a less degree than an open one. A maximum pressure of 20 lb./sq. in. is needed to give the same area radiator as for a glycol-cooled installation with an outlet temperature of 130° C.

Controlled Cooling.

Radial air-cooled engines are cowled with a cowling of the NACA or Townend ring type. The engine may develop its maximum power either at its maximum forward speed, or at a very low forward speed as in the take-off or climb. So if the cowling is designed for the former case, the engine is liable to overheat in the latter. It has therefore been found necessary to control the flow of air by means of 'gills' on the exit of the cowling. These restrict the exit during high speed flight and may be adjusted to give the correct amount of cooling air for any condition. A cooling fan may also be used.

The radiator of the *liquid-cooled* engine is enclosed in an air duct so designed that the stream of air is slowed down to about one-third of its velocity just before going through the cooling tubes. After emerging from these tubes the air increases in velocity by reason of the duct narrowing and it is speeded up to its original velocity as nearly as possible so that it emerges again into the main stream with a minimum of turbulence. This procedure is necessary in order to reduce cooling drag as the increasing speed of aircraft was making cooling very expensive in terms of drag.

The heat which is imparted to the air stream as it goes through the tubes causes it to expand and so increases its velocity. This sets up a 'jet effect' which gives a forward thrust tending to reduce the drag of the cooling system. This effect becomes increasingly important with increase in forward speed of aircraft and it may be that, with speeds somewhat over 400 m.p.h., cooling will be accomplished without drag.

Air Cooled v. Liquid Cooled.

Though in the smaller sizes, up to about 400 or 500 h.p., the air-cooled engine seems to be established to the exclusion of the liquid-cooled, in the larger sizes the struggle still continues and engines of both types are in everyday use. U.S.A. has concentrated most on air-cooled, while German and British development has been in both types.

The liquid-cooled has smaller head resistance, but its cooling system adds complication; therefore it has been widely adopted in fighters and not widely adopted in airliners. It might seem that engines of greater power could be built as liquid-cooled units for it is difficult to see how more then 18 cylinders could be arranged radially and cooled by air. The air-cooled engine has the advantage in weight per h.p. as reference to Table XI shows, but at full throttle the liquid-cooled has a better fuel consumption. This advantage, however, does not hold so much at cruising conditions. Power required to cool the engine is approximately equal for the two types at about 3 per cent. of take-off power, though for the most modern types it is more like 2 per cent. From this brief summary it will be seen that neither type has a clear cut supremacy over the other in the larger sizes of engine from 500 to 1,500 h.p.

Installation Weights.

The following weights per h.p. of engine and installation come from a paper published in 1941 by John G. Lee, of United Aircraft Corporation. They refer to the larger size of aero engine in about the 800 to 1,200 h.p. range.

TABLE X.—ENGINE INSTALLATION WEIGHTS.

	Air-cooled.	Liquid-cooled.
Weight of engine installation:		
Airscrews and controls	0·302 to 0·320	0·302 to 0·320
Starting system (less batteries)	0·020 „ 0·045	0·020 „ 0·045
Engine mounting	0·045 „ 0·080	0·045 „ 0·080
Cowling	0·063 „ 0·100	0·063 „ 0·100
Oil system (including tanks)	0·040 „ 0·060	0·040 „ 0·060
Fuel system (less tanks)	0·020 „ 0·040	0·020 „ 0·040
Exhaust system	0·027 „ 0·040	0·027 „ 0·040
Radiators and coolant	— —	0·275 „ 0·300
Miscellaneous (ducts, controls, etc.)	0·015 „ 0·040	0·015 „ 0·040
Total normal installation weight	0·532 „ 0·725	0·807 „ 1·025
Dry weight of engine	1·26 „ 1·35	1·10 „ 1·26
Engine and installation—lb. per h.p.	1·792 „ 2·075	1·907 „ 2·285

Other items. Intercoolers and ducts may weigh 0·090 to 0·095 lb. per h.p.; turbo-superchargers, 0·109 to 0·132.

Supercharging.

The power of an engine falls off with decrease of atmospheric density since the quantity of charge entering the cylinder each stroke is proportional to the density. So the power of an aero engine falls off with increase of altitude unless it is supercharged.

Supercharging consists in fitting the engine with a pump which forces the explosive charge into the cylinders under a pressure greater than atmospheric. Superchargers were first fitted in order to maintain sea-level power at altitude but they were soon used to increase sea-level power by

increasing the manifold pressure above sea-level atmospheric pressure. Take-off powers with a manifold pressure of 6 lb. per sq. in. and more are now quite common.

Superchargers may be divided into two main types: the centrifugal blower and the positive displacement blower (the Roots type and the vane type). As far as modern aero engines are concerned, the centrifugal supercharger is fitted to the exclusion of all other types. It may be gear-driven from the engine, driven by a fluid drive or driven by a turbine run by the exhaust gases. Before 1941 no exhaust turbo-supercharger had been put into production and all superchargers had been gear-driven.

The centrifugal supercharger consists of a rotating impeller (running at speeds which may be between 15,000 and 25,000 r.p.m. in different engines); a casing which encloses it and contains diffuser blades; and a collector duct. The air enters at the impeller duct and is given a very high tangential velocity by the impeller. As the air passes through the fixed diffuser blades the kinetic energy is converted into pressure energy.

A supercharged engine is designed to deliver its maximum power at a certain altitude referred to as its 'rated altitude.' This is, of course, full throttle power; above this altitude the full throttle power falls off just as for an unsupercharged engine. Below the rated altitude full throttle cannot be used as it would result in a manifold pressure being built up which would be too great for the engine. (It might be too great because it would cause detonation or because the power developed would be too great for the structural strength of some of the parts or because the cooling system could not deal with the excessive quantity of heat generated.) So below the rated altitude the engine must be throttled to keep the manifold pressure to the maximum allowable. This results in the sea-level power usually being less than the power at rated altitude.

Owing to the power taken to drive the supercharger and due also to the fact that there is a rise in temperature of the air during compression, a supercharged engine at its rated altitude delivers at the same crankshaft speed and manifold pressure less power than a similar unsupercharged engine at sea level, although this loss in power is offset by the gain due to the increase of the difference between the exhaust back pressure and the induction manifold pressure at altitude. A supercharger capable of maintaining sea-level power at 12,000 ft. absorbs nearly 5 per cent. of the engine power on the ground.

The use of a take-off power, higher than the maximum continuous rated power at sea level, is allowed on the strict condition that it is only permissible for a short time, usually one or three minutes. For such a short time only can the engine deal with the greatly increased heat flow.

The first type of supercharger developed was geared to the engine through a train of gears causing it to run at several times engine speed (modern engines have ratios varying between 6 and 12). The higher the rated altitude of the engine, the greater would be the excess manifold pressure at sea level if the throttle were opened wide. So, for high-rated engines it became very desirable to run the supercharger slower at sea level to reduce the waste of power due to throttling. This called for a *two-speed supercharger*, necessitating a two-speed gearbox between engine and supercharger the lower supercharger speed being used at low altitudes.

High rated altitudes also called for another development, that of the *two-stage supercharger*. There is a limit to the pressure difference which it is efficient to handle in one compression stage, and as the increase of temperature in the compressed charge becomes very great it is necessary also to have an intercooler between the two stages.

The *exhaust turbo-supercharger* has been recognised for many years as the most desirable because the pressure-difference driving it (and therefore the power absorbed by it) is lowest at sea level and increases with altitude. Also it utilises some heat energy of the exhaust, much of which would otherwise be wasted. But the practical difficulties of making a turbine which would stand up to the very great temperatures of the exhaust gases has prevented this type appearing in production until 1941. But the Wright Cyclone engines of the high-altitude bomber, the Boeing Flying Fortress, have turbo-superchargers which have been developed by the General Electric Company in U.S.A. The exhaust turbo-supercharger is able to maintain sea-level power to a higher altitude than any other type and this is evident from the following extracts from a 1940 paper by Erold Pierce of the Wright Aeronautical Corporation:

'The two-speed supercharger rather falls by the wayside when any considerable altitude performance is desired. . . . For operation at 20,000 ft. or higher at rated power the two-speed engine (supercharging without intercooling) is entirely inadequate. . . . Below 25,000 ft., it would appear that the method of supercharging will depend upon the critical altitude for which operation is desired. In the range from sea level to 15,000 ft., the two-speed engine has the field almost to itself because of installation simplicity coupled with maximum power for take-off and reasonable power output at altitude. Above 15,000 ft. the choice of two-stage or turbo depends upon installation complexity and the availability of equipment. The increased power output of the turbo-supercharged engine compared with that of the two-stage engine appears most desirable and worth considerable installation complication.' Above 25,000 ft. he indicates that the exhaust turbo-supercharger is supreme.

Exhaust Valves.

The power developed by aero engines in production in 1941 exceeded 100 h.p. per cylinder and the exhaust valve had to be made capable of dealing with very great heat flows because of the exhaust gas being at temperatures of 850° or 1,000° C. Steels have been developed which are capable of continuous work at over 850° C., these temperatures being encountered in truck engines, but due to refinements in design aero engine valves can be kept down to a maximum of about 700° C. Typical exhaust valve temperatures are shown in fig. 3. Valves can now be obtained which have a life of over 5,000 hours in engines which have maximum r.p.m. of 3,000 and B.M.E.P. of 200 lb. per sq. in.

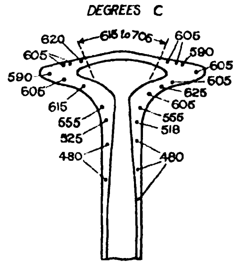

FIG. 3.—Exhaust Valve Temperatures.

This is due to three major developments: sodium cooling; development of the one-piece forging technique giving the hollow-head valve; and advances in cylinder head design. Three minor developments also contribute: use of austenitic steels; substitution of austenitic steel for bronze in the seat insert; and use of stellite facing on the valve seat.

Sodium is used in the hollow stem of the valve because it is a good conductor of heat, wets steel, is light, has no vapour pressure at operating temperatures, and melts at a low temperature (97·5° C.). Its boiling point is 880° C. and its heat conductivity about 9 times that of austenitic valve steel. Specific gravity is 0·95. In smaller valves 60 per cent. of the hollow space is filled with sodium, so allowing it to splash about and conduct heat from the crown to the stem and so to the valve guide. In larger valves 40 or 50 per cent. of the cavity is filled. Care must be taken in filling that the sodium is not contaminated, as any oxide of sodium will attack the steel. Before filling, the interior is carefully hand-polished to remove all scratches to prevent the start of fatigue cracks. After filling the end of the stem is swaged closed.

Improvements in forging technique have done much to reduce valve failures by keeping the grain of the metal in the right direction and much more is now known about valve shape design. The provision of a 'button' onthe crown of the valve is no longer good practice as it concentrates stress. Valve stems are usually nitrided and honed, with a tip of cobalt-chrome welded on the end. Such valves can handle 130 h.p. each. In marking valves no stamping is permissible as it may start a fatigue crack; only the electric pencil is allowed and only curved lines, no straight ones. Marking is done near the tip.

Austenitic steels have been adopted for exhaust valves because they have a high hot strength, good corrosion resistance and high impact value. KE 965 and TPA are two such steels. Their analyses are:

	C.	Mn.	P.	S.	Cr.	Ni.	Si.	Mo.	W.
KE 965 .	·35–·50	1·5 max.	—	—	12–16	10 min.	1–2·5	—	2–4
TPA .	·40–·50	·70 max.	·03 max.	·025 max.	13–15	13–15	·30–·80	·50 max.	1·75–3

Bronze seat inserts have been superseded for high-output aero engines by steel seats because of corrosion and loosening. It is necessary that the material of the insert have a high coefficient of expansion approximating to that of the aluminium alloy cylinder head so that loosening will not occur and so that the contact between the two will facilitate heat flow. The Firth NMC steel has a good resistance to corrosion and scaling at high temperature, is very tough and 'work

hardens' to a high degree. Other insert steels are Silcrome No. 9 and TPA. Their analyses follow:

	C.	Mn.	P.	S.	Cr.	Ni.	Si.	Mo.	W.
NMO	·5–·6	5·0	—	—	3·5	12	·5	—	—
Silcrome No. 9	·40–·50	·7 max.	·03 max.	·03 max.	13–15	13–15	2·75–3·25	·50 max.	1·75–3·0
TPA	·40–·50	·7 max.	·03 max.	·025 max.	13–15	13–15	·3–·8	·50 max.	1·75–3·0

The coefficient of expansion of NMO steel between 200° and 300° C. is 0·0000223.

Differential seat angle is a feature of modern design. To allow for changes of shape due to heating, the included angle of the valve face is made 1° greater than that of the faces of the insert.

Stellite is a material which has a very high degree of hot hardness and resistance to corrosion. It is used widely all over the world for facing both valves and inserts. Consisting largely of chromium and cobalt, Stellite No. 6 has this composition: C, 1·2; Cr 26·7; Si 2·7; W, 4·0; Co, 65·0 per cent. Another material, Brightray, is also used for the same purpose, this having the composition: C, 0·27; Cr, 19·75; Ni, 76·4; Fe, 2·2; Mn, 1·77 per cent.; with small amounts of others.

Stellite or Brightray is applied by oxy-acetylene flame to the valve or insert surface by a 'puddling' process which is more of a high temperature brazing process than a welding process. The melting point of Stellite is about 1,270° C.

In general, American design conforms to two valves per cylinder whereas both Rolls-Royce and Bristol have four, which of course leads to smaller size valves. The two-valve design leads to less complicated valve gear. A typical Bristol exhaust valve is made of KE 965 steel, sodium-cooled with 40 per cent. of the stem cavity filled with sodium. The small size of the valve prevents

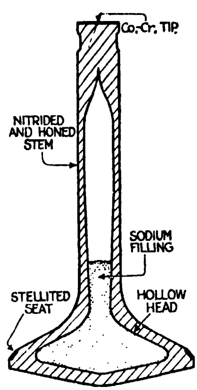

FIG. 4.—Cross Section of Modern Hollow-head Exhaust Valve

the adoption of a hollow head. The seat has ·040 in. of Stellite and the head of the valve has ·020 in. of a material similar to Brightray. American practice does not generally Stellite the seat inserts as they claim that Stellited valves work equally well with inserts with or without Stellite on them. Stellited inserts are common European practice. The most modern aero engines have enclosed valve gear and forced lubrication.

Cleaning Exhaust Valves.

To remove lead deposits and scale from the heads of exhaust valves after they have been in service, a method has been developed by the Ethyl Gasoline Corporation. This consists in electrolysing a fused mixture of 60 per cent. sodium hydroxide and 40 per cent. anhydrous sodium

carbonate by weight, using the valve to be cleaned as cathode. To prevent any reaction between oily material on the valve and the electrolyte, the valve must first be cleaned by heating in a flame or washing in petrol. The salt is maintained at from 430° to 480° C. by a burner or electric heat and a current of one-half ampere passed from a 6-volt storage battery. Time of immersion depends on the thickness of the deposit, but 10 minutes is usually sufficient, after which the valve is easily wire-brushed.

Inlet Valves.

Inlet valves do not have to operate at such high temperatures as exhaust valves, as shown in fig. 5. It is therefore not general practice to have them sodium-cooled, though this is occasionally

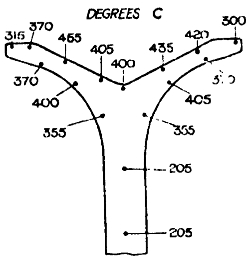

FIG. 5.—Inlet Valve Temperatures.

done. The hollow stem is general, however, for reasons of lightness, but the hollow head is not necessary. As well as KE 965 and TPA, other steels used are SAE 7260 and Silcrome No. 1 of the following composition :

	C.	Mn.	P.	S.	Cr.	Si.	W.
SAE 7260 . .	·5–·7	·3 max.	·035 max.	·04 max.	·5–1·0	—	1·5–2·0
Silcrome No. 1 .	·4–·5	·2–·6	·02 max.	·02 max.	8–9	3–5	—

It is both British and American practice to use aluminium bronze for the material of the inlet valve seat inserts. This has the composition of Cu, 89 ; Al, 10·5 ; Fe, 0·50 per cent. American valve guide material is a bronze consisting of Cu. 80 to 86 per cent. ; Al or Sn, 10 to 11 ; and other constituents.

Crankcases.

Crankcases may be made of alloys of aluminium or magnesium or, a new development for radial air-cooled engines in U.S.A., of steel. The small in-line air-cooled engines with powers up to about 200 h.p. frequently have crankcases of Elektron or other cast magnesium alloy. Larger engines, both in-line and radial, usually have crankcases of aluminium alloy. Two alloys suitable for casting are RR 50 and RR 53. Radial engine crankcases can also be made as forgings in two pieces out of aluminium alloys. But in U.S.A. forged aluminium alloy crankcases are going out of favour and it has been found that a steel crankcase can be made of the same weight. This has the advantage of higher fatigue strength and better strength at high operating temperatures.

Pistons and Piston Rings.

Pistons are die or sand castings or forgings of aluminium alloy and a late development in piston design to aid cooling is to have 'stalactites' of metal projecting downward from the crown of the piston. Piston speeds have increased greatly from figures such as 1,700 ft. per min. in 1921 to 2,600 in 1939. Now piston speeds of 3,000 ft. per min. in both air- and liquid-cooled engines are in common use. Hottest part of the piston is the centre of the crown and this can reach 300° or 350° C. in modern designs. Maximum gas pressure loads usually lie between 450 and 550 lb. per sq. in. Aluminium alloys frequently used are RR 53 and RR 59, and Y alloy. These contain Cu, Mg, Si, Ni, Fe.

Piston rings are of cast iron and the latest development is to coat them to reduce scuffing. Wear can be reduced by half by a plating of tin or a coating of iron oxide or phosphate or ferrous

sulphide. A usual design is to have three compression rings at the top of the piston and an oil control (scraper) ring at the bottom of the skirt. In the latest Wright 'Uniflow' design, the piston has five upper rings and one lower, this one being 'inverted' to act as a pump, so giving a good oil supply to the skirt. The oil thus pumped is conducted away through drainage holes to the inside of the piston. Oil consumption is reduced by this design.

Cylinders and Cylinder Heads.

Cylinder heads of both air- and liquid-cooled engines are of aluminium alloy such as RR 50 or RR 53 (for sand casting) or Hiduminium 59 or Y alloy (for forged and machined heads). Aluminium alloy is necessitated both for lightness and good heat conduction. Temperatures in an air-cooled head may range from 375° C. (exhaust valve seating) down to 100° C. Corresponding temperatures for liquid-cooled are 350° and 100° C. Adequate finning is most important to ensure cooling and advances have been made both in design and in casting technique to enable the very high power of the modern cylinder to be developed.

The barrels of air-cooled cylinders are usually machined from hollow forgings of Ni-Cr-Mo steel (DTD 228) suitable for nitriding for hardness to minimum value of 600 Vickers diamond. Connection between the barrel and the head is usually by screwing and shrinking, though the head may be held to the crankcase by long steel bolts.

The barrel of a liquid-cooled engine such as the Rolls-Royce Merlin is of high carbon steel and is of the 'wet' type, that is, is in contact with the coolant. A liquid-tight joint is made at the bottom with a rubber ring and a gas-tight joint at the top with soft aluminium. The assembly is held together with long bolts. A design with 'dry' cylinder liner may also be adopted.

Cylinder blocks for both types are of aluminium alloy castings such as RR 50.

Bearing Metals.

In early designs of aero engines the common bearing material, a tin base babbitt, was used but this has been superseded in high output engines by copper-lead and more lately still by cadmium-silver. Work is proceeding on the use of aluminium-tin alloys.

Tin base babbitt can be used up to a maximum permissible unit pressure of 1,000 lb. per sq. in. for standard quality bearings and 1,500 for higher quality. The maximum PV (rubbing factor) should not exceed 32,000 and 42,500 respectively; oil reservoir temperature 235° F. Composition: Sn 89, Sb 7·5, Cu 3·5, Pb 0·25 max. per cent.

High lead babbitt can be used up to 1,800 lb. per sq. in. with a maximum PV of 40,000 and oil reservoir temperature of 225° F. Composition: Pb 82 to 86, Sb 9 to 11, Sn 5 to 7, Cu 0·25 max. per cent. With both the babbitts minimum crankshaft hardness is not important.

Copper-lead can be used over 1,800 lb. per sq. in. with a maximum PV of 90,000 and upwards and oil temperature of 260° F. Composition: Cu 60, Pb 40 per cent. Minimum crankshaft hardness, 300 Brinell.

Cadmium-silver can be used over 1,800 and up to 3,850 lb. per sq. in. with maximum PV 90,000 and oil temperature of 260° F. Composition: Cd 98·75, Cu 0·50, Ag 0·75 per cent. Minimum crankshaft hardness, 250 Brinell.

Spark Plugs.

The conditions under which spark plugs have to operate have been constantly increasing in severity, particularly due to the use of leaded fuel, the increase of cylinder head temperature and the enclosing of the plug in a metal cover to 'screen' it. As mica is attacked by the products of combustion of leaded fuel, mica plugs are now superseded for high duty engines by ones with an insulating body of sintered aluminium oxide known as 'sinterkorund' or 'sintox.'

Sleeve Valve Engines.

The Bristol Aeroplane Co. has led the world in the development of the sleeve valve aero engine and has a range of air-cooled radials of various powers. These engines have a single sleeve which both rotates and reciprocates.

Advantages claimed for the sleeve valve design are:

1. By the elimination of the exhaust valve a 'hot spot' is removed, so enabling a higher compression ratio to be used (in some cases up to one unit higher) with fuel of the same octane rating.

2. A flatter consumption 'loop' is possible without running into troubles often associated with poppet valves at weak mixtures.

3. Its volumetric efficiency at high speeds is better than that of the poppet valve because its 'breathing' is better.

DART	Rolls-Royce	Turboprop.	7	Centrifugal	Two-stage	1,000 shaft h.p. + 310 lb. thrust	14,500

4. It allows a much neater design than the poppet valve, particularly for the cylinder head, and the number of moving parts is smaller.

5. It is less susceptible to the troubles resulting from the use of leaded fuel and needs less maintenance between complete overhaul periods. (The poppet valve engine continues to make advances and is little if any behind the sleeve valve in these respects.)

Compression Ignition Engines.

The compression-ignition engine, properly developed, can have several advantages over the petrol engine. These are: (1) reduced fire hazard; (2) lower fuel consumption, which gives either greater range with the same payload or greater payload for the same range; (3) lower cost of fuel per gallon and, even more so, per mile; (4) absence of ratio interference due to ignition system; (5) absence of carbon monoxide in the exhaust gases; (6) freedom from carburettor icing.

The engine does not operate with the typical Diesel cycle of constant-pressure combustion but has a highly peaked indicator diagram rather like that of the spark-ignition engine. It should therefore not be called a Diesel engine but simply a 'compression ignition' engine. A comparison of the pressures in C.I. and S.I. engines (quoted by Maleev) follows:

	C.I.	S.I.
Compression ratio . . .	15	7·5
Maximum combustion pressure .	1,450 lb. per sq. in.	880
Mean effective pressure . .	112 „	135

The higher combustion pressure necessitates larger dimensions for some of the parts, thereby making the engine heavier. S.I. engines are now close to 1·0 lb. per h.p. at take-off, but C.I. engines are not likely to be less than 40 or 60 per cent. heavier. So their advantage in lower specific fuel consumption is offset by heavier engine weight.

Petrol Injection.

Petrol injection was adopted whole-heartedly by Germany just before the start of the war in 1939 and her combat types of aircraft were fitted with petrol injection systems instead of carburettors. There was one pump for each cylinder and this supplied the petrol to the cylinder through an injection nozzle. Advantages claimed for petrol injection are these: (1) more accurate metering of the fuel to each cylinder so giving better distribution and better specific fuel consumption. (2) A fuel of lower volatility can be used. (3) The system is free from the deposition of ice such as can occur in a carburettor. (4) Accelerations caused by aerobatics and air fighting have no effect on an injection system as they have on a carburettor.

As against these advantages the pumps have to be very accurately made as they meter out very small quantities of fuel and precision work of a high order is called for in making these reciprocating pumps which consist of a plunger about ¼ in. diameter in a barrel about 6 in. long. This has been the main obstacle to more widespread adoption of the system. A partial adoption of petrol injection is occurring in U.S.A. This is with a single pump injecting into the manifold as in the Stromberg injection carburettor. Small engines are also adopting it.

The 'Dynamic Damper.'

The *dynamic damper* fitted to the crankshaft of radial engines has done a great deal to reduce crankshaft stress as it reduces angular deflections to about one-tenth of the value they would have without it. The important angular vibration in a crankshaft is that due to the torque from gas pressure and it therefore has a frequency $\frac{N}{2} \times \frac{n}{60}$ per second, where N = number of cylinders in single row engine, and n = r.p.m of the engine. If this vibration happens to be in resonance with the natural frequency of the crankshaft, the angular deflection can be multiplied many times; for a 9-cylinder engine the stress may be 5 times as great as that resulting from a steady application of the maximum torque. This cannot be tolerated, particularly as the stress may be repeated as much as 1,000,000 times in 2 hours.

Mathematics indicated that it was necessary to find an 'absorber' with a frequency equal to that of the forcing vibration and with a restoring force varying as the square of the r.p.m. A simple pendulum attached to and forming part of the counterweight of the crankshaft has these

properties. As its weight is effective as part of the counterweight, the pendulum adds no weight to the engine. For a 9-cylinder engine, $\frac{r_1}{L} = (4 \cdot 5)^2$. This means that L must be very small (a

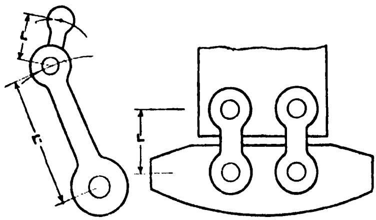

FIG. 6.—Principle of the Dynamic Damper.

fraction of an inch) which can be accomplished by hanging the pendulum on two links as indicated in fig. 6. Actually, in the design as evolved by the Wright Company, the pendulum part of the counterweight is supported on two rollers which are loose in their holes in both the pendulum and the crank cheek, so ensuring a very short pendulum length. This 'dynamic damper' was one of the most important developments of the late 1930's.

RAILS.

With the principal exception of Great Britain, where bull-head rails in cast-iron chairs are still the standard for railway track, the flat-bottom rail—with or without baseplates—is in universal use. The merits of each type of rail have been debated from time to time and it is of interest to record that British Railways are laying in a considerable mileage of flat-bottom rail for purposes of comparison under similar conditions, particularly from the maintenance point of view, since the initial cost of flat-bottom track with heavier rails is undoubtedly higher than that for bull-head track under present circumstances in this country. Further details of these experimental lengths are given in the next section, 'Permanent Way on British Railways.'

The general increase in speeds and axle loads in the years prior to 1939 had emphasised the necessity for a very high standard of track maintenance and there was a tendency to increase the weight of new rails everywhere. In Great Britain some miles of 100-lb. bull-head rail were laid in but the greatest increases were to be seen in the United States of America where rails weighing 131 lb. per yd. soon became common with 150 lb. rails being used on certain lines. In comparing these figures it must be borne in mind that, whereas very high speeds were attained in both countries, axle loads in the U.S.A. reached 34 tons, whereas the heaviest British locomotives

had maximum axle weights of about 23 tons. Other factors also need to be taken into consideration. For instance, in Great Britain track maintenance is normally possible throughout the year whereas thousands of miles of American track receive no attention for months on end due to the extremes of temperature making it unsafe or impossible to fettle the track, and the permanent way must therefore be designed to withstand this lack of attention, particularly the stresses associated with the heaving of the road bed during the winter months.

Permanent Way on British Railways.*

The present standard for main lines is the 95 B.S.R. bull-head rail in 60-ft. lengths joined by four-bolt fishplates. The rails are supported in cast-iron chairs, weighing 46 lb. each, which are secured to creosoted softwood sleepers (8 ft. 6 in. long, 10 in. wide, 5 in. deep), by means of either three chair screws or two through bolts. In the former case the chairs usually have plain smooth bases, although various types of projections have been experimented with as anti-spread measures. Where through bolts are used the underside of the chair is cast with transverse serrations which engage corresponding recesses adzed on the top face of the sleeper. The bolts are inserted from below with the nuts on top for tightening purposes and have a large square ribbed steel washer under the head to prevent the bolt turning. The rails are held in the chairs by means of tapered hardwood or spring steel keys driven as far as practicable in the direction of traffic.

The usual number of sleepers is 2,112 per mile of road but an additional one or two sleepers per rail length are generally used where the formation is soft, in tunnels and on curves sharper than ½-mile radius. As mentioned in a later section a considerable mileage of track has been laid with welded rails up to 240 ft. in length. It should also be recorded that various designs of semi-supported rail joints are being tried with the object of obtaining smoother running and, in some instances, the special joints provide for additional expansion of long welded rails.

In 1936 the London, Midland & Scottish Railway Company laid in for trial purposes a tota of about five miles of track with B.S. 110 lb. flat-bottom rail, and in 1939 this was increased by another six miles, the A.R.E.A. 131 lb. flat-bottom rail being used in the latter case. Both tests included trials with various designs of baseplates—rolled and drop-forged steel and cast iron—with a variety of fastenings. The London & North Eastern Railway Company also laid many miles of 110 lb. flat-bottom rails and about two miles of the same section were laid on the Great Western Railway in 1945.

In 1945 a new flat-bottom rail section, weighing approximately 113 lbs. per yd., was designed by the railway companies jointly and details are shown in fig. 1. A considerable mileage of this rail has been laid on the Western, London Midland and Southern Regions of British Railways during the last few years.

Fig. 1 also shows the cast-iron base plate and elastic rail spike fastening adopted for the experimental lengths. The following comparison of the moments of inertia for various rail sections now in use is interesting.

95 R.B.S. Bull-head	35·2 ins.⁴
110 B.S. Flat-bottom	57·2 „
113 lb. „	66·0 „
131 A.R.E.A. Flat-bottom	88·5 „

In addition to their greater vertical stiffness as girders the flat-bottom rail sections are by reason of the wide flange far more rigid laterally than the bull-head rail and one of the principal objects of the tests now being made in Great Britain is to obtain comparable data in regard to the maintenance of bull-head and flat-bottom track respectively under similar service conditions.

Concurrently with the above all Regions of British Railways are laying a proportion of switches and crossings in flat-bottom rail.

BRITISH STANDARD SPECIFICATION AND SECTIONS OF BULL-HEAD RAILWAY RAILS.*

(No. 9—1935.) (*Abstract.*)

2. The steel for the rails shall be of the best quality made by the Open Hearth or Acid Bessemer process, as may be specified or required by the engineer (or the purchaser), and shall show on analysis that in chemical composition it conforms to the limits given for such processes respectively in Tables 1 and 2.

The steel shall conform to the limits of chemical composition appearing in Tables 1 and 2 under the headings of 'Higher Carbon' and 'Medium Manganese' respectively, as may be specified or required by the engineer (or the purchaser).

TABLE 1.—STEEL MADE BY THE OPEN HEARTH PROCESS.

Element.	Acid.		Basic.	
	Higher. Carbon.	Medium Manganese.	Higher Carbon.	Medium Manganese.
	Per cent.	Per cent.	Per cent.	Per cent.
Carbon . .	0·50 to 0·60	0·45 to 0·55	0·55 to 0·65	0·50 to 0·60
Manganese . .	0·90 (max.)	0·90 to 1·20	0·90 (max.)	0·90 to 1·20
Silicon . .	0·10 to 0·30	0·10 to 0·30	0·10 to 0·30	0·10 to 0·30
Phosphorus .	0·06 (max.)	0·06 (max.)	0·05 (max.)	0·05 (max.)
Sulphur . .	0·06 (max.)	0·06 (max.)	0·05 (max.)	0·05 (max.)

TABLE 2.—STEEL MADE BY THE ACID BESSEMER PROCESS.

Element.	Higher. Carbon.	Medium Manganese.
	Per cent.	Per cent.
Carbon . .	0·45 to 0·55	0·40 to 0·50
Manganese . .	0·90 (max.)	0·90 to 1·20
Silicon . .	0·10 to 0·30	0·10 to 0·30
Phosphorus .	0·06 (max.)	0·66 (max.)
Sulphur . .	0·06 (max.)	0·06 (max.)

6. A falling weight test shall be made in the following manner :—A piece of rail 5 feet (1·52 m.) long, taken from one of the rails selected by the engineer or the inspector (or the purchaser), shall be placed in a horizontal position with the head uppermost upon the two steel bearers of the British Standard Falling Weight Testing Machine, the bearers being 3 feet 6 inches (1·07 m.) apart at their centres, and having their upper surfaces curved to a radius of 3 inches (76·20 mm.).

The test shall comprise two blows delivered midway between the bearers from a falling iron weight. The height of the drop for the various sections of rails shall be as tabulated below. The blows shall be sustained without fracture, and the permanent set measured on the specified distance between the centres of the bearers resulting from the two blows must not exceed the limits given in the table, p. 474.

* By permission of the British Standards Institution.

14. All ingots used in the manufacture of the rails shall be not less than 200 square inches (1,290·32 cm.²) in area at the larger end. The ingot shall be so fed into the cogging rolls that the bottom end arrives at the shears or hot saws first. From each end of the bloom and/or rail bar sufficient crop shall be cut to ensure that all unsound portions have been removed.

24. Dimensions and Weights of 'B.S.' Bull-Head Railway Rails.

31. The holes for fishbolts shall be drilled through the web from the solid at each end of the rail of the sizes and in the position shown in the British Standard Specification for Steel Fishplates for Bull-head Railway Rails (Report No. 47—1928) or on a drawing to be supplied by the engineer (or the purchaser).

These holes shall be at right angles to the web of the rail, and clean cut, all burrs being carefully removed, and shall be checked by the manufacturer with suitable templates and gauges to be furnished by him and at his expense, and approved by the engineer (or the purchaser).

32. Should any of the holes vary from the correct size or position more than one-thirty-second ($\frac{1}{32}$) of an inch (0·79 mm.) the rail or rails in which such deviation occurs may be rejected.

WEIGHT OF RAILS PER MILE OF SINGLE TRACK.

Area.	Weight per Yard.	Weight per Mile.	Area.	Weight per Yard.	Weight per Mile.
Sq. ins.	Lb.	Tons.	Sq. ins.	Lb.	Tons.
5	51·0	80	7½	76·5	120
5¼	53·5	84	8	81·5	128
5½	56·0	88	8½	86·5	136
5¾	58·5	92	9	91·5	144
6	61·1	96	10	102·0	160
6½	66·0	104	11	112·0	176
7	71·0	112			
No. of 30 ft. rails per mile = 352			No. of 45 ft. rails per mile = 234		
No. of 40 ft. rails per mile = 264			No. of 60 ft. rails per mile = 176		

Area of rail in square inches multiplied by 10·188 equals weight in lb. per yard.

Weight of rail per yard in lb. multiplied by $\frac{11}{7}$ equals tons per mile of single track.

Weight of rail in kgms. per metre multiplied by 2 equals weight in lb. per yard (approximately).

STRENGTH OF RAILS.

The following formula provides for the dynamic impact effects of engine hammer blow and lurching and affords a means of assessing the relative strength of rails :—

$$f = \frac{Wl}{5 \cdot 3\ Z}\left(\frac{V^2}{c} + \frac{V}{k} + 0 \cdot 5\right)$$

where f = max. stress in rail foot (tons per sq. in.).
W = ,, static axle weight (tons).
l = sleeper spacing (ins.).
Z = section modulus—tension (ins.^{3}).
V = max. speed (miles per hour).

The co-efficients 'c' and 'k' vary with individual classes of locomotives according to the maximum wheel hammer blow and diameter of driving wheels. Typical values for some express passenger locomotives of British Railways are given below.

Region.	*Locomotive.*	*c.*	*k.*
Eastern and N. Eastern	4-6-2 3 cyl. A-4	51,960	715
	4-6-0 2 ,, B-1	62,130	660
London Midland	4-6-2 4 ,,	89,780	725

Western	4-6-0 4 ,, 'Castle'	51,580	715
	4-6-0 4 ,, 'King'	60,530	700
	4-6-0 2 ,, 'County'	23,540	670

SPECIAL STEELS FOR RAILWAY RAILS.

Experiments are continually being carried out in endeavours to produce rails capable of giving a longer life in the track before their removal is indicated owing to loss of weight by abrasion, corrosion, etc.

Rails rolled from steel containing from 12 per cent. to 14 per cent. manganese appear to meet the requirement for a greater abrasive resistance but owing to their comparatively high initial cost are only economical when, in the ordinary course, the rails have a very short life and their frequent renewal entails heavy labour charges, such as in the case of complicated blocks of crossing work or in electrified lines.

For situations in which they are subjected to the action of chemical fumes, water, etc., rails containing from 0·25 per cent. to 0·30 per cent copper have been tried, and in one instance where such rails were laid in the vicinity of water troughs, the records show that after two and one-third years' life they had lost in weight about 20 per cent. less than ordinary Bessemer Acid steel rails laid at the same time for comparison.

Experiments are still being conducted with rails containing various percentages of chromium, but no definite conclusions have yet been arrived at as to their comparative superiority or otherwise over ordinary rails.

In the U.S.A. crossings (frogs) made from ordinary rails with manganese (cast) steel inserts are used extensively and have been used to some extent by British Railways.

Rails—Heat Treatment.

Many railways specify the Sandberg Regulated Sorbitizing process for rails to be used in situations where rapid wear is experienced. Briefly this treatment comprises a partial quenching of the treads of the rails, after rolling, by means of an atomized water spray followed by retarded cooling from about 550° C. to 300° C., after which the rails are allowed to cool out in the normal manner. The Sandberg treatment has the effect of considerably hardening the treads of the rails whilst the webs and feet retain their normal structure, but experience has shown that such rails are prone to develop a corrugated surface unless laid in lines carrying intensive traffic.

It is contended that rails are particularly prone to develop incipient internal fissures whilst cooling between the above-mentioned range since the tensile strength of the metal has been shown to be at its lowest at a temperature of about 400° C. The effect of slow cooling is to even out the temperature as between the external and internal metal of the rails until they are sufficiently cool to resist this tendency. Retarded cooling is now specified by British Railways for ordinary rails and undoubtedly reduces internal residual stresses in the steel.

Various other methods of heat treatment are applied to rails on the Continent, whilst in America rail ends are also hardened in the track by means of the oxy-acetylene flame followed by suitable quenching.

Maximum Allowable Axle Load.

For Light Railways.

Weight of rail in lb. per yard	30	35	40	45	50	55	60	65	70
Max. axle loading in tons	4 to 6	5 to 7	6 to 8	7 to 9	8 to 10	9 to 11	11 to 13	13 to 15	15 to 17

(*Ministry of Transport.*)

Steel Conductor Rails for Electrified Track.

Typical modern specification:

	Per cent.
Carbon	0·06 max.
Silicon	0·05 „
Manganese	0·10 to 0·20
Sulphur	0·03 max.
Phosphorus	0·04 „

Resistance not exceeding 16 microhms per 100 lb./yd. (6·5 times that of pure copper of equal ength and section area) at 60 ° Fahr.

The tensile breaking strength of such rails is approximately 20 tons per sq. in.

Short Rails in Curves, etc.

Owing to the length of the outer rail of a curve exceeding that of the inner, it is necessary in order to keep the rail joints square to insert at intervals on the inside of the curve special rails, usually from 2 inches to 5 inches shorter than the standard length.

The necessary decrease in rail length is given by:

$$d = \frac{GL}{R}$$

Where G = gauge of track,
L = length of outer rail,
R = radius of outer rail.
(All in feet.)

Also $R = \frac{GL}{d}$

For 60 ft. rails and 4 ft. 8½ in. gauge, d in inches $= \frac{3390}{R}$

On the former Great Western Railway such special rails are laid opposite one another in pairs to the extent of about 10 per cent. of the total length of track when long lengths of straight or very flatly curved lines are laid. The object of this is to obviate the cutting of short rails for curves when the main line material is eventually recovered and relaid in secondary lines or branches, as the latter as a rule contain a larger proportion of sharp curves than the main lines.

Fishplates.

British Standard Specification and Sections for Steel Fishplates for Railway Rails. (No. 47—1928.) (*Abstract.*)*

The steel for fishplates to B.S.S. 47—1928 must show on analysis that it conforms to the following limits:

	Class A. Steel.	*Class B. Steel.*
Carbon	0·20 to 0·30 per cent.	0·30 to 0·42 per cent.
Manganese	Not to exceed 0·80 per cent.	
Silicon	" " " 0·15 "	
Phosphorus	" " " 0·075 "	
Sulphur	" " " 0·075 "	

Standard C or D tensile test pieces must give the following results:

	Class A. Steel.	*Class B. Steel.*
Breaking strength, tons per sq. in.	28 to 35	36 to 42
Minimum elongation, per cent. .	22	20

Worn and Reconditioned Fishplates.

Extensive use of Wonham True Temper Tapered Rail Joint Shims is now made in this country and America in connection with the maintenance of worn rail ends and fishplates.

* By permission of the British Standards Institution.
† K and L are given to the nearest $\frac{1}{64}$ inch.

To meet the various conditions of wear usually encountered these shims or packings are made in several lengths, from 9 to 16 ins., and vary in thickness at the centre from 0·03 to 0·15 ins., tapering towards the two ends. A special stepped type of shim is also available for use where unequal wear on adjoining rail ends obtains. (See fig. 7.)

These shims are proving very satisfactory in restoring dished joints and also enable fishplates to be re-used which would otherwise be scrapped.

Some railway companies recondition worn fishplates by re-forming them in suitable dies to fit the worn fishing surfaces of the rails.

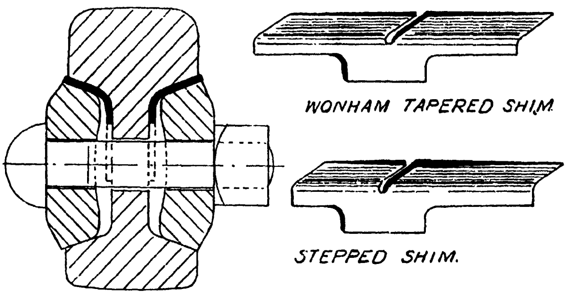

FIG. 7.

CHECK RAILS AND WIDENING OF GAUGE ON CURVES.

In accordance with the Ministry of Transport Requirements (1928), curves of ten chains radius or under in passenger lines are provided with continuous check rails. Flatter curves are sometimes similarly checked if the speeds over them are high and if they have superelevation adverse to the curvature which, although undesirable, is occasionally necessary in the case of turn-outs from the outside of a curved main line.

For curves flatter than ten chains (660 ft.) radius no widening of gauge is usual, but for sharper curves the following represents average although not universal practice.

Radius of Curve.	Gauge Widening.
From 10 chains to 8 chains	$\frac{1}{4}$ inch
Below 8 chains	$\frac{7}{16}$ inch

At level crossings, the usual practice is to provide check rails giving 2-in. flangeway clearance, although in some cases wooden guards are used in place of check rails.

The inside fishplates on continuous check rails are generally grooved to provide flange clearance when the running rails become worn.

FISHBOLTS AND NUTS.—ABSTRACT FROM B.S. 64—1946.

Tensile Test.—Shall be made either on a test piece taken from the bar or on a test piece turned from the finished bolts. The test shall be carried out in accordance with the provisions of B.S. 18 and shall comply with the requirements set out below :—

Material.	Ult. Tensile Stress. Tons per sq. in.	Min. Elongation Per Cent. on			
		Test Piece A.	Test Piece B.	Test Piece B1.	Test Piece C or Subs.
Material for bolts. Test piece cut from bar . . .	35 to 40	—	18	22	23
Test piece from finished bolt .	35 to 42	—	—	—	20
Material for nuts . .	35 to 40	20	—	—	25

Bend Test.—The bend test piece shall when cold be capable of being bent, either by pressure or by blows from a hammer, round a bar equal to its diameter or thickness until its sides are parallel without showing any signs of fracture.

Screw Threads.—Shall be either B.S.W. or B.S.F. as specified by the purchaser who shall also state to which of the following alternatives the bolts and nuts are required to conform:

(*a*) The bolts and nuts shall pass the unscrewing test. Threads cut to B.S.W. form.

(*b*) The threads shall be cut either to B.S.W. or B.S.F. form and shall confirm to the ' medium fit ' tolerances specified in B.S. 84—1940.

Unscrewing Tests.

First Test.—The nut shall be screwed on the fishbolt until it is flush with the end of the bolt and a spanner as described below shall then be affixed to the nut in a horizontal position and weighted as specified.

Second Test.—The nut shall then be screwed further on to the fishbolt until the end of the bolt projects four threads beyond the top of the nut and the spanner weighted as before shall be again similarly applied to the nut. Under each test the nut shall carry neither less nor more than the minimum and maximum weights specified in the following table.

Test.	Dia. of Fishbolt.	Test Weight in lb.	
		Min.	Max.
A	$\frac{1}{2}$ in. and $\frac{9}{16}$ in.	3	15
	$\frac{5}{8}$ in. and $\frac{11}{16}$ in.	4	20
B	$\frac{3}{4}$ in.	3	15
	$\frac{13}{16}$ in. and $\frac{7}{8}$ in.	4	20
	$\frac{15}{16}$ in. and 1 in.	5	25
	$1\frac{1}{8}$ in.	6	30

For tests A the spanner shall weigh $7\frac{1}{2}$ lb. and the test weight shall be suspended at a distance of 2 ft. 6 in. from the centre of the nut.

For tests B the spanner shall weigh 10 lb. and the distance between the centre of the nut and the point of suspension of the test weight shall be 3 ft.

Wooden Sleepers.

In normal times British Railways make large use of creosoted softwood sleepers, usually Baltic Redwood (*Pinus Sylvestris*) or Douglas Fir (*Pseudotsuga Douglasii*), although hardwoods such as Jarrah are preferred by certain Lines for electrified track. The standard sizes are 8 ft. 6 ins. long, 10 ins. wide, 5 ins. thick, and where special joint sleepers are used they are 12 ins. wide.

In 1938-9 a considerable number of French Maritime Pine (Landes Fir) sleepers were imported and these, if well selected, are considered to be very little if any inferior to Baltic Redwood.

Restrictions on imports from the Baltic and Mediterranean ports in war time have necessitated the use of larger numbers of Canadian Douglas Fir sleepers. Owing to the difficulty of effectively creosoting this species of timber by the ordinary pressure process, disappointing results had frequently arisen from the use of Douglas Fir sleepers in the past, but a longer life is anticipated from later supplies which have been made to a more rigid specification and subjected to incising before creosoting.

The incising operation consists in passing the sleepers through a machine provided with four rollers each equipped with removable cutters, designed to part the fibres of the wood without crushing or breaking, and if creosoting is carried out immediately, it is found that uniform penetration results with this otherwise refractory timber.

Incising and creosoting are carried out in accordance with B.S.S. 913—1940.

Whilst pressure creosoting is still the most used preservative treatment for railway sleepers, extensive trials are being undertaken with various water soluble salts. One of these treatments known as Tanalizing (originally Wolmanising) is being very largely used for crossing timbers on one Region of British Railways. Sleepers have also been treated experimentally with belcure preservative.

Another result of the restricted imports of sleepers is the use of home grown softwoods and hardwoods, principally Scots fir, larch, oak, beech and elm, for less important branches and siding work. These can be utilised uncreosoted when required for more or less temporary sidings, but under such conditions their life is short compared with properly treated sleepers.

Crossing timber is usually 12 ins. × 6 ins. and 14 ins. × 6 ins., and varies in length from 8 ft. 6 ins. to 40 ft., whilst longitudinal bridge timbers may be 16 ins. × 7 ins. upwards where they are required to take standard chaired track.

LENGTH OF WOODEN SLEEPERS.

	Ft. Ins.	Ft. Ins.	Ft. Ins.	Ft. Ins.	Ft. Ins.	Ft. Ins.
Gauge . . .	5 6	4 8½	3 6	metre	2 6	2 0
Sleeper length .	9 0 to 10 0	8 0 to 9 0	6 0 to 6 6	6 0 to 6 6	5 0	4 0

Metal Sleepers.

Whilst wooden sleepers predominate throughout the world there are considerable mileages of track laid on steel or cast-iron sleepers.

Cast-iron sleepers of the circular pot type have been used in India for very many years and, during the last two decades, other types of cast-iron sleepers have been designed and laid with both flat-bottom and bull-head rail. The basic design of steel sleepers for flat-bottom track has remained practically unaltered for over forty years but improved types of fastenings have been developed, and fig. 8 shows the 'loose jaw' pattern which is commonly used in India. Gauge is maintained

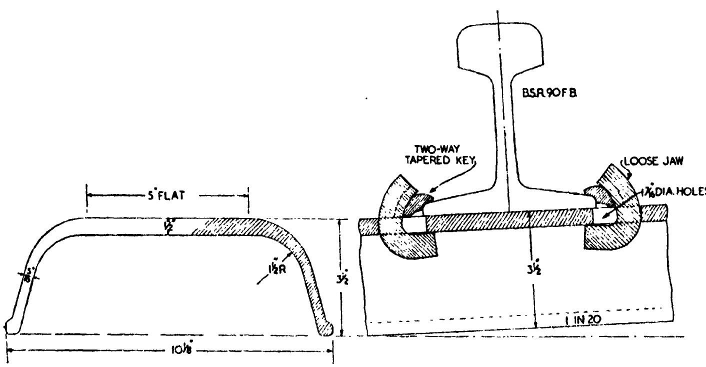

FIG. 8.

or, where necessary, widened to a limited extent on curves, by adjustment of the tapered steel keys which are driven in opposite directions.

Between 1929 and 1936 considerable numbers of steel sleepers were laid in Great Britain. Generally speaking, these have given fairly satisfactory service but many lengths have suffered from extensive corrosion and in others some distortion of the trough section has occurred with the result that premature renewal has been necessary.

The following is a brief description of some of the designs of steel sleepers laid in by the former Great Western Railway Company, which still has a considerable mileage of steel-sleepered track on its system.

(1) G.K.N. Composite Type (fig. 9).—This consists of the usual rolled and pressed mild steel trough section, the chairs, which are of cast iron, being cast in position on the plate by means of

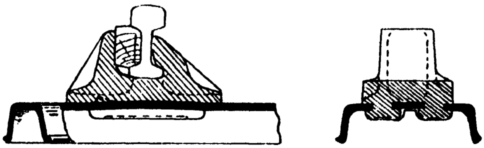

FIG. 9.—G.K.N. Composite Steel Sleeper.

two elongated snugs projecting on the underside. It is 8 ft. 6 ins. long by 3 ins. deep and was manufactured in two widths, 11 ins. and 10¼ ins., the weights of the complete sleepers being 245 lb. and 228 lb. respectively.

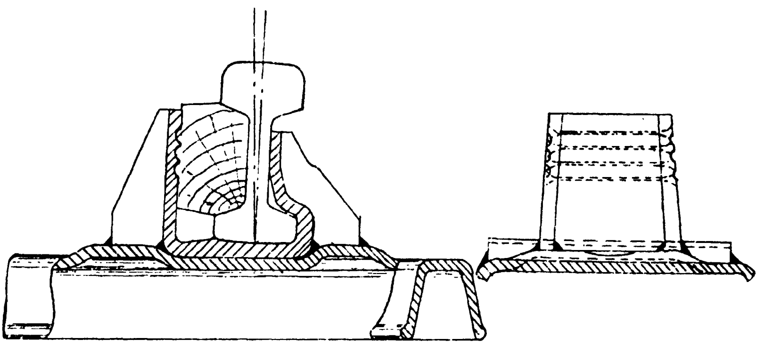

FIG. 10.—Workington Steel Sleeper.

(2) Workington Type (fig. 10).—This sleeper also is 8 ft. 6 ins. long but is 11¼ ins. wide overall and 2¾ ins. deep, weighing 196 lb. The chairs are pressed from rolled steel plate and are welded to the sleeper with a continuous fillet round the base.

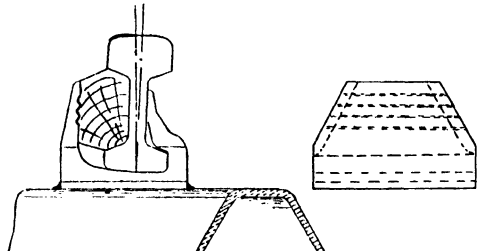

FIG. 11.—Dorman Long Steel Sleeper.

(3) Dorman Long Type (fig. 11).—This is somewhat similar to the previous design but weighs only 180 lb.

(4) Sandberg Type (fig. 12).—The Sandberg sleeper is pressed from a special rolled section having a deep central rib, the jaws being punched and pressed from the metal of the sleeper plate.

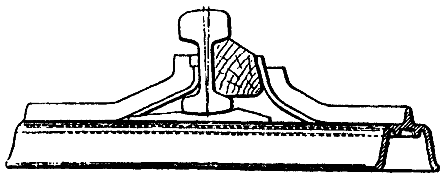

FIG. 12.—Sandberg Steel Sleeper.

A loose-bearing plate forms the rail seating and is prevented from moving laterally by a slot which engages the rail jaw. Total weight 190 lb.

PREVENTION OF RAIL CREEP.

Many 'anti-creep' devices have been submitted to tests during the past few years in an endeavour to reduce the large annual expenditure necessitated on certain lines in pulling back rails subject to creep. These comprise various forms of spring steel keys, e.g. the 'Mills,' 'Stuart,' 'Tees Side,' and 'Turplat'; also rail anchors, of which the 'Phillips,' 'Yates,' and 'Winby' are typical examples.

Steel keys or rail anchors for the prevention of creep are usually fixed at the rate of about six per 45 ft. rail and the former are of various types, some having separate tapered wedges for tightening, whilst others are made in one piece. Fig. 13 illustrates a steel key of the latter type known as the 'Turplat,' manufactured by George Turton Platts & Co., Ltd.

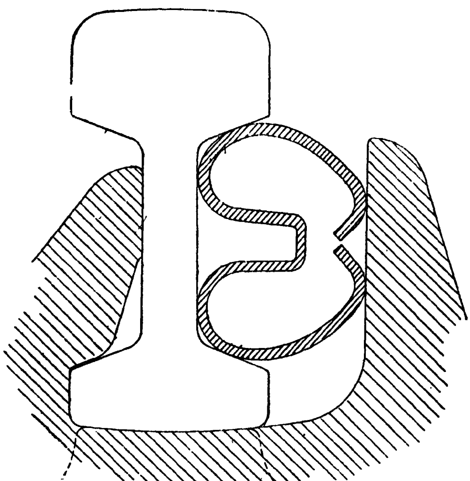

FIG. 13.—Turplat Steel Key.

In recent years steel keys have been used exclusively in some lengths of bull-head track, but experience on one railway at least indicates that it is desirable after relaying to re-use the wooden keys until the new track has settled down, after which the steel keys can be driven. Failure to adopt this practice has resulted in difficulties being experienced in connection with alignment.

Rail anchors may also be classified as one-piece or otherwise in design, and fig. 14 illustrates the 'Phillips' anchor, which belongs to the former category. This device is forced over the foot of the rail (close to a chair), which causes it to exert a vicelike grip, and by its bearing against

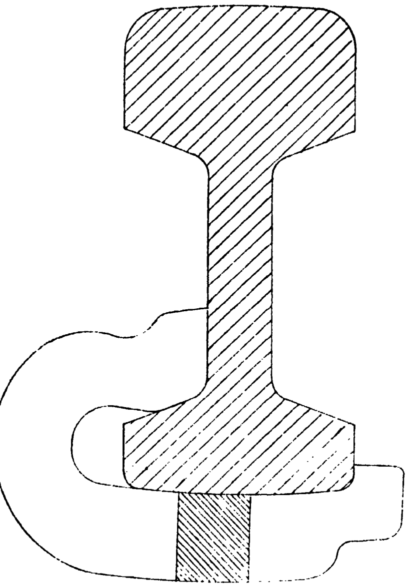

FIG. 14.—Phillips Rail Anchor.

the side of the chair, lessens the tendency for the rail to slide forward. The sleepers should, of course, be well boxed to prevent them 'skewing.'

Rail anchors are made for bull-head and flat bottom-rails.

The use of teak keys in place of oak is also stated to be beneficial in regard to the prevention of rail creep, as after a few years in the line oak keys tend to shrink.

Steel keys need less redriving than wooden ones.

Ballast.

The purpose of ballast is (*a*) to distribute the load over a larger area of the formation, (*b*) to provide a more or less uniform elastic medium between the track and the bed, (*c*) to provide rapid and efficient drainage of surface water, and (*d*) to hold the sleepers in position.

There are usually two distinct layers: the 'bottom,' consisting of stone or slag varying in size from 4 ins. to 8 ins., is laid directly on the formation to a thickness of about 9 ins.; the upper or top ballast extending from about 3 ins. below the underside of the sleepers to the level of their tops. The average size of top ballast, consisting of crushed stone, slag or gravel, varies from ½ in. to 2½ ins., but for steel sleepers the maximum is about 1½ in.

For sidings, unimportant branch lines, and for clay cuttings and banks, ashes are largely used for both bottom and top ballast.

The top ballast should extend for about 12 ins. or 18 ins. beyond the ends of the sleepers, with a 1 to 1 slope at the sides; the bottom ballast being carried about 2 ft. or 3 ft. beyond the sleeper ends.

In modern railway practice, the formation is 2 ft. below rail level, and is cambered 6 ins., dry stone cross-drains being formed as required into open jointed pipes or 'U' shaped drains (in the case of cuttings) laid in the cesses.

For single lines the width of top ballast required is about 12 ft. with 18 ft. of bottom ballast, and for double lines, top ballast 23 ft., bottom ballast 28 ft. to 30 ft.

CUBIC YARDS OF BALLAST PER MILE OF TRACK.

Side Slope of Ballast, 1 to 1. 6-in. Formation Camber.						
Depth of Ballast in Inches.	Width in Feet.					
	Single Track.			Double Track.		
	10	11	12	21	22	23
12	1,930	2,120	2,320	3,860	4,060	4,260
18	3,160	3,440	3,740	6,160	6,460	6,760
24	4,480	4,880	5,260	8,560	8,960	9,340
30	5,880	6,380	6,880	11,050	11,560	12,030

NOTE.—Allowance has been made for wooden sleepers in this table.

Blast-furnace and steel slags are much used as ballast where supplies are readily available. Cinder ballast is now being superseded by stone or slag where a sufficient supply can be obtained at an economical cost; but where the railway is subjected to subsidences cinder ballast is used, otherwise successive liftings of the tracks would cause large quantities of the ballast gradually to disappear below the ordinary level of the ballasting. The use of slag ballast is generally avoided in tunnels, because in damp and confined situations it is considered to increase corrosion of the track; it is not used on electrified lines of at least one administration, on account of certain chemical properties, and also because it is considered too retentive of moisture; this opinion is, however, not general, as it is ordinarily laid on other important electrified railways.

In course of time ballast becomes dirty and consolidated so that it interferes with the drainage and on this account should be periodically cleaned by screening. This is usually done by the use of ballast forks or screens. In some countries mechanical screening machines are employed.

PACKING OF SLEEPERS.

Hand packing of sleepers as opposed to mechanical tamping is still the general practice in Great Britain, and recent years have seen developments in this respect which make the operation more effective.

There are four principal methods of hand packing:

(i) By beater picks.

(ii) By ordinary shovel.

(iii) By small shovel and fine chippings.

(iv) Similar to (iii) but embodying precise measurement of the lift required.

The last process is known as measured packing, and the necessary equipment is supplied by Abtus, Limited. (i) and (ii) are still used to a large extent for general lifting of the track with ordinary ballast, whilst (iii) and (iv) are confined to taking out slacks, etc., in the ordinary course of maintenance.

By method (iii) the quantity of chippings to be distributed under the previously jacked up sleepers is determined by the ganger from experience and with practice gives good results, but in common with measured packing is not suitable on soft formations.

Measured packing, as now practised on a fairly extensive scale, comprises the following operations:

(i) Determining by means of adjustable graduated sighting boards the quantity of chippings required under each sleeper to bring the rail top level.

(ii) Ascertaining by the readings of 'Voidmeters' the amount of chippings required to fill up voids which allow sleepers to be depressed under traffic.

(iii) Lifting the track by jacks and spreading the required quantity of chippings evenly over the sleeper beds (under the rails) by means of specially designed small flat shovels.

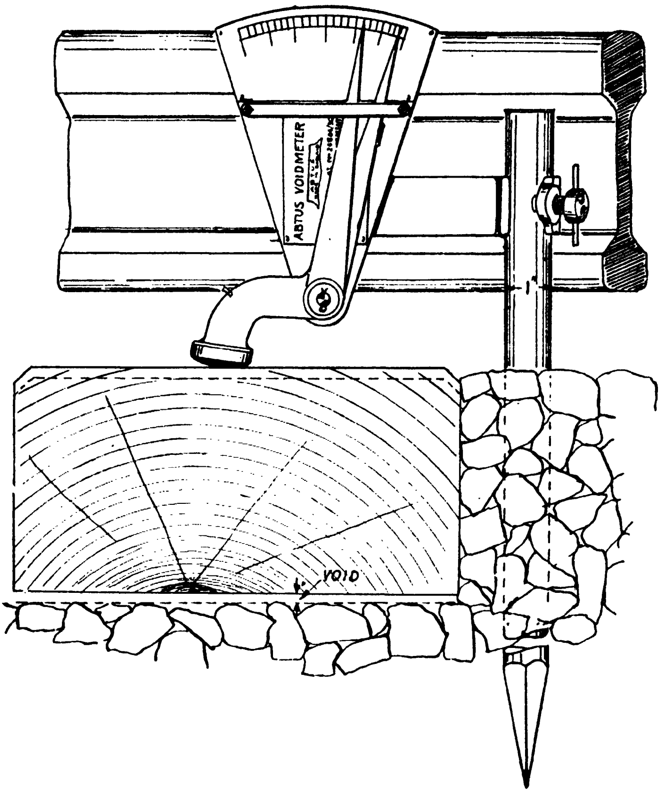

FIG. 15.

Fig. 15 shows the Voidmeter in position. If the sleeper is depressed during the passage of a train owing to a void immediately under it, the amount of such movement is indicated by the distance between the fixed and moving pointers and is read from the scale which is graduated in terms of the special canisters used for the stone chippings.

Rail and Flange Lubricators.

The use of automatic lubricators on the outer or high rail of curves to reduce side wear of rails due to flange pressure is being extended rapidly in view of the benefits derived and improved designs of lubricators now available. An efficient machine will at least double the life of the rail. Fig. 16 illustrates a design of grease lubricator now favoured in Great Britain and also available for flange rail track. Grease (graphite) is forced on the side of the rail head through a series of orifices in a plate situated close to the running face of the rail by means of two small plunger pumps which are operated by the treads of wheels.

Another type of lubricator employs oil which is fed to the rail and wheel flange by a soft felt pad. The efficiency of oilers of this design depends to a large extent on the maintenance of the felt pad which must be kept clean and soft as well as being correctly adjusted as regards position.

Special lubricators have been designed by the makers of both types referred to for greasing the rubbing faces of check or guard rails.

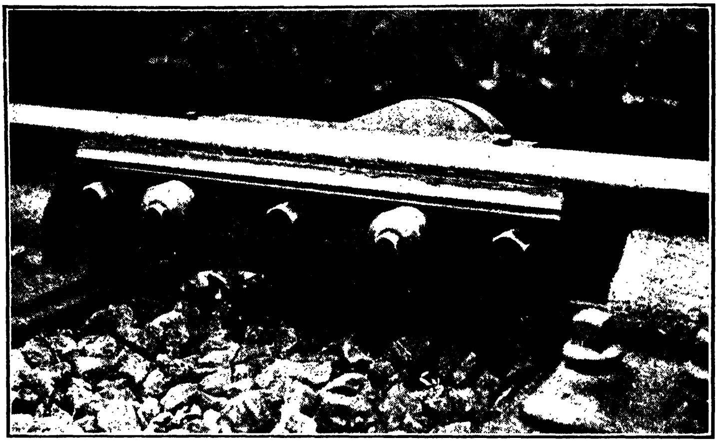

FIG. 16.—Rail and Flange Lubricator.

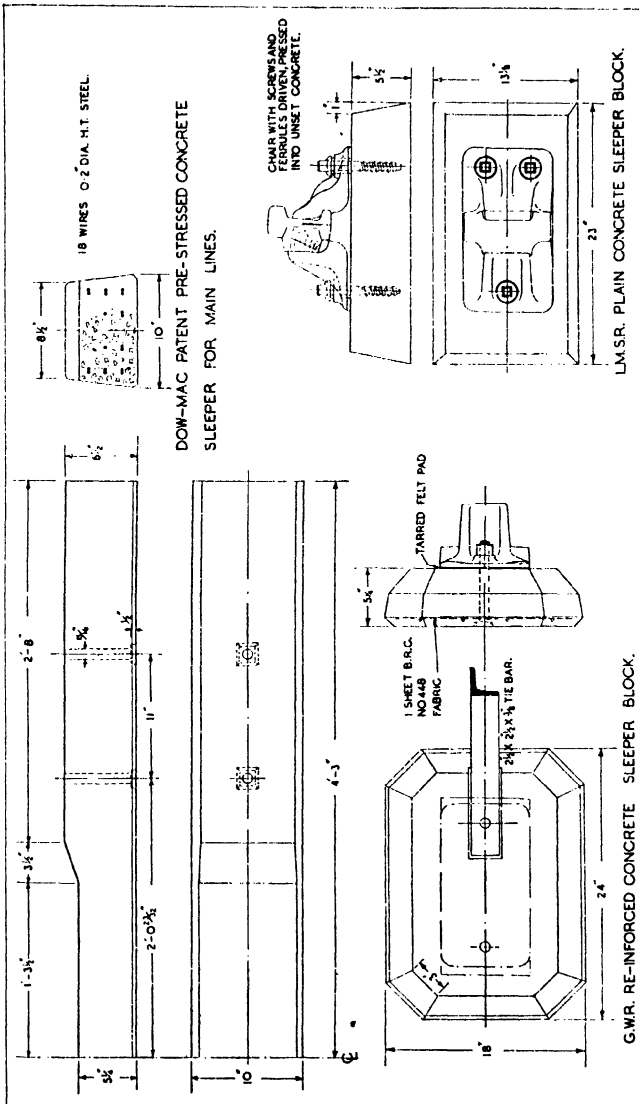
Concrete Sleepers.

The shortage of timber since 1939 owing to restrictions on imports into Great Britain has resulted in extensive trials of sleepers made in re-inforced concrete. In sidings, goods running loops and lightly operated mineral and branch lines independent concrete block sleepers have been largely used, every third or fourth pair of blocks being connected together by steel gauge ties or replaced by transverse concrete sleepers. Fig. 17 illustrates a typical block sleeper of which about 875,000 have been made and used by the former Great Western Railway Company since early 1940. The drawing shows the latest design with a single sheet of steel mesh fabric reinforcement. Fig. 17 also depicts another type of concrete block sleeper made by the London, Midland & Scottish Railway Company for siding use. These blocks were not re-inforced and the method of attaching the rail chair is interesting. First the ferrules were inserted into the holes in the casting, after which the chair screws were driven tightly into the ferrules and the whole assembly was then pressed firmly into the wet concrete in the moulds and allowed to set.

Numerous types of transverse concrete sleepers have been designed and many have been tested in the track. For sidings and large depots, etc., ordinary reinforced concrete may give a reasonably long life but for running lines where speeds exceed say 30 mile per hour the most promising results so far have been obtained with concrete sleepers embodying the principle of pre-stressing. The DOW-MAC Patent Pre-stressed Concrete Sleeper shown in Fig. 18 is a typical example of sleepers designed for main line speeds and axle loads.

All types of concrete sleepers, however, possess one disadvantage compared with timber, namely, excessive weight, which may be from four to five times that of a wooden sleeper and requiring at least six men to handle them.

B.S.S. No. 986—1944 provides for block and transverse concrete sleepers for bull-head and flat-bottom rails suitable for use in sidings, goods lines, etc., over which the speed is limited to 30 miles per hour. This specification includes requirements for both ordinary re-inforced concrete and pre-stressed concrete and provides for various means of fastening the rails or chairs.



CONCRETE RAILWAY SLEEPERS.

FIG. 17.

Cast-Iron Rail Chairs.

Abstract from Great Western Railway Specification :—

Quality of Material and Castings.—**The chairs shall be cast from a mixture of tough grey iron run from the cupola and shall be good smooth clean castings properly dressed, free from honeycomb, air bubbles, cold shuts, sponginess, and other defects.**

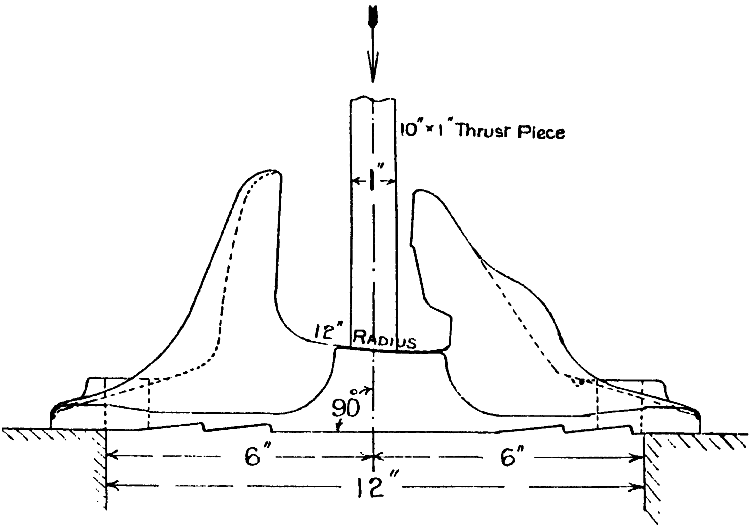


Fig. 18.—G.W.R. Rail Chair Test.

Cooling of Chairs.—**Immediately after the removal of each chair from the mould it shall be protected in such manner as shall satisfy the engineer or his deputy that its strength will not in any way be diminished by too rapid or unequal cooling.**

Variation of Weight.—**No chair will be accepted the weight of which varies more than ½ lb. above or below the computed weight.**

Tests.—**Each 25 tons of chairs cast shall be kept separate and three chairs shall be selected therefrom by the engineer or his deputy for test purposes.**

Each chair shall be supported in its normal position and for its full width on two perfectly true, level and rigid bearings, each bearing being placed six inches clear of and parallel to the centre line of the rail seat. The test load shall be fairly and uniformly applied along the full length of the centre line through a vertical thrust-piece 1 in. thick having the face in contact with the chair curved to a radius of 12 ins. in cross section (see fig. 18).

Each type of chair shall be required to sustain without fracture the following test load :—

'95' Chair	19 tons
'85' „	15 „

The test shall be continued in each case until the chair is broken.

Mechanical Platelaying Appliances.

The ever-increasing necessity for the utmost economy in maintenance and renewal expenditure has inevitably led to a more extended use of mechanical tools, etc., for various platelaying operations, and the following appliances are at present being tried on British Railways.

Mechanical Tampers.

Although extensively used in America, pneumatic, electric and self-contained petrol-engined tie or sleeper tampers have not yet been largely adopted in Great Britain. Most railways, however, are giving these tools a trial, as there are undoubtedly certain situations where their use would be beneficial. One of the chief disadvantages of the pneumatic and electric type of tamper is the necessity for some form of heavy, expensive power unit, usually a petrol engine, which has to be loaded and off-loaded at the site of the work.

Ballast Cleaning and Tamping Machines.

Self-propelled diesel-engined machines for the automatic screening of ballast are under trial in various parts of the world. The 'Matisa' machine, manufactured in Switzerland, is undergoing tests in Great Britain and North America.

A separate machine from the same factory performs automatic tamping of track, and several of these machines are now operating in this country.

Drilling, Sawing, Boring and Screwing Machines.

Portable machines for drilling and sawing rails and girders, boring sleepers and timbers, screwing home fastenings, etc., have been developed during recent years, and are useful time-saving devices for relaying and repair work.

Ratchet Jacks, Track Liners, Rail Lifters, etc.

The older types of screw jacks used for many years by platelayers are now being replaced by quick-acting ratchet jacks with trip release and the sluing of the track by small gangs has been rendered possible by the introduction of track liners, two of which can be made to do the work previously performed by six to eight men equipped with slewing bars.

Rail lifters enable 60 ft. rails to be lifted from the sleeper ends and dropped into the rail chairs by a gang of about six men where twenty-four would normally be required.

Rail creep adjusters, operated by means of right- and left-hand screw threads, enable up to 15 rails (45 ft. long) to be pulled or pushed at a time when track subjected to creep calls for adjustment.

Use of Cranes for Track Renewals.

Relaying of plain line track is now frequently performed by means of cranes. These, in conjunction with specially designed lifting beams, lift out the old track and load it on to wagons, then lay the new track previously assembled at a depot into 60 ft. lengths. This method of renewal considerably reduces the number of line 'occupations' but entails the occupation of an adjoining track in addition to the one being relaid, during the time the actual renewal is in progress. The Southern and Western Regions of British Railways have also developed special diesel-electric crane vehicles to enable relaying with pre-fabricated track to be undertaken in tunnels.

Track-Laying Machine.

One of these machines, designed and patented by Mr. A. W. Bretland, Deputy Chief Engineer, Great Southern Railways, Ireland, has been in use on that railway for several years. The special train forming the track-layer consists of engine, brake van, a number of wagons each loaded with six pairs of 45-ft. lengths of track, and empty wagons to receive the lengths of old track removed from the line, the special cantilever track-layer and wagon containing an electric winch for hauling the new track into its final position. The wagons used are ordinary rail wagons provided with side runners for the traverser.

The new track is framed up by means of crane power, complete with cross-sleepers, etc., at the depot, and the recovered track dismantled and sorted at the same place.

In Ireland the track-layer reduced labour costs in relaying by 40 per cent., and the results obtained were stated to be completely satisfactory from every point of view.

Loading and Unloading Rails Mechanically.

It is possible to effect considerable economies in the operations of loading and unloading new and old rails by a method now being used on the Great Western Railway. The rails are unloaded over the ends of the wagons by means of wire ropes and chains fastened at one end to the existing track, and at the other to the ends of rails to be unloaded. The wagon is then drawn forward by an engine and the rails slide on to the track via a 2-wheeled ramp attached to the rail wagon. Sixty-foot rails are dealt with in this manner without crippling. In the operation of loading the rails, one end of a wire rope is attached to the draw bar hook of the engine (or adjacent wagon) and the other end, to which are fastened twin chains and shackles, is carried over the truck to be loaded, and attached to the rails lying on the ground. The brake is then applied lightly to the truck, and the engine moved back, drawing the rails over a roller fixed to the end of the wagon. These two operations can be performed at considerably less cost than by the old methods of unloading by skids, etc.

Continuous Welded Rail.

During the last ten years considerable progress has been made in the direction of attaining smoother running track by the elimination of rail joints. This may be effected by the provision

of special type joints such as the Ellson (fig. 19), by welding the rails into longer lengths or by a combination of both. One of the longest lengths of continuously welded track in existence is to be found in the U.S.A. where one railroad company has over five miles broken only by a number of turnouts and insulated block joints. Many other comparatively long lengths of welded rail exist in America and other parts of the world, especially in tunnels where temperatures are generally fairly constant. In the Moffat Tunnel of the Denver & Rio Grande Western Rail Road, for instance, there is a continuous length of 18,000 ft. of rail welded by the Full-fusion Thermit process, the rails being the A.R.E.A. 112 lb. section.

The comparative lateral flexibility of the bull-head rail compared with the flat-bottom section has so far confined welding of rails in Great Britain to lengths not much exceeding 200 ft. It is now fairly well established as the result of special tests that the expansion and contraction of long lengths of welded rail due to temperature variations are limited to a length of say 40 or 50 ft. at each end of the long rail, the resistance to movement of the intermediate portion resulting in

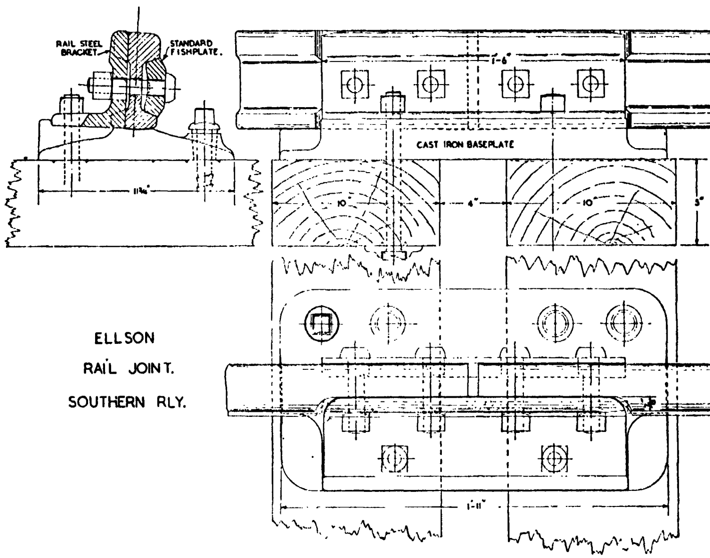

FIG. 19.

tensile or compressive stresses in the rail itself. Experiments to determine the intensity of such stresses under various conditions have been made, but further work is necessary before definite conclusions can be drawn.

The methods adopted for rail welding are either the Thermit process (with or without the insertion of a soft steel shim), the Oxy-acetylene Pressure weld or the Automatic Electric Flash-Butt Weld. The latter process has been used in England to an increasing extent for welding running and conductor rails. Generally speaking the finished lengths of the welded rail has varied from 78 ft. to 180 ft. although conductor rails have been much longer. There is every indication that the next few years will witness an extension of continuous rail welding.

The normal electric flash-butt welded rail joint will withstand a falling weight test almost if not quite as well as the rail prior to welding, whereas the Thermit process does not produce a weld capable of standing up to even a moderate drop test. In spite of this, however, Thermit welded rails are giving satisfactory service after ten or more years' life in main lines.

Resurfacing Worn Rails by Welding.

The practice of building up or resurfacing *in situ* worn switch and crossing rails is now practically universal. For a number of years prior to 1937–38 the electric arc process held the field in this respect, but modern practice favours the oxy-acetylene method, and on some railways the portable electric arc welding plant is now used almost exclusively for structural and shop welding.

Clearances on Curves.

The greatest distance by which the end of a vehicle overhangs the running face of the rail on the outside of a curve is termed the End Throw.

If

R = radius of curve;
G = gauge of track;
W = width of vehicle;
L = overall length of vehicle;
B = wheelbase or distance between bogie centres. (All in feet.)

$$\text{End throw} = \frac{W - G}{2} + \frac{L^2 - B^2}{8R}.$$

The overhang of the centre of the vehicle on the inside of a curve is known as the Centre Throw, and with the same notation

$$\text{Centre Throw} = \frac{W - G}{2} + \frac{B^2}{8R}.$$

In the case of structures adjoining the inner rail of a curve having superelevation, additional clearance should be allowed.

Permanent Way—Heights and Widths.

Ministry of Transport Requirements or Recommendations.

	Ft.	Ins.	
Outside of widest stock to face of structure	2	4	minimum
Face of signal posts, water columns, etc., between tracks spaced at 9 ft. intervals to bodywork of stock		18	minimum
Between outside heads of rails for double track	6	0	minimum
For additional single running lines or double lines alongside existing main lines	10	0	minimum
Running face of rail to structure	4	9½	
Overhead clearance between load gauge and structure		6	minimum
		12	desirable
Clearance between bodywork of stock on adjacent lines	1	6	minimum
Maximum height of existing load gauge above rail level varies from	13 ft. to 13 ft. 9 ins.		
Height of structure above rail level	15	0	desirable
Width between structures, single track	14	4	minimum
" " " double track	25	6	minimum

Note.—Additional clearances required for curved or canted track.

Total breadth on top of embankments and bottom of cuttings about 18 ft. for single, and 30 ft. for double lines.

Platforms.

The minimum clear width of any platform throughout its length to be 6 ft. At important stations the width to be not less than 12 ft., except for short distances at either end in any case of difficulty. In the case of island platforms, the minimum width for an adequate distance on each side of the centre of its length to be 12 ft. The descent at the ends of platforms to be by ramps and not by steps.

Columns for the support of roofs, and other fixed works, not to be less than 6 ft. clear from the edge of platforms. A general clear headway of not less than 8 ft. to be provided over platforms. The height of platforms above rail level may vary according to traffic and other conditions; as a rule, it should be 3 ft., but in no case less than 2 ft. 9 ins. or more than 3 ft. at permanent stations, without special approval.

The edges of the platforms to overhang not less than 12 ins., and the recess so formed to be kept clear as far as possible of permanent obstruction.

Gradients.

It is desirable to avoid constructing a station on, or providing a siding in connection with a line which is laid upon a gradient steeper than 1 in 260.

Economic System of Track Maintenance.

On branch lines where traffic is light and the sections extensive, considerable success has been attained in this country by the use of rail motor trollies and a system of 'occupation keys.' Key boxes in telephonic communication with the signal boxes are fixed at convenient intervals along the section of line and before a trolley is placed on the running line the ganger withdraws the key, which is electrically released from the signal box. The key can be removed from, and replaced in, any of the key boxes and affords complete protection to the holder, as whilst the key is withdrawn the signalman cannot allow a train to enter the section of line occupied by the trolley. On arrival at the site of work the trolley is removed clear of the line and the key replaced in the nearest convenient occupation box; the ganger then informs the signalman by telephone from

the box that the section is clear and normal working may be resumed. The key cannot be withdrawn again without the signalman's permission. The G.W.R. were the pioneers of the use of the motor trolley for track maintenance purposes in this country, and at present over 1,000 miles of track is maintained by this system.

Chemical Weed Killing.

The reduction in the strength of branch line gangs brought about by economic systems of maintenance, has made it necessary to use chemical weed killers in increasing quantities, and so far as Great Britain is concerned excellent results are being obtained by the use of 'Atlacide' (calcium chlorate), which is obtained in the form of a liquid concentrate.

The chemical is sprayed on the foliage of the weeds after mixing with water in the proportion 1 gallon of concentrate to 6 gallons of water, which represents a 7·2 per cent. solution by weight of chemicals.

On the former G.W.R. a considerable mileage of track is treated in this manner by a special weed-killing train, which, travelling at 20 m.p.h., can deal with about 25 miles of single line at one filling. In addition to the engine and brake van the train comprises three water tenders (total capacity 9,500 gallons) and a rail tank wagon containing the concentrate. The tenders are filled to six-sevenths of their capacity with water, and concentrate is pumped into them from the tank wagon until full and thoroughly mixed by steam from the engine, which also operates the spray pump on the tenders.

The action of 'Atlacide' on weed growth depends on the absorption of the chemical by the leaves and stems, hence it is necessary to delay spraying until the weeds have made sufficient growth to enable the foliage to be well covered. Fine grass is not affected to the same extent as the larger weeds.

Switches and Crossings.

***Design.*—The older types of switches, or points, in which the tongues were hinged on the fishplates at the heel necessitating the fishbolts being left slack, are now generally being superseded by 'heel-less' flexible switches, the tongues of which are made longer and held in fixed chairs for a distance of about 3 ft. 6 ins. from the heel joint, giving a minimum length of approximately 17 ft. for springing them to the required opening at the toe, which varies from 3⅜ ins. to 4½ ins. Most English railways have now adopted as standard, designs which provide for a straight tongue for the length of the side planing, the remainder of the switch being curved. The practice of the G.W.R. is to curve the tongue throughout, which gives a smaller deflection angle at the toe for the same length of switch. Switches and crossings are usually laid on creosoted cross timbers, 12 ins. or 14 ins. wide, 6 ins. deep, and varying in length from 9 to 35 ft.**

***Calculations.*—The method now generally adopted for describing the angle of a crossing (1 in N) is by the length in feet (N) along the centre line to the point where the gauge lines are 1 ft. apart (measured perpendicularly to the centre line) and this method (Centre Line Measure) is used in the formulae on pages 2039 to 2044.**

If

θ is the crossing angle measured in degrees,

$$N = \tfrac{1}{2}\cot\frac{\theta}{2}$$

and

$$\theta = 2\cot^{-1} 2N.$$

Ministry of Transport Regulations for Permanent Way.

British Standard Specifications and Sections for all details of permanent-way to be adopted, unless authority to the contrary is given. On lines on which the normal traffic is heavy and worked at high speed, the weight of new rails should not be less than 85 lbs. per yard, and, in the case of a chaired road, the common chairs should not weigh less than 45 lbs. each. On lines where traffic conditions are less severe, chairs weighing not less than 40 lbs. each may be used. The minimum length of rail, as a rule, to be 30 ft. On lines normally used for light traffic and moderate speeds, lower weights of rails and chairs may be used.

Chairs, if used, must be secured to the sleepers, at least partially, by metal bolts, screws, or spikes. With flat-bottom rails, or bridge rails, the fastenings at joints and at one or more intermediate places to consist of fang or other through bolts, and such rails, on curves with radii of 15 chains or less, to be tied to gauge by iron or steel ties at suitable intervals.

Fixed diamond crossings must not be flatter than 1 in 8 except in special circumstances. Movable diamond crossings may be at any angle and are to be treated as worked facing points.

Lengthening Life of Track.

Apart from the use of the most suitable material and design for individual components the life of track as a whole for equal traffic and atmospheric conditions depends very largely upon the standard of maintenance attained and particularly to the attention it receives during the early period of its service life.

Good drainage is of prime importance and this demands clean ballast free from dirt and weeds and, where they exist, regular attention to drains, ditches and catchpits.

The maintenance of good top, regular alignment and gauge does much to prolong the life of the track. Rail joints need special attention and wear should be taken up, if necessary by the use

FIG. 22.

of shims, and rail ends should be oiled or greased periodically to assist free expansion and contraction. Sleeper fastenings should be kept tight to minimise vertical movement between sleeper and chair or baseplate and any tendency for the sleepers to split should be corrected at an early stage if possible by the application of suitable dogs or clamps.

In the case of bull-head track wooden rail keys call for close attention in dry warm weather when they are liable to work loose due to shrinkage. New keys should be driven or the old ones re-driven with liners of the required thickness. Inefficient keying results in movement between rail and chair increasing galling of both components and causing gauge irregularities which in turn lead to intermittent side wear of the rails and lateral oscillation of rolling stock.

In some districts and especially in tunnels rail corrosion is a serious problem leading in some instances to failures attributable to corrosion fatigue—minute cracks developing at the bottom of corrosion pits due to concentration of stress.

Most railways have experimented from time to time with various methods designed to delay corrosion in such circumstances, *e.g.* painting with red lead, tarring, etc., and the Norfolk and Western Railroad (U.S.A.), has set up a special plant for spraying tunnel rails with Texas 45 Preservative Coating (containing 45 per cent. asphalt), following a thorough descaling by special oxy-acetylene flame heads. Joint bars (fishplates) are dealt with similarly.

The Great Western Railway of England is faced with a particularly difficult problem of rail corrosion in its Severn Tunnel—4 miles 624 yds. long and varying from 30 to 45 ft. from bed of river to crown. The normal practice here for many years has been to clean the new rails as thoroughly as possible by wire brushing, etc., and apply a coating of carbon tar paint, but a special test is in progress in which the rails were first flame cleaned, then chipped and wire brushed as necessary, followed whilst still warm by a coat of red lead brushed well in. This was followed by a second coating of a special tar mixture containing small proportions of tallow, lime and creosote. Similar coatings but without flame cleaning have been experimented with amongst other preservatives by the London and North Eastern Railway.

Cost of Railway Construction.

In England, taking a fairly representative section of one of the main lines, outside the Metropolis, and constructed prior to 1914, as an example, the percentages of the cost of about 40,000*l.* per mile, work out somewhat as follows :—

	Per Cent.		Per Cent.
Land and compensation	10	Sidings	3
Fencing	1½	Junctions and signals	1
Earthworks	24	Stations, including buildings (roadside only)	6½
Tunnels	12	Contingencies, including parliamentary, administration, legal and engineering expenses	6
Viaducts	8	Maintenance	½
Bridges for roads	9		
Accommodation works	2		
Culverts and drainage	5		
Permanent way, ballast, including main line	11½		
			100

From this it will be seen that, for country lines, the value of land does not form so important a factor in the total cost as is generally understood. The necessity for very easy gradients, and flat curves, in order to admit of high speeds, involves heavy earthworks, viaducts and tunnels, and expensive, well-ballasted permanent way, whilst stations and sidings have to be extensive to accommodate the traffic.

Experience has shown how to adapt the design of railways to their special surroundings. Their cost has varied from about 630,000*l.* per mile in London, and from an average of 52,378*l.* per mile in the United Kingdom, and of 8,127*l.* per mile in India, to a cost, in some parts of South Africa and South America, of 3,200*l.* to 3,500*l.* per mile, or, with equipment, of 4,000*l.* per mile—a rate at which, in new countries and under fairly normal conditions, railways can be provided, suitable for a speed of 30 miles per hour, and for heavy trains. Quantity of Land required for a Line of Railway.

This depends upon the width as determined by the depth of cuttings and height of embankments. Assuming average depth and height of 3 feet, and slopes of 1½ to 1, 5 to 6 acres will be required per mile of single line (4 ft. 8½ ins. gauge), made as in England, exclusive of sidings or stations. For each foot added to or deducted from the average of 3 feet given above (same slopes), 1 yard in width, or ⅜ acre per mile, must be added or deducted.

Light or Narrow-Gauge Railways.

Narrow-gauge railways will be found very suitable in districts where a standard-gauge line could not be made to pay, on account of the greater cost of construction and working of the latter. Narrow-gauge railways occupy less land, and the earthworks are of a less expensive kind

than for standard-gauge lines, as heavy embankments and cuttings can be avoided by adopting sharper curves than are admissible with the standard gauge.

For the permanent way light material can be used, the rolling stock can be constructed to give a more favourable proportion between the dead and the paying loads than is possible on standard-gauge lines, particularly if the traffic is made up of a great number of small consignments. On narrow-gauge lines the average proportion of dead load to paying load may be taken at about 1 to 2·33.

Whether steel or wood sleepers should be used is principally a question of cost, but it should be borne in mind that steel sleepers have a much greater life than wood sleepers.

The gauge and weight of rail should be determined in every case after a careful inquiry into the earning powers of the line. For the rails a weight of 25 lbs. per yard would be about the minimum. The 2-ft. gauge has the great advantage that it can be worked best in combination with portable railways which are joined on to branches of permanent line and continued to the farmyards, fields, or factories. The 2-ft. gauge is especially suitable for private lines and for lines of public utility with limited goods and little passenger traffic. It can be worked at a speed of fifteen miles per hour with curves 100 to 150 feet radius and gradients 1 in 80, for public lines; while on private lines, curves down to 60 feet radius and gradients up to 1 in 25 are admissible, according to the speed required and the amount of traffic. For lines with extensive goods traffic or principally for passenger traffic, 2 ft. 6 in. or 3 ft. gauge would be preferable.

If the goods are of a nature that they will not stand handling, the narrow-gauge wagon bodies could be made of such dimensions that three or four would fit into one main-line truck. A very simple device is also in practical use, of putting the main-line trucks on specially constructed bogies, and thus transporting them over the narrow-gauge railway.

(*A. Koppel.*)

The use of locomotives is not profitable on gauges of less than 18 inches.

The speed on narrow gauges may be as follows:—

2 ft. 0 in. gauge, 15 miles per hour.	3 ft. 0 in. gauge, 25 miles per hour.
2 ft. 6 in. gauge, 20 miles per hour.	3 ft. 6 in. gauge, 30 miles per hour.

Cost of Light Railways.

A fact which has militated against light railway construction is that the cost in Great Britain is very little less than that of building standard railways, ranging from £12,000 per mile in difficult country to £3,333 under easy conditions, while the average return on capital has been only a little over 2 per cent. On the other hand, the Decauville system of light railway adopted in the Argentine can be laid for £1,240 per mile, and the Road-Rail system, as tested in Uganda, South Africa, and Morocco, for £1,250 per mile. Another cheap form of rail transport is the Rutway, which it is said can on ordinary ground, such as the plains of India, be laid down, in lengths of 20 miles or more, at a cost of only about £1,000 per mile, including the provision of rolling stock. In this case the wheels run without any flanges on flat metal surfaces at the bottom of two deep ruts in the lowest part of the permanent way, and are confined to these ruts by the vertical sides of the rail angles and by the stone ballast heaped up along either side of each rail.

Superelevation of Outer Rail on Curves.

The effect of centrifugal force on vehicles travelling round a curve is usually counteracted, at least partially, by raising the outer rail of the curve above the level of the inner rail, thus giving the track a transverse slope.

If G = gauge (rail centres) in feet, V = speed of vehicle in miles per hour, R = radius of curve in feet, and e = amount of superelevation in inches, then theoretically

$$e = \frac{GV^2}{1 \cdot 25R}$$

In practice only three-quarters or seven-eighths of this cant is usually applied with a maximum of about 6 ins., or approximately one-tenth of the gauge, but it is now generally agreed that the desirable superelevation in any particular instance is not very critical provided the amount selected is attained from the level very gradually and maintained at a strictly uniform figure throughout the length of the curve. There is in fact a general tendency among railway engineers to-day to permit a deficiency of cant to the extent of from 2 to 3 ins. below the theoretical figure without a corresponding reduction in the permissible maximum speed.

The gain or loss of superelevation on high-speed lines should not be effected at a greater rate than 1 in 1200 where practicable, whilst 1 in 300 should be considered the absolute limiting cant gradient in all cases.

Whilst superelevation is desirable for reasons of comfort its safety value has in the past undoubtedly been largely over-rated and there are in existence many junctions which, for various reasons, have had to be laid without superelevation and which are regularly run over at speeds of 40 m.p.h. and over without noticeable discomfort or excessive rail wear.

A recent innovation consists of two-level rail chairs the use of which enables a certain amount of superelevation to be provided through junctions of fairly sharp curvature. In one such case this treatment has permitted a speed restriction of 20 m.p.h. to be relaxed to 40 m.p.h. These chairs were produced by Taylor Brothers (Sandiacre), Limited, in collaboration with the Chief Engineer of the former L.M. & S.R. Company.

The following is an extract from a table giving particulars of the superelevation provided for in the regulations of one of the Home railways according to the curvature, and speed of trains.

Radius of Curve. Chains.	Superelevation in Inches. Speed in m.p.h.

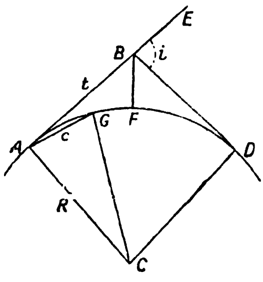

FIG. 33.

RANGING OUT CURVES.

Ranging out Curves with a Theodolite.

R = radius of curve = AC. i = angle of inclination of intersection = EBD. t = tangent AB or BD = R tan $\frac{i}{2}$.

Length of curve = AFD = ·0002909Ri.

Tangential (or 'setting off') angle (angle between c and t) in minutes for any chord c

$$= 1718{\cdot}873\ \frac{c}{R}.$$

R and c being expressed in feet or chains and i in minutes.

The angle ACG is called the 'deflection' angle, and is twice the tangential angle, *i.e.* the tangential angle is one-half the deflection angle.

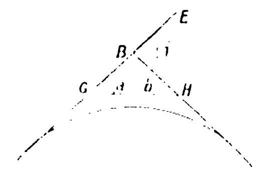

FIG. 34.

To find the Angle of Intersection and Point of Intersection where the latter is inaccessible.

If B is the inaccessible point, then—

Range the line GH.

$$i = a + b,$$

$$GB = \frac{GH \sin b}{\sin i}, \quad HB = \frac{GH \sin a}{\sin i}$$

TABLE OF TANGENTIAL ANGLES FOR CHORDS OF 1 FOOT AND 100 FEET.

A curve in America is expressed as an $n°$ curve (deflection angle), and is one of such a radius that a chord of 100 ft. subtends an angle of $n°$ at the centre.

$$R \text{ in feet} = \frac{5730}{n°}$$

Setting out Curves by Offsets.

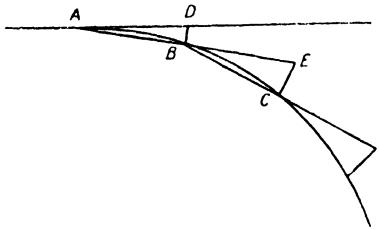

FIG. 35.

First offset BD from the tangent line.

$$DB = \frac{AD^2}{2\ \text{radius}}.$$

Offset from any chord AB produced

$$\text{to E} = EC = \frac{AE \times EB}{2\ \text{radius}}.$$

Or where AB = BE, then

$$EC = \frac{AB^2}{\text{radius}}.$$

Transition Curves.

When a train travels round a circular curve radial acceleration varies directly as the square of the speed and inversely as the radius, disappearing entirely when the radius is infinite, that is, when the track is straight. A transition curve or easement spiral (fig. 36) is, therefore, inserted between a tangent and a regular circular curve or between two curves of the same 'hand' but differing in radius in order that the radial acceleration shall be attained gradually in the length of the transition curve. The absence of suitable transition curves not only gives rise to very uncomfortable running conditions but also makes it impossible to maintain the track in its proper alignment.

Many forms of spiral have been advocated for this purpose but the curve which best fulfils all the requirements of a true transition is the spiral, the intrinsic equation of which is :—

$$l = m\sqrt{\phi}$$

It can be shown, however, that for the majority of railway purposes the cubic parabola is a very close approximation and can be set out by means of rectangular offsets from the tangent by the formulae shown in fig. 36.

The length L can be determined by one or other of the following methods :—

(*a*) If, as usual, it is required to run up a given amount of superelevation required on the circular arc in the transition length, the latter (in feet) should not be less than $V^3/17\ R$, where V is in miles per hour and R is measured in chains. This formula provides for the superelevation being attained at a maximum rate of $1\frac{1}{2}$-in. per second, which is generally recognised as reasonable.

(*b*) If there is no superelevation to be considered L should not be less than $V^3/21\ R$. This assumes that radial acceleration can be increased without discomfort at the rate of 1 ft. per second per second per second.

When using the formulae of fig. 36 it will be found that where the ratio R/L is much less than say 4, difficulties in setting out arise, especially near the junction of the transition with the circular

curve. This is due to the approximations employed in the derivation of the usual formulae and in such instances more accurate formulae should be used to ensure the best results. Such formulae are not difficult to derive from the equation to the cubic parabola but are somewhat cumbersome. If, however, 'c' is substituted for the ratio R/L the following simple relations can be established.

$$p = \frac{(4c^2 - 1)^{\frac{3}{2}}}{8c^3} \qquad Y = \frac{1}{6p} L = qL$$

$$D = \frac{c}{\sqrt{1 - 4p^2}} L = mL$$

$$S = (q + 2mp - c)L = nL$$

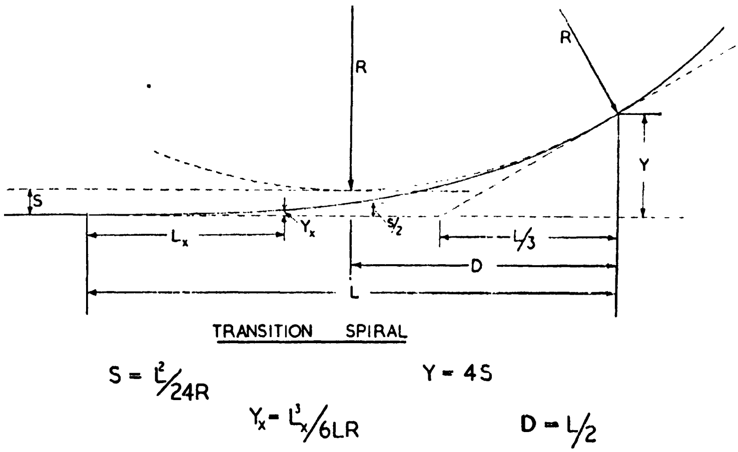

FIG. 36.

From this the following table of factors may be calculated for obtaining Y, D and S for selected values of '*c*.' To use the table select the nearest suitable ratio '*c*' for the transition to be set out and, if necessary, adjust the length L slightly so that the resulting ratio R/L corresponds exactly with one of the ratios in the table.

Ratio R/L.	Multiply L by these Factors to Obtain		
c	Y	S	D

It has been shown that the radius of a curve may be reduced 15 per cent. without the necessity for introducing a transition between the original and sharpened curves.

The alignment and superelevation for all transition curves should be marked on the ground by means of permanent concrete monument blocks so that the transition may be maintained to correct shape and reproduced accurately following renewal of the track.

Vertical Curves for Joining Gradients.

For important railways, rates of change of 0·1 per 100 ft. on summits, and 0·05 in sags should not be exceeded. On minor railways 0·2 per 100 ft. on summits and 0·1 in sags might be used.

The length of curve should be about 600 ft. at summits, and 800–1,200 ft. in sags.

(American Railway Engineering Association.)

Track Circuits—Insulated Rail Joints.

The steadily increasing mileage of track circuits installed in recent years has resulted in the necessity for providing a larger number of insulated rail joints.

Numerous arrangements have been experimented with from time to time but until a few years ago block joints on the whole consisted of ordinary steel fishplates machined on the bearing surfaces to permit the insertion of thin fibre channels between the plates and rails, the gap between adjoining rails being filled by a suitably shaped fibre end post. The fishbolt holes in the rails were enlarged to take fibre ferrules surrounding the bolts.

In heavily worked yards or where atmospheric conditions were unfavourable this type of joint gave a short life and the fibre insulation required frequent renewal.

Alternative joints now used to some extent are illustrated in figs. 37 and 38.

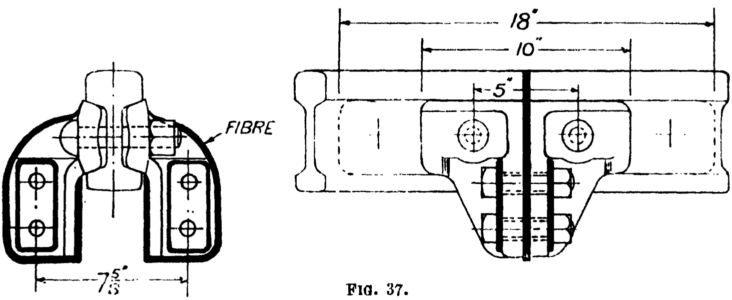

FIG. 37.

Fig. 37 is the Henry Williams drop-forged fishplate in which the insulating fibre is not subject to mechanical wear, the load on the joint being transmitted by means of side flanges secured together by bolts.

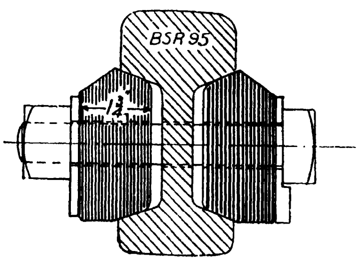

FIG. 38.

Fig. 38 shows the cross section of a pair of laminated wooden fishplates manufactured from 'Permali,' an efficient insulator made from compressed laminations of various woods impregnated with synthetic resin. This type requires no fibres and both designs obviate the use of bushes in the fishbolt holes, thus being easier and cheaper to install.

WEAR OF RAILS—CONTOUR OF TOP TABLE.

A comprehensive survey of worn rails of varying sections carried out by the Great Western Railway a few years ago led to the conclusion that whatever the original profile of the head might have been it sooner or later conformed to the average curvature shown in fig. 39.

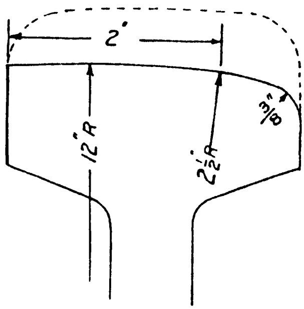

FIG. 39.

As will be seen the worn curves are considerably sharper than the 12-in. radius of a new B.S.95 R.B.H. rail, and this fact probably accounts for the bad running due to bogie hunting sometimes experienced when high speeds are attained over straight track recently relaid with new materials.

In 1935 the G.W.R. designed a new rail section (95½ lb. per yd.) with a modified head to conform as far as practicable with the curvature of this average worn rail and later embodied the same alteration in a new 100-lb. rail.

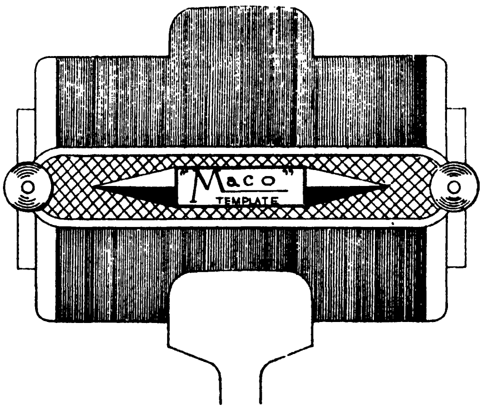

FIG. 40.

The profiles of worn rails may conveniently be ascertained by means of the 'Maco' Adjustable Template (The P. & M. Co. (England), Ltd.) illustrated in fig. 40. This comprises innumerable very fine strips of brass securely clamped in a metal framework and capable of following practically any irregular outline. The device gives male and female profiles simultaneously and pencil sections may conveniently be obtained by drawing round the template on to a suitably backed sheet of paper.

New Standard Rails—British Railways

Early in 1949 the British Transport Commission approved a recommendation from the Railway Executive to adopt flat bottom rails as the future standard for British Railways. Two sections have been designed, viz. 109 lb. for main lines and 98 lb. for less important routes, and the following table gives their salient features compared with the nearest sections in B.S.S. 11–1936.

		109 lb.	98 lb.	B.S. 110	B.S. 100	B.S. 95A

SECTION XXXII

PART II

LOCOMOTIVES AND ROLLING STOCK.

LOCOMOTIVES — RAIL MOTOR CARS — CARRIAGES AND WAGONS—BRAKES.

(Revised by H. Holcroft, Member of Council, Institution of Locomotive Engineers.)

STEAM LOCOMOTIVES.

Some Recent Additions to British Locomotives.

No standard types have as yet been produced under the unification of the four Groups as British Railways. In the meanwhile each Region is continuing the construction of existing designs by the former Companies.

For the heaviest main line work the London Midland Region has adopted a 4–6–2 or ' Pacific ' type locomotive with four high-pressure cylinders. The Eastern and Southern Regions also use the same type, but with three high-pressure cylinders. Otherwise the bulk of the heavy work on British railways is performed by the 4–6–0 type, with two, three or four cylinders and wheels about 6 ft. 8 ins. diameter. The S.R. and E.R. have a number of powerful engines of the 4–4–0 type, with three high-pressure cylinders. The L.M.R. has many engines of the same type, but they are three-cylinder compounds.

For mixed traffic all the British railways have engines of the 4–6–0 type with two cylinders and wheels about 6 ft. diameter. The E.R. has also three-cylinder engines of the 2–6–2 type, and the S.R. two- and three-cylinder engines of the 2–6–0 type with 6 ft. diameter wheels.

All the British railways have a large number of fast freight engines of the 2–6–0 type with wheels about 5 ft. 6 ins. diameter, both two- and three-cylinder. The Western Region is, however, now building a two-cylinder 4–6–0 type with this wheel diameter instead of the 2–6–0 type. The S.R. have also a number of similar engines.

The heaviest mineral traffic on the E.R. is run by three-cylinder engines of the 2–8–2 or 2–8–0 types. Two-cylinder engines of the 2–8–0 type with wheels about 4 ft. 8 in. diameter have been uilt by the L.M.R. and W.R.

The 0–6–0 type is still being built by British railways in the form of a superheater engine with inside cylinders. The greater part of the freight traffic is handled by this type, and many of the older engines have been modernised by re-building and superheating.

Passenger tank engines of the 2–6–4 type, both two- and three-cylinder, have been constructed by the L.M.R. Other three-cylinder engines for freight service are those of the 2–6–4 type on the S.R. and the 2–6–2 type on the E.R. The latter is now putting into service two-cylinder tanks of the 2–6–4 type. The L.M.R. and the W.R. build the 2–6–2 type with two cylinders.

The ' Garratt ' articulated type of locomotive, which is extensively used on colonial railways, has been adopted to a limited extent on the L.M.R. for hauling heavy mineral traffic. An engine of this type, but having two sets of three cylinders, is in use on the E.R. for banking heavy mineral trains up a steep gradient.

Although no radical departures from normal locomotive design have been made on British railways, various experimental locomotives, having novel features, have been tried from time to time. The L.M.R. has a 4–6–2 type driven by a high-pressure turbine through reduction gearing. No condensing is provided in this case, the turbine exhausting at a pressure slightly above atmospheric through the blast pipe in the smoke-box.

DEVELOPMENTS ABROAD.

Immediately before the war the Germans put a 4–8–4 type express locomotive into service. Two turbine-driven locomotives on hand were destroyed by bombing. During the war years locomotives were of the 'utility' pattern, of the plainest and simplest construction. In Germany a large number of Class 52, 2–10–0 type locomotives were built in which hand and machine work was cut down to a minimum. Flame-cut plates, brake work, etc., were left unmachined. Coupling and connecting rods were made from drop-forged ends welded to a length of rolled bar. Later engines of the class had boilers with cylindrical corrugated fireboxes. Some of these locomotives were built as condensing engines.

Prior to the war the most striking developments in locomotives were, perhaps, those made on the French railways. A programme of modernisation of existing engines was undertaken and special attention given to the design of steam pipes and passages, valves and valve-gear, exhaust passages, in order to minimise the drop in pressure between boiler and cylinders and to reduce back pressure. Boiler pressure was increased to 290 lb. per sq. in. and a thermic syphon added to the firebox, while a new form of superheater, feed-water heating and improved smokebox arrangement increased the capacity. The horse-power output of the engines was raised by 50 to 100 per cent., and remarkable results in the way of hauling very heavy passenger trains at high speed were realised.

Since the war the French railways have introduced a number of new types experimentally, of both high-pressure and compound working. They include a 2–12–0, six-cylinder compound heavy freight engine, a 4–6–4 type, one of which is three-cylinder simple and the other four-cylinder compound; and a 4–8–4 type three-cylinder compound.

Elsewhere on the Continent the three-cylinder simple engine continues in favour. In Czecho-Slovakia express engines of the 4–8–2 three-cylinder type have been built with all-welded boilers, bar frames and roller bearings to all axleboxes. A three-cylinder 4–8–0 type in Sweden also has bar frames and roller bearings to all axles. In Holland a 4–6–0 three-cylinder passenger locomotive and a three-cylinder 0–8–0 freight engine have roller bearings throughout. A 4–8–2 type has been supplied to one of the Spanish railways.

Large numbers of American-built 2–8–2 and 2–8–0 'Liberation' locomotives of the two-cylinder type have been brought over for the rehabilitation of Continental railways.

In Australia, the use of three-cylinder locomotives is being extended.

American locomotives are of larger size than those in use elsewhere, and fireboxes have grown to such an extent that a four-wheeled truck is required at the trailing end, hence such types as the 4–6–4, 4–8–4 and 2–10–4. The speed of freight services is increasing and freight engines are built with larger diameter wheels in consequence. Two-cylinder engines are preferred and the cylinders can be of large size on account of the wide loading gauge. Boiler pressures tend to increase. New construction has, however, been considerably slowed down by the increasing use of diesel-electric traction.

As a result of the competition of lightweight high-speed trains propelled by oil engines several steam locomotives have been designed in Germany, France, Belgium, and the United States for operating lightweight trains. These locomotives are partly or fully stream-lined and are capable of speeds in excess of 100 miles per hour, but otherwise follow conventional design in their construction.

Locomotive Types.

The classification of locomotives is by wheel arrangement. Abbreviations are used, the Anglo-American system denoting in their order leading carrying wheels, coupled wheels, and trailing carrying wheels by number of wheels to each group. Where there are no carrying wheels at either end a cipher is added. The letter T denotes a tank engine. Articulated engines are denoted by the wheel arrangement of their separate parts. The Continental system merely states number of axles coupled and total axles of engine, and gives the proportion of adhesive weight without specifying the actual arrangement of wheels. In addition to identity by wheel grouping, the various types receive code names in America. Example:

Diagram.	Code Name.	Anglo-American Notation.	Continental Notation.
	**Atlantic**	**4–4–2**	**2–5**
	**Mogul**	**2–6–0**	**3–4**

In France it is usual to classify a locomotive by groups of axles in their order, instead of by wheels: thus a 4–4–2 engine is known there as type 2–2–1 ; and a 2–6–0 engine is expressed as type 1–3–0.

Another system coming into general use is similar to the French, but groups of coupled axles are represented by letters—A for one driving axle, B for two, C for three, etc. : so that a 4–4–2 engine becomes type 2–B–1. A 2–6–0 engine is denoted by 1–C only, a cipher not being necessary to indicate absence of carrying wheels with this system. Uncoupled driving axles are denoted by the suffix ' O,' thus 2–D$_o$–1 represents a locomotive with a four-wheeled bogie, four uncoupled driving axles and a pair of trailing wheels. This system is used in the case of electric or Diesel-electric locomotives.

Types of Locomotives most generally used on British Railways.

Tender Engines.

Type.	Principal Use.	Type.	Principal Use.
0–6–0	Ordinary goods traffic	4–4–0	Fast passenger trains
0–8–0	Mineral traffic	4–4–2	Main line express
2–8–0	Heavy goods traffic	4–6–0	Heavy express and fast freight
2–6–0	Mixed traffic	4–6–2	Exceptionally heavy express

Tank Engines.

Type.	Principal Use.	Type.	Principal Use.
0–4–0	Private yard shunting	2–6–2	
0–6–0	Ordinary shunting	4–6–0	Main line goods trains
		0–6–2	
		0–4–2	Light and Suburban passenger trains
0–8–0		0–4–4	
0–8–2		0–6–4	
0–8–4	Heavy shunting, banking and mineral trains	2–6–4	
2–8–4		4–4–2	
4–8–0		4–6–2	Main line passenger trains
2–8–0		4–6–4	

The particular uses of the various types of tank engines are not so well defined as with tender engines. Several of the engines specified for goods traffic are often used on passenger trains, and *vice-versa*. Generally speaking, the total adhesion type (i.e. engines without carrying wheels) are mostly used for shunting and local work. Carrying wheels are added as the water and coal capacity are enlarged to permit of greater radius of action. The tank engines with two or more pairs of carrying wheels are capable of travelling considerable distances without replenishing fuel and water.

Articulated Locomotives.

On railways having a limited axle loading and tracks abounding in sharp curves and often of narrow gauge, a powerful locomotive can be provided by a division of the driving wheels into two independent groups, one or both being separated from the main framing of the engine and attached only by flexible connections. In the Fairlie and Kitson-Meyer designs the boiler, tanks, and coal-bunker are carried on a main frame supported by two steam-driven bogies, the centres of articulation being near the centre of the wheel base of each bogie. The ' Mallet ' type, first used in France, has been developed to an enormous size on American railways as a tender engine. High-pressure cylinders drive the axles on the main frame which carries the boiler, while a steam bogie driven by high- or low-pressure cylinders supports the smoke-box end of the boiler. The ' Garratt ' type is now extensively used on British colonial railways, in South America, and elsewhere. The boiler alone is carried on the main frame, the water-tanks and coal-bunker being supported by two steam-driven bogies. By this arrangement the centres of articulation are brought nearer together, the pivots being towards the inner ends of the bogies. Very powerful locomotives of this type have been constructed for the 3 ft. 6 ins. gauge in South Africa, Western Australia, and New Zealand, both for passenger and freight services.

The 4–6–2 + 2–6–4 Garratt type has recently been used for high speed passenger trains in Algeria and has been tested in Northern France for speed and haulage on heavy expresses ; the driving wheels are 5 ft. 11 ins. diameter and speeds up to 72 miles per hour have been run with safety.

The leading particulars of a recent 'Garratt' engine for the South African Railways are as follows:—Type 4–8–2 + 2–8–4, class GL, freight service, cylinders 4, size 22 ins. by 26 ins., bogie wheels 2 ft. 4½ ins. diameter, coupled wheels 4 ft. 0 ins., trailing wheels 2 ft. 9 ins. Coupled wheel base 13 ft. 3 ins., total wheel base of each unit 27 ft. 8 ins., total wheel base 83 ft. 7 ins. Centres of articulation 41 ft. 6 ins., working pressure 200 lbs. per sq. in. Grate area 74·5 sq. ft. Heating surface of tubes 3,036 sq. ft., of firebox 340 sq. ft., superheater surface 809 sq. ft. Adhesive weight 147 tons 8 cwt. Total weight 214 tons 2 cwt. Coal 12 tons, water in tanks 7,000 galls. Tractive effort at 75 per cent. of boiler pressure 78,650 lbs. The track on which these engines run is of 3 ft. 6 ins. gauge laid with 80-lb. rails, for which the maximum axle load is 18½ tons. The maximum gradient is 1 in 30, and the curves 300 ft. radius.

FIRELESS LOCOMOTIVES.

The fireless steam locomotive is adopted in industrial areas where fire prevention is essential. It is capable of performing shunting work and operating short distance traffic. Simplicity and low cost of maintenance are factors in its favour. A good deal of development has taken place in Austria in recent years. At one works 400-ton trains are drawn a distance of 4½ miles over gradients of 1 in 50 at a speed of 20 m.p.h., involving a cylinder horse power of 1,000. The storage pressure of 1,200 lbs. per sq. in. is reduced to 215 lbs. for the cylinders. Recharging from power station boilers takes 15 mins.

In Italy it is proposed to charge the steam accumulators electrically and so obviate need for stationary plant.

General Design of Locomotives.

The principal limitations governing locomotive design are:—

(1) *Loading gauge*, giving extreme dimensions as to heights and widths.

(2) *Rail gauge*, affecting stability, etc.

(3) *The track*, which limits the maximum axle load.

(4) *Bridges*, the strength of which restricts the weight per ft. run over total wheel base.

(5) *Curves*, which limit the length of engine and determine rigid wheel base.

Other factors to be taken into consideration are:—

(1) *Loads*, as to weight and type of rolling stock.

(2) *Gradients*, both ruling and maximum.

(3) *Resistance of curves.*

(4) *Speed.*

(5) *Prevailing atmospheric conditions.*

These are inter-related, load becoming a maximum for both directions of travel when there are no gradients or curves and the speed is low. An increase in speed or the presence of gradients, curves, and side winds reduces loads.

Some further points to be looked into when designing new engines are:—

(1) *Length and strength of turn-tables* and clearances round them.

(2) *Engine sheds*, as to clearances, length of pits, etc.

(3) *Coal stages* height of platform, method of coaling, etc.

(4) *Position of water columns* at stations and in yards in relation to signals and points.

(5) *Distance between available coal and water supplies.*

(6) *Capacity of workshops*, in regard to load on cranes, length of pits and traversers, necessity for special tools, etc.

The bulk of the work on British railways is done by tender engines of the 0–6–0 type for goods and 4–4–0 type for passenger trains. Many of these engines are of fairly recent construction. Some of the older engines have been brought up to date by being rebuilt with larger boilers fitted with superheaters and with new cylinders provided with piston valves. The goods engines usually have cylinders 19 ins. × 26 ins. and wheels 5 ft. 0 ins. diameter; the passenger engines 20 ins. × 26 ins. cylinders and 6 ft. 6 ins. wheels. Boiler pressure is about 180 lbs. per sq. in.

For heavy passenger work the 4–6–0 type is resorted to. The 4–6–2 type hauls exceptionally heavy trains at high speeds. For mineral traffic and long goods trains an eight-wheel coupled engine is used. The 2–6–0 type with wheels about 5 ft. 6 ins. is extensively used as a mixed traffic engine, and a similar engine of the 2–8–0 type has been introduced for heavier trains of this description. They are especially suitable for fast goods, excursion trains, etc. In the large passenger and goods engines outside cylinders predominate. The advantages claimed for the outside position are shorter wheel base, long connecting rods, no crank axle, direct drive through rods on all wheels, horizontal cylinders. The distance between centres of cylinders is about 6 ft. 8 ins. and cannot be reduced very appreciably on account of the necessity for finding sufficient bearing surface for coupling and connecting rods. Thus, the diameter of cylinders is limited by the remaining space within the load gauge, which varies on the different railways. Since the load gauge is at its narrowest near rail level, advantage can sometimes be gained by inclining outside cylinders so that they are brought up into a wider part of the gauge.

The demand for larger cylinder capacity can be met by increased diameter or stroke of cylinders, or both. Another way is to multiply the number of cylinders, hence three- and four-cylinder high-pressure engines. Multi-cylinders are also being adopted for mechanical reasons, as they give better balancing and turning movement, less disturbance in running, subdivision of driving forces, increased bearing areas and other advantages. Multi-cylinder engines are necessarily more costly and complicated than two-cylinder. It is therefore desirable to reduce their working parts to a minimum. This can be done in the case of four-cylinder engines by providing two sets of valve gear only and operating the additional valves through rocking levers attached to the valve gears.

Three-cylinder engines can be arranged in a similar manner by adopting a conjugated gear for the inside cylinder. In this case the valves of the outside cylinders are directly operated by their respective valve gears which also indirectly operate the inside valve through a simple system of levers attached to them. Some designers prefer an independent valve gear for the middle valve.

Boiler pressures tend to increase; 200 to 250 lbs. per sq. in. is now common, and 280 lbs. has been reached.

'Poppet' or double-beat lift valves, which have been used to a limited extent on the Continent for some years, have undergone trials under British railway conditions and a small number of engines have been so equipped. Indian and Colonial railways are adopting them more extensively.

Current American practice includes bedplates of cast steel with integral cylinders, roller bearing axleboxes, boosters, fireboxes with arch tubes and syphons, and feed water heaters.

Some recent American locomotives are of enormous size. For the heaviest freight traffic Mallet articulated compounds are in use on the Virginian R.R. weighing, with tender, nearly 400 tons, a pair of cylinders being added to the tender to make use of its adhesive weight, the total tractive effort being about 80 tons. The latest engines on the New York Central and other lines have a trailing bogie below the firebox, being of the 4–6–4 and 4–8–4 types. The axle loads on the Pennsylvania R.R. reach 30 tons. In order to reduce dynamic loading of wheels the reciprocating parts are of alloy steel. With small wheels the revolving masses must likewise be reduced, since it is not always possible to make the balance weights in the wheel large enough. Outside valve gears such as the Walschaert, Baker, or Southern are general, and piston valves are of large diameter with inside admission. Tank engines are not common, even switching engines having tenders.

New locomotives for passenger service are of the 4–6–4 and 4–8–4 types. For freight traffic the 2–8–2 or 2–8–4 type is mostly favoured, but the 2–10–4 type and the Mallet locomotives are also being built. Construction has been slowed down by extensive adoption of diesel traction, but a good deal of reconstruction and modernising of existing locomotives is taking place.

For operating over long distances the Union Pacific R.R. has adopted tenders having a capacity of 23,500 gallons of water and 25 tons of coal. They are carried on fourteen wheels, the first four of which are arranged as a bogie and the remainder are rigid.

The Canadian Pacific R.R. has constructed a 2–10–4 type having a tractive effort of 76,900 lbs. The twelve-wheeled tender carries 12,000 gallons of water and 4,100 gallons of oil.

The Union Pacific R.R. are trying a steam-electric locomotive rated at 5,000 h.p. consisting of two units of 2,500 h.p. coupled together, each equipped with oil-fired boiler, H.P. and L.P. turbines and condenser. Generators are driven through helical reduction gears and these supply current to traction motors suspended on the driving axles.

The Chesapeake & Ohio R.R. have three 6,000 h.p. coal-burning steam-turbo-electric locomotives. Steam at 290 lbs. per sq. in. is supplied to an atmospheric exhaust steam turbine driving two generators which supply current to eight traction motors.

Another new type is a 6–4–4–6 express passenger engine with four outside cylinders, 22 in. × 26 in., driving two independent groups of coupled wheels of 7 ft. in diameter. One pair of cylinders is located immediately to the rear of the leading six-wheeled bogie and the other pair in rear of the first set of coupled wheels. This engine will develop 6,500 h.p. at a speed of 100 m.p.h. It has a sixteen-wheeled tender carrying 23½ tons of coal and 20,200 gallons of water.

A similar engine of the 4–4–4–4 type has been put to work on the Pennsylvania R.R. for passenger service and one of the 4–4–6–4 type for freight.

In the largest American locomotives a bogie is required under the firebox, in addition to a pony truck or bogie at the leading end, so that a large percentage of the weight of the engine is not available for adhesion. The addition of a booster partly overcomes this drawback, and enables the engine to start with a heavier train than it could do in the normal manner.

The 'booster' is a small steam engine geared to the carrying wheels, and which can be thrown in or out of action as required. It is used to assist the main engine when starting a heavy train from rest or in climbing grades. The device has also been applied to the tender wheels.

The Pennsylvania R.R. have in service a turbine-driven locomotive of 6,500 h.p. It exhausts to atmosphere through a blast pipe in the smoke-box, as in the case of the L.M.S.R. engine in England. It is of the 6–8–6 type and has a conventional boiler with pressure of 310 lbs. per sq. in.

Another feature peculiar to American practice is the 'limited cut-off' locomotive, in which the maximum cut-off is fixed at about 60 per cent. in full gear. Under the operating conditions prevailing engines are at times worked 'all-out' at the full gear cut-off of 80 to 90 per cent. of the stroke for long periods, which is most wasteful of steam. By enlarging the cylinder diameter and reducing the cut-off, and consequently the mean effective pressure, an equally powerful but more economical engine can be constructed. Positive starting is ensured by means of notched ports in the valve liners which allow a small supply of steam to fill the cylinders should the engine be on a 'dead centre.'

The Norfolk & Western R.R. has some 4-8-0 type shunting engines, or 'switchers,' in which exhaust steam is discharged to atmosphere through a silencer. A mechanical stoker meters coal and controls an induced draft fan in the smokebox so that fuel and air are automatically supplied as required to maintain steam supply.

A locomotive fitted **with a 'Velox' boiler has been constructed for one of the French railways.**

Consideration is being given on the Continent and in the U.S.A. to the design of steam locomotives with individual axle drives, each axle being driven by one or more small enclosed high-speed engines. In France a $2\text{-}C_0\text{-}2$ type has two reciprocating engines per axle connected through reduction gears. In Germany a $1\text{-}D_0\text{-}1$ type was completed during the war. Each axle is driven by one enclosed steam engine. Another French $2\text{-}C_0\text{-}2$ type has individual turbines with double reduction gear to each axle, totalling 2,000 h.p.

TRAIN RESISTANCE.

There are numerous train resistance formulæ, and they differ considerably. It is only safe to apply them to similar rolling stock to that from which the experimental results were obtained, as conditions vary. For instance, American formulæ are unsuitable for British or Continental rolling stock, and *vice versa*. In estimating the resistance of a train, it should be observed that the results can only be taken as approximate, due to various small factors which may influence them, such as condition of track, play between flange and rail; also empty rolling stock has a relatively higher resistance than when fully or partially loaded, etc.

The *starting* resistance of a train is very variable, and usually ranges from 12 to 18 lbs. per ton where plain bearings are used. It is dependent on how long the vehicles have been standing and on the temperature of the atmosphere, this variation being due to a deficiency in the lubrication and to the viscosity of the lubricant. In warm weather oil boxes offer greater resistance than grease boxes, as the oil is more quickly squeezed out of the bearing while standing, while the reverse occurs in cold weather when the grease is solidified and so causes a high starting resistance. Once movement of the vehicle takes place, efficient lubrication is restarted and the resistance falls to about 5 lbs. per ton at slow speed.

Trains fitted with roller bearings have a lower starting resistance than those fitted with plain bearings lubricated by oil, but when running speed has been attained there is very little difference between them.

Resistance of Air to Train.

(1) The area of resistance presented by the first carriage is its front superficies; that of the following carriages, about 10 square feet, but depending upon the distance between them.

Q = resistance of air, in lbs. A = surface of resistance, in sq. ft. = about 70 ft. + 10(*n* − 1) for railway waggons, where *n* = number of waggons in train. (54 ft. according to M. Vuillemin, &c., 50 ft. Unwin.) *v* = velocity, in feet per second. *e* = 1·43 for a thin surface = 1·17 for a cube, = 1·07 for a train of 5 waggons, = 1·04 for a train of 25 waggons.

$$Q = \cdot 0011896 eAv^2 \ (\textit{Pambour}).$$

(2) If P = pressure on the front ends in pounds per square foot; V = velocity in miles per hour:—

$$P = \cdot 00265 \ V^2.$$

Assuming the superficial area of the front end to be about 75 sq. ft., the following table shows the total pressure and the power required to overcome that pressure at various speeds:—

Speed in miles per hour.	Total pressure, lbs.	H.P.
20	79·5	4·24
40	318·0	33·92
60	715·5	115·28
80	1272·0	271·36
100	1987·5	530·0

It will be seen that at speeds below 40 miles an hour the effect of head end resistance is practically negligible; but at speeds of 60 miles an hour or more the power required to overcome head end resistance is by far the most important element in train resistance. As the number of cars in a train is increased, the relative effect of head end resistance is decreased.

Experiments made on models of trains in a wind tunnel at the National Physical Laboratory indicate that about 400 horse-power is expended on overcoming air resistance at a speed of 60 miles per hour with a 10-coach train made up as follows:—

	Per cent. of total.	Horse-power.
Engine and tender	29	116
First coach	$8\frac{1}{2}$	34
Second to ninth ($6\frac{1}{2}$ each)	52	208
Tenth coach	9	38

For reduction of Air Resistance see 'Wind Tunnel Experiments in Canadian National Laboratory.' *The Engineer*, April 14th, 1933.

An engineer of the firm which furnishes electric locomotives for the Simplon Tunnel says that at a speed of 50 miles an hour in the tunnel the air-resistance absorbs 400 horse-power, or 40 per cent. of the capacity of the locomotive, against 95 horse-power in the open air.

In a paper read before the Institution of Mechanical Engineers in 1936 by Mr. F. O. Johansen, M.Sc. (Eng.), the results were given of tests in a wind tunnel of various rakes of trains, standard and modified, of L.M.S.R. and L.N.E.R. designs.

The models were in most cases made to $\frac{1}{40}$th scale and were tested at various wind velocities and various angles of yaw.

The following conclusions were among those reached:—

(1) The air resistance of a train of conventional British type is equivalent to about $0{\cdot}0016\,T^2$ lbs. per ton of train weight, where T is the speed in still air in miles per hour. This represents upwards of half the total train resistance at speeds above 80 m.p.h.

(2) The air resistance can be reduced by 50 per cent. without drastic departure from conventional design, and by 75 per cent. by ideal streamlining.

(3) Air resistance is augmented by side winds, the increase being mainly due to frontal pressure on exposed surfaces. The lateral wind force, perpendicular to the train, is large, but the consequent increase of forward resistance due to flange and bearing friction is relatively small, except for highly streamlined trains.

(4) The worst natural wind is not directly ahead but ranges from 30° to 60° on either side of the ahead direction.

(5) The gaps between the coach bodies of an ordinary train account for relatively little air resistance, and much of it can be obviated by abutting coaches as close together as practicable and covering the remaining gap to the general contour of the train. The resistance is roughly proportional to the width of the gaps and arises far more from frontal pressure than from suction on the trailing end.

(6) A surprisingly large proportion of the air resistance of a coach, especially under the action of oblique winds, is contributed by the bogies and undercarriage structure. The air resistance is less if the undercarriage is totally enclosed than if only side valances are fitted.

(7) A fair shape at the tail end of a train reduces air resistance to an extent which is more marked the more complete the streamlining, but greater advantage can be gained by fairing the front than by fairing the rear end.

(8) The air resistance of a conventional locomotive, amounting to 30–40 per cent. of that of a complete six-coach train, can be reduced 25 per cent. by rounding the smokebox front and covering the tender to the general contour of the train. An important advantage of the covered tender is in reducing the air resistance of the first coach.

(9) The ideal streamlined train is a continuous cylindrical body with well-rounded ends, having a polished surface free from external fittings and irregularities.

In the first resistance formula the weight of a coach has been taken at about 30 tons.

The resistance of the last coach can be reduced only by thorough streamlining.

The gap between coaches is of considerable importance for ideally streamlined trains only.

In comparing air resistance with mechanical resistance, the formulæ used for the latter were:—

$$\text{Resistance of locomotive} = 8{\cdot}8 + 0{\cdot}126T \text{ lbs. per ton}$$
$$\text{Resistance of coach} = 4{\cdot}0 + 0{\cdot}025T \quad ,, \quad ,,$$

where T = velocity in m.p.h.

The tractive resistance due to lateral force arising from wind pressure is 1·45 per cent. of that force.

Lateral air resistance is practically constant for a standard L.M. & S.R. train and for an ideal train. Therefore, in the case of a streamlined train the lateral air resistance is a greater percentage of the total longitudinal and lateral resistance than in the case of an ordinary train.

The ratio $\frac{\text{Streamlined}}{\text{Standard}}$ Total Air Resistance for a locomotive and six coaches at 100 m.p.h. is about ⅓ at 0° and 10° yaw, dropping to about ½ at 30° yaw.

The direction of the wind for the greatest resistance depends on the relative speeds of the train and the wind, and on the angle ϕ between them, and on the form of the rolling stock with respect to streamlining.

As the ideal shape of the train is approached, so the angle ϕ approaches 180°, the nearest for practical conditions being about 160° and 200°.

Resistance to Traction on a Level Railroad.

FORMULÆ FOR TRAIN RESISTANCE.

Authority.	Value of R.	Conditions.	Reference.
Aspinall	$2{\cdot}5+\frac{V^{\frac{5}{3}}}{50{\cdot}8+0{\cdot}0278L}$	General formula, bogie-coaches, oil axle boxes	**R = tractive resistance in lbs. per ton (2240 lbs.). V = velocity in miles per hour. w_1 = average weight of each vehicle in tons (2240 lbs.). L = length of train in feet.** w_a = average weight per axle in tons. n = number of axles per vehicle.
Great Indian Peninsular Railway	$3{\cdot}20+\frac{4000-41w_1}{2500w_1}V+\frac{1000+7w_1}{2000w_1}V^2$	Passenger coaches on 5 ft. 6 in. gauge	*The Engineer*, June 21, 1935, p. 640.
	$\frac{1190-13w_1}{250}+\frac{(7w_1)}{10{,}000}V+\frac{(331)}{10{,}000w_1}V^2$	Covered goods wagons, 4-wheeled, 11 ft. 6 in. wheel base, 5 ft. 6 in. gauge.	
	$\frac{53-w_1}{10}+\frac{7w_1}{10{,}000}V+\frac{(369)}{10{,}000w_1}V^2$	Open goods wagons 4 wheeled, 11 ft. 6 in. wheel base, 5 ft. 6 in. gauge	
L.M.S.R. (W. A. Stanier)	$\frac{5{\cdot}5(V+15)}{V+3{\cdot}5}+\frac{V^{1{\cdot}18}}{520}$	**Locomotives**	***Engineering*, September 18, 1936.**
”	$\frac{4(V+12)}{V+4{\cdot}5}+\frac{V^{1{\cdot}87}}{322}$	**Carriages**	” ”
Davis	$\left(1{\cdot}45+\frac{29}{w_a}+0{\cdot}034V+\frac{0{\cdot}041V^2}{w_a n}\right)$	**Carriages.**	U.S.A. Formula, translated for English tons.

From tests carried out on the former L. & N.E.R. with four-wheeled goods wagons of 6 tons tare and 10 tons capacity, and with bogie wagons of 17 tons tare and 50 tons capacity, the following results were obtained :—

Speed—m.p.h.	**10**	**20**	**30**	**40**	**50**
Resistance in lbs. per ton—10-ton wagons	**4½**	**4¾**	**5½**	**8**	**12½**
Resistance in lbs. per ton—50-ton wagons	**3½**	**3½**	**3¾**	**4¾**	**6¾**

All wagons were fitted with oil axle boxes, and were fully loaded.

Resistance of Curves.

Resistance due to curvature of track varies inversely as the radius, and directly as the rail-gauge and length of rigid wheel base. It also depends to some extent on the state of the surfaces of wheels and rails. The practice of watering the rails or lubricating the flanges of the wheels lessens the resistance, whilst the occasional necessity of sanding the rails for the locomotive greatly increases it. On main lines the curve resistance is usually very small, and no allowance is made for it. In special cases, where the curves are sharper, such as in sidings, station yards, or at junctions, it is sometimes necessary to form some estimate of the resistance. The American Master Mechanics' Association gives the resistance per ton (of 2,240 lbs.) as 0·77 lbs. for each degree of curvature of track in the case of cars (with bogies), and double this amount—1·54 lbs. —for locomotives.

In British practice, curvature is expressed by the radius in feet or chains. As 1° of curvature corresponds to a radius of 5,730 feet, the radius of any curve in degrees is given in feet by $\frac{5{,}730}{x^\circ}$ **or in chains by** $\frac{87}{x^\circ}$.

$$\text{Resistance in lbs. per ton} = \frac{4{,}412}{\text{radius in ft.}} \text{ or } \frac{67}{\text{radius in chains}} \text{ for cars.}$$

$$\text{,,} \qquad \text{,,} \qquad = \frac{8{,}824}{\text{radius in ft.}}\,;\text{ or } \frac{134}{\text{radius in chains}} \text{ for locomotives.}$$

To find the equivalent up-gradient, 1 in n, **that offers same resistance as curve :—**

$$n = \text{radius in ft.} \times 0{\cdot}5.$$
$$= \text{radius in chains} \times 33.$$
$$= \frac{2{,}871}{\text{curvature in degrees.}}$$

Resistance due to Gradients on Railways.

The force, F, required to move 1 ton up a slope of 1 in n, **neglecting friction and resistance of air** $= \frac{1 \text{ ton}}{n} = \frac{2{,}240 \text{ lbs.}}{n}$, **or resistance in lbs. due to gravity on any incline** $= \frac{2{,}240}{\text{rate of gradient}}$ **per ton of train.**

On a gradient of 1 in 300 the total resistance becomes about twice that on a level at a speed of 30 m.p.h., and therefore only half the utmost load can be carried, or the speed must be diminished. Gradients above 1 in 330 are considered first class ; 1 in 330 to 1 in 150, fair working gradients.

In American and Continental practice, gradient is given as rise per cent. or per thousand, so that grade of 1 in $n = \frac{100}{n}$ **per cent., or** $\frac{1000}{n}$ **per thousand. Thus 1 in 300 = 0·33 per cent. or 3·3 per mille.**

Rise in feet per mile $= \frac{5280}{n}$ **or 17·6 ft. for 1 in 300.**

Effect of Gradients on Speed of Passenger Trains.

The work done by the locomotive in a given time is proportional to total resistance × speed. For speeds over 25 m.p.h. on the level, the resistance of an average engine and train may be fairly represented in lbs. per ton by the simple formula $R = 5 + \cdot 003v^2$. The work done on the level is therefore proportional to $v\,(5 + \cdot 003v^2)$. On a gradient of 1 in n this becomes

$v\left\{(5 + \cdot 003\,v^2) + \frac{2240}{n}\right\}$. If the engine is capable of maintaining a speed of 60 m.p.h. on the level, and the horse-power output is constant, the effect of the gradients on the speed is as follows:—

Inclination.	Level.	1 in 2,500	1 in 1,000	1 in 750	1 in 500	1 in 250	1 in 150	1 in 120	1 in 100	1 in 90	1 in 80	1 in 70
Speed { Miles per hour	60	59	57	55	53	47	40	36	33	31	28	26

Resistance of Locomotives.

The resistance of a locomotive is a very uncertain quantity, and there is no formula which can take account of all the variables. There are, however, several formulæ which give results approximating to the average resistances in ordinary working.

The resistance may be divided into three components:—

(1) Internal resistance of engine machinery, including driving wheels.
(2) Resistance of locomotive as a vehicle, including head-on air resistance.
(3) Resistance of tender as a vehicle.

According to Professor W. F. Goss, the internal resistance is fairly constant for any given cut-off for a wide range of speed, but that the later the cut-off, and consequently more even the turning moment, the less the friction.

As a vehicle the locomotive not only has the usual rolling resistance, journal friction, etc., but it has to encounter the atmospheric pressure on the surfaces perpendicular to the direction of travel, and it shelters to some extent the train behind.

The reaction of the steam pressure on the cylinder covers, applied alternatively to either side of the engine, causes it to move in a sinuous path and sets up further flange friction.

The tender has a resistance very similar to any other vehicle of the train, but it is modified a little by the movement of the engine to which it is closely coupled.

A method in use in the U.S.A. for estimating locomotive resistance is to calculate the resistance of the carrying and tender wheels by means of the Davis formulae (see page 528), add to this 25 lb. per ton (of 2,000 lb.) of weight on the coupled wheels and $0 \cdot 36V^2$ pounds as frontal air resistance on an area of 15 ft. × 10 ft. Converted to English tons and a frontal area of 13 ft. × 9 ft. total resistance can be expressed as follows:—

$$WR = nw_a\left(1 \cdot 45 + \frac{29}{w_a} + 0 \cdot 031V\right) + 0 \cdot 315V^2 + 28w_d$$

where

w_a = average weight per carrying axle, n = number of carrying axles, V = speed in m.p.h., w_d = total weight on coupled wheels, W = total weight of engine and tender in working order and R = resistance in lbs./ton.

Mr. Lawford H. Fry gives separate formulæ for engines with 4, 6, and 8 coupled wheels. which in lbs. per ton (2,240 lbs.) of engine and tender can be expressed as:—

$$R = 8 \cdot 5 + 0 \cdot 09V + 0 \cdot 004V^2 \text{ for 4 wheels coupled.}$$
$$= 10 \cdot 0 + 0 \cdot 12V + 0 \cdot 004V^2 \text{ for 6 wheels coupled.}$$
$$= 13 \cdot 4 + 0 \cdot 48V + 0 \cdot 004V^2 \text{ for 8 wheels coupled.}$$

The equations are derived from the mean of the results obtained by numerous European experimenters. (*The Engineer.*)

According to L. H. Fry a general expression for the machine friction of a steam locomotive is given by the formula

$$F = \frac{0 \cdot 33nW}{D}.$$

Where n = number of driving axles coupled in a group, W = the weight on all driving wheel in pounds, D = driving-wheel diameter in inches and F = the machine friction in pounds of draw-bar pull.

About 22 lbs. per ton at 50 m.p.h. is the usual resistance of a British 4-4-0 type engine; and at 60 m.p.h. some 4 h.p. per ton is expended in moving the engine and tender.

In order to see how much power the locomotive absorbed as compared with the train, a certain number of experiments were tried on the former Lancashire and Yorkshire Railway, and it was found that the ten-wheeled engine No. 1392 absorbed 34 per cent. of the total horse-power. Mr. W. M. Smith (the Institution of Mechanical Engineers) gave the result of his experiments as about 36 per cent. of the total horse-power; but the actual figure depends on the load behind the engine, the percentage being higher with light loads.

Train Acceleration.

The resistances to be overcome in moving a train are frictional and gravitational. Any draw-bar pull in excess of them is available for accelerating the train; or

$$F = T - W(R_1 + R_2 \pm R_3),$$

where

F = accelerating force in lbs.; T = tractive effort in lbs.; W = weight of train in tons; R_1 R_2 and R_3 = opposition to traction in lbs. per ton due to train resistance, curves, and gradients respectively. A negative result indicates retardation.

For the actual acceleration or retardation produced, allowing 10 per cent. for rotary acceleration of wheels and axles,

$$a = \frac{F \times 32}{1{\cdot}10W \times 2240} = \frac{F}{77W} \text{ ft./sec.}^2$$

In American practice about 5 per cent. is allowed for rotary acceleration, as the car wheels are smaller in diameter and also bear a lesser ratio to the weight of car.

To produce a speed of V miles per hour in distance S feet,

$$F = \frac{82V^2W}{S} \text{ lbs.; or } F = \frac{82(V^2 - v^2)W}{S} \text{ lbs., } v \text{ being initial speed.}$$

To produce a speed of V miles per hour in t seconds,

$$F = \frac{112VW}{t} \text{ lbs.; or } F = \frac{112(V - v)W}{t} \text{ lbs.}$$

Power, Tractive Force, and Adhesion of Locomotives.

The pressure exerted on the piston is to the force exerted in the traction of the train inversely s the velocities of the piston and train, i.e., as twice the stroke of the piston to the circumference of the wheel.

Piston Speed.—Ordinary piston speed is about 900 feet per minute.

If d = diameter of piston, in inches; a = area of piston, in sq. inches; l = length of stroke, in inches; p = indicated pressure per square inch, in lbs.; D = diameter of driving-wheel, in inches; V = velocity, in miles per hour; n = number of revolutions per minute = $336\frac{V}{D}$; then

$$\text{Tractive force at rails} = \frac{d^2\,lp}{D} \text{ lbs.}$$

$$\text{Indicated horse-power} = \frac{d^2plV}{375D} = \frac{4an\,pl}{33{,}000} \times \tfrac{1}{12}.$$

The calculated tractive (or starting) effort

$$T = \frac{cd^2Pl}{D} \text{ lbs.}$$

where

P = boiler pressure, and c is a coefficient varying from 0·8 to 0·9, but usually taken at 0·85 both in British and American practice.

The above relates to the ordinary two-cylinder high-pressure engines. Multiply results by 1·5 for three-cylinder, and by 2 for four-cylinder locomotives. (For compound locomotives, see p. 536.)

Cylinder Horse Power.—According to F. J. Cole, horse-power is at a maximum at a piston speed of 1,000 ft. per minute. Based on this

$$\text{I.H.P.} = 0{\cdot}0212 \times P \times A \text{ for saturated steam;}$$
$$\text{I.H.P.} = 0{\cdot}0229 \times P \times A \text{ for superheated steam}$$

where

P = boiler pressure in lbs. per sq. in. and A = area of one cylinder in sq. ins. (in the case of two-cylinder engines).

The horse-power given out at the draw-bar is less than the indicated horse-power by the amount expended in moving the engine and tender. This is approximately 400 h.p. in modern locomotives running at 60 m.p.h., representing about 35 per cent. of the maximum indicated horse-power. (See Resistance of Locomotives, p. 530.)

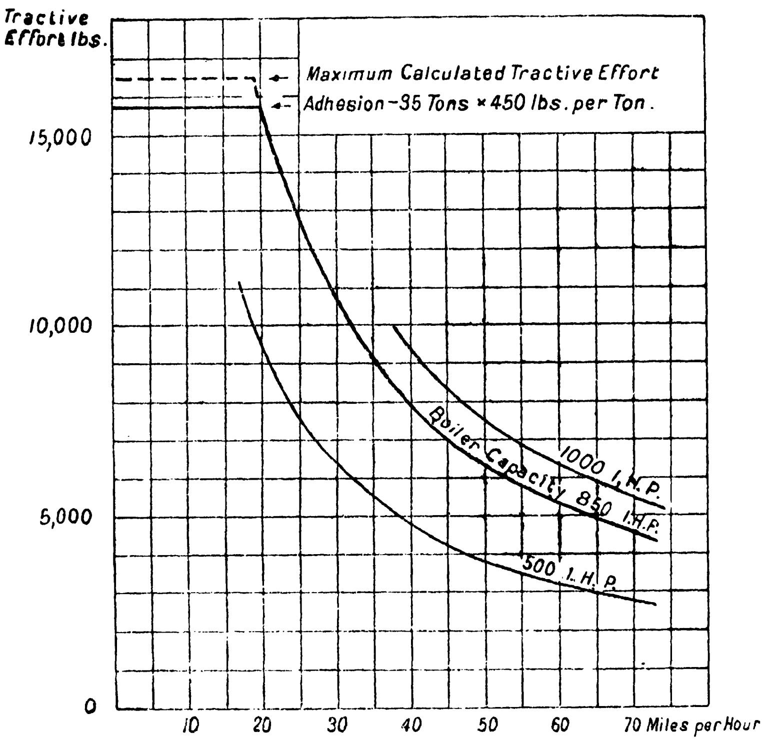

FIG. 1.

Draw-bar horse-power = 5·97 × pull (in tons) × speed (m.p.h.) = 0·00267 × pull (in lbs.) × speed m.p.h.).

ADHESION.

The proportion of the weight on the driving wheels giving *adhesion* and available as tractive force varies considerably, from about 200 lbs. per ton in frosty and greasy weather to 600 lbs. in dry weather. It must, of course, exceed the tractive power, and is generally taken at about 350 lbs. per ton, this being quite feasible, as all locomotives are fitted with a sanding arrangement.

In average British practice, the factor of adhesion, that is, the ratio between adhesive weight and calculated tractive effort, is between 4 and 5 for four and eight-wheel coupled engines, and between 5 and 6 for six wheels coupled. In tank engines the factor varies with the amount of water and coal present. Multi-cylinder engines may have a lower factor on account of their more even turning moment.

The permissible axle load in relation to the maximum tractive effort determines the number of axles to be coupled, thus :—

$$\text{Max. T.E.} = \text{adhesion, } i.e. = \frac{\text{Adhesive weight}}{\text{Factor of Adhesion}}.$$

If n = number of axles to be coupled, W = permissible weight on each axle, and K = factor of adhesion

$$\text{Max. T.E.} = \frac{nW}{K} \text{ or } n = \frac{\text{T.E.} \times K}{W}.$$

The relation between horse-power, tractive effort, and adhesion, is shown by the characteristic curve of a locomotive in fig. 1, where tractive effort is plotted against speed. Horse-power appears on the diagram as a hyperbolic curve, since for any given horse-power pull × speed = a constant. In the example given the maximum calculated tractive effort is 16,500 lbs. The actual pull is limited by adhesion to 15,750 lbs., adhesive weight being 35 tons and the adhesion 450 lbs. per ton. The boiler capacity is taken as 850 i.h.p. and is plotted as a hyperbolic curve. The intersection of the curve with the maximum available tractive effort gives the lowest speed at which the boiler is fully used. Until this point is reached horse-power is limited by cylinder capacity or adhesion, as the case may be. Beyond it, the horse-power is approximately constant and the pull falls off as the speed rises. A deduction must be made for engine and tender resistance to obtain actual draw-bar pull.

Relation of Power to Weight of Locomotives.

Ordinary locomotives are capable of developing from 9 to 12 horse-power for each ton of their weight (inclusive of tender).

Weight Restriction in Locomotives.

On English railways the heaviest load is usually 20 tons, but in the latest 3- and 4-cylinder engines a load of about 22½ tons has been permitted on account of the lighter hammer blow.

The axle loads carried with the goods engines are about 15 tons in Germany and Italy, 17 tons in England, Belgium, and France, and 23 to 30 tons in the United States. (In tons of 2,240 lb.)

The following is a formula given by F. J. E. Spring for locomotive driving-wheels :—

Safe load = 200 × diameter of wheel in inches × width of rail head on which wheel bears in inches.

In addition to restriction of individual loads on wheels, the total weight of a locomotive is limited by the strength of permanent-way structures. In designing a new locomotive, or rebuilding an existing one, it is essential to study the resulting bending moment imposed on bridges. This varies with the total length of engine, wheel base and spacing of wheels, and the weights on individual pairs of wheels. A short engine with the wheels close together may stress a bridge more than a heavier engine in which the weight is spaced over a longer base. The locomotive engineer, however, is not concerned in the actual stresses produced, but his problem is to keep within the boundaries of a limiting bending moment curve. The permanent-way engineer sets out the strength of the weakest bridges of various spans, and from them deduces a curve showing the maximum equivalent uniformly distributed load that the different spans can sustain. The curve is either set out giving the total load on the spans, or the tons per foot run of span. In fig. 3 the upper curve shows a limit determined by the permanent-way engineer in lb. per ft. run. No locomotive may run that sets up on any bridge a greater bending moment than this. If the excess is small, a slight modification of the wheel spacing or distribution of loads may rectify matters. As the locomotive constitutes a rolling load, any direct calculation is very tedious. The loads must be advanced across the span a foot or so at a time, and the bending moment ascertained for each step. It is obvious that maximum bending will occur under one of the loads, but it is not always certain which load it is. The maximum also changes from under one wheel to another at a certain point. The most satisfactory way is to first of all solve the problem graphically : if care is taken the results are very reliable. Once a solution is obtained the bending moment can be exactly calculated, and this acts as a check on the drawing and reading of scales. For the loading of the span it is assumed that there are several locomotives of the type under consideration, coupled together. As an example of the method, a 4–4–0 type engine is taken, the loads and spacing of wheels being shown on the line diagram at the foot of fig. 2. The first step is to set up a vertical line and mark it off to a convenient scale, say 1 in. = 10 ft., to represent the wheel loads to scale. Thus, *c–d* is the weight on the leading bogie wheels, *d–e* on the next pair, *e–f* that on the first pair of coupled wheels, and *f–g* for the trailing wheels. The loads on tender wheels are represented by *g–h*, *h–j*, *j–k*. The lengths *a–b*, *b–c*, are tender wheels of the preceding engine; while *k–l*, *l–m*, are for bogie wheels of the following engine. If the span is a long one more loads must be added in their proper order. Having done this a pole O is taken, approximately in line with the centre of gravity of the loads, and at a distance of, say, 5 ins. from the vertical line. The various points on the line are then joined to the pole. The next step is to draw a horizontal base line and mark on it the wheel base of the engine to a scale of, say, ½ in. = 1 ft. Verticals are projected through the points, and the spaces are lettered A, B, C, etc., to correspond with the letters *a*, *b*, *c*, etc., on the vertical load line.

FIG. 2.

Commencing at any convenient place, a line is drawn through space A parallel to the polar line o–a. This is followed by line through space B parallel to o–b, and so on until complete. For convenience a number of vertical lines are spaced at intervals representing each foot of the span. In order to ascertain the bending moment for a 10-ft. span, the intersection of a vertical with the curve is joined to another ten spaces away and scaling 10 ft. when measured horizontally. The next and succeeding points are treated in the same way, and it will soon be evident where the greatest bending moment is enclosed. This is equivalent to moving the bridge span along under the engine. Having ascertained the greatest bending for a 10-ft. span, that for a 20-ft.

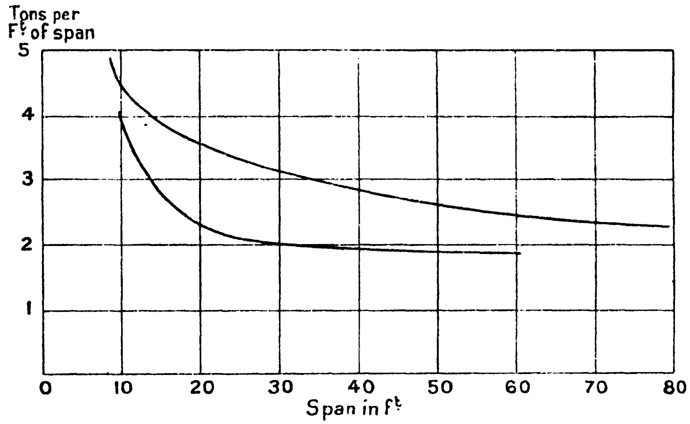

FIG. 3.

is obtained in the same way by joining verticals 20 ft. apart. The 30, 40, 50 ft., etc., spans are treated in like manner. It will be observed that the maximum B.M. moves from under the driving to the trailing wheels between 40- and 50-ft. spans. The maximum B.M. can be scaled by measuring vertically, and the results tabulated. If 1 in. = 10 tons of weight, and 1 in. = 2 ft. of span, and the polar distance is 5 in., the scale of bending will be 1 in. = 10 × 2 × 5 = 100 ton-ft. The final step is to obtain the equivalent uniformly distributed load by equating each result to it—i.e., B.M. = $\frac{WL}{8}$, so that W = $\frac{8 \times \text{B.M.}}{L}$, where W = total distributed load on span. For load per ft. run of span, B.M. = $\frac{wl^2}{8}$, and $w = \frac{8 \times \text{B.M.}}{l^2}$.

The results obtained can be plotted on the bridge curve supplied by the permanent-way engineer (as the lower curve in fig. 3), and unless all the plotted points fall below the upper curve, the design of the engine will have to be modified in some way, either by reduction of weight, or possibly by an alteration to the wheel base, or the addition of another pair of wheels.

When the position of maximum bending and the loads producing it are known, calculation is a simple matter, and it acts as a check on the graphical working. The position of load system giving maximum bending is such that the centre of span bisects the distance between point of maximum bending (which occurs under one of the loads) and centre of gravity of loads on span.

British Standard Unit Loadings for Railway Girder Bridges are given in B.S.S. No. 153, Parts 3, 4 and 5. The unit of axle load is taken as 1 ton. For British railways, the loading recommended in the Requirements for Passenger Lines and Recommendations for Goods Lines of the Minister of Transport in regard to Railway Construction and Operation (1925) is 20 units for heavy main lines, with lower multiples for lines constructed for lighter loading.

Thus the bending moments given in the Specification must be multiplied by 20 to obtain a 20 units loading, or by 16 in the case of a 16 units loading, etc.

Compound Locomotives.

The general claim for compound locomotives, by most authorities, is a saving of about 20 per cent. in the case of saturated steam. With superheated steam the saving is very much less. Expansive working, and consequently exhausting at a low temperature, is the main object.

Many of the larger locomotives recently constructed on the Continent are four-cylinder compounds, while the two-cylinder cross-compounds are favoured in the Argentine. A number of three-cylinder compounds has been built in England for the L.M.R. and in Ireland for the G.N.R. Some of the latest French locomotives are three-cylinder compounds, but four-cylinder compounds have also been built. Some experimental engines have been put into service in the U.S.A., including one for triple expansion working.

Ratios of the Areas of the High-pressure Cylinders to the Low-pressure.

Wordsell, Von Borries, and others, 1 to 2–2½ ; Webb, 1 to 2·3 ; Vauclain and America, 1 to 3. In modern compounds ratio is 1 to 2·4 on L.M.R., 1 to 2·5 Mallet compounds in U.S.A., and about 1 to 2·2 on Continent. Latest French practice 1 to 2·7.

Tractive Force.

Von Borries, who recommends a ratio of 1 : 2·2 or 2·3, gives tractive power of two-cylinder compounds as,

$$\text{T. F.} = \frac{psd^2}{4\,\text{D}},$$

where,

p = boiler pressure ; s = stroke in inches ; D = diameter of wheel in inches ; d = diameter of low-pressure piston.

For four-cylinder compounds, Baldwin gives

$$\text{T.F.} = \frac{2\,psc^2}{3\text{D}} + \frac{psd^2}{4\text{D}},$$

c being diameter of high-pressure piston.

Another formula is given as

$$\text{T.F.} = \frac{0\cdot 8\,psd^2}{(r+1)\text{D}} \text{ for two-cylinder compounds} = \frac{1\cdot 6\,psd^2}{(r+1)\text{D}} \text{ for four-cylinder compounds,}$$

r being ratio of low to high-pressure piston area.

Cylinders of Simple and Compound Locomotives of Equivalent Power.

For proportioning the diameters of the cylinders of compound locomotives when designing them to generate a power equivalent to that of a given size of simple cylinder and of the same piston stroke, the average ratio of area of the simple cylinder and the high-pressure cylinder area of compound locomotives is 1 to 1·25 for the 2-cylinder and 1·10 for the 4-cylinder. In the case of the 4-cylinder engines the area is that of the sum of the two high-pressure cylinders. (*Railroad Gazette.*)

Parts of Locomotives.

CYLINDERS.

The size of cylinders is governed by the maximum tractive effort required for starting the train, boiler pressure, diameter of driving wheels and adhesive weight available. $d^2l = \dfrac{\text{T.E.} \times \text{D}}{0\cdot 85\text{P}}$

where d = diameter of piston in inches, l = length of stroke in inches, P = boiler pressure, D = diameter of driving wheels in inches, and T.E. = tractive effort in lb.

The above formula refers to two-cylinder engines.

For two-cylinder engines, the diameter in inches is approximately $\dfrac{120}{\text{P.}}\sqrt{\text{I.H.P.}}$ **where I.H.P. = maximum H.P. that engine will be required to develop for any length of time, and P. = working pressure.**

For three- and four-cylinder engines the equivalent cylinder area can be calculated.

Stroke and diameter of driving wheels should be so proportional that the piston speed is about 900 ft. per minute, as this is found to be the most economical speed.

For steam pressures from 150 to 250 lb. per sq. in. and cylinder diameters from 15 in. to 22 in. thickness of barrel in inches may be taken as $t = \dfrac{pd}{4000} + 0\cdot 3$.

Thickness of metal of steam passages may by ·7 t and of the flanges 1·25 t, where t = thickness of barrel in inches.

The studs for the cylinder cover should be calculated for a stress of 4,000 lb. per sq. inch to allow a large margin of safety in case of priming.

For Flat Slide Valves.—Area of steam port $= d^2 \div 15$. Length of ports should not be less than $\cdot 85\,d$. Area of exhaust port should be two and a half times that of the steam port.

Clearance between cylinder covers and piston is usually made from ½ in. to ⅝ in. The *clearance volume*, including the passages, varies from 6 to 8 per cent. of the cylinder volume. If the clearance is too small the compression line at high speeds rises above the steam chest pressure, and the engine does not run well. *(Wolff.)*

Cylinders for Highly-superheated Steam.—Owing to the very high temperatures, it is necessary that the steam chest walls should be separate from the walls of the cylinders. There is a very great variation in the temperatures of superheated steam, on the one side, and of the exhaust steam on the other. If a common wall is used between the two the result is that the cylinders are liable to fracture. *(H. N. Gresley, 'Proceedings, Inst. Loco. Engineers.')*

Pistons.—One railway company makes all pistons 0·0625 in. smaller in diameter than the bore of the cylinder. Another railway allows 0·002 in. per inch of diameter for clearance.

VALVES.

For Flat Slide Valves.—*Outside lap* usually $= 0\cdot 8a$, where a is the width of the steam port. As a rule there is no inside lap, but in some cases a small inside clearance not exceeding $\frac{1}{16}$ in. is allowed. The *lead* is about ⅛ in., and the *maximum travel* is about $2\cdot 7a$. Valves of tank engines and others that make frequent stops should be of soft grey cast iron. For long-run engines, 5 parts copper, 1 part tin. *(Wolff.)*

PISTON VALVES.

Cylindrical or piston valves are extensively used in connection with superheated steam. A large proportion have internal admission of steam. Various packings are in use; some consist of spring rings, of which there are several kinds. The advantages over flat slide valves are reduced friction, larger port opening, and wear is confined to the easily renewable packing rings.

The diameter of piston valves is about half that of the cylinders, so that circumferential length of ports is approximately $1\cdot 5d$, where d equals diameter of cylinders.

The lap of the valves on the admission side is usually ¾ in. or 1 in., but this has been increased in recent years to 1¼ ins. or 1⅝ ins., and the travel in full gear working has increased correspondingly from about 4½ ins. to 6½ ins. The advantages gained are sharper cut-off and freer exhaust, leading to greater mean effective pressure at high speed and greater economy in steam consumption.

Piston valves are of two kinds, inside admission and outside admission. In the former, steam is admitted between the heads, and exhaust takes place on the outside. The advantages are reduced area for radiation of heat and packing of spindle is only subjected to exhaust steam pressure. Outside admission valves are arranged like flat slide valves, with admission of steam on outside and exhaust inside, thus giving a shorter and more direct passage to the blast pipe.

The cast-iron valve liners are turned 0·003 in. to 0·004 in. larger than the steam chest, and are drawn into position by means of screw tackle. At the W.R. works, Swindon, liners are shrunk in diameter by subjecting them to intense cold through contact with solid carbon dioxide. They are then pushed into position and allowed to expand.

LIMITS AND FITS FOR LOCOMOTIVE WORK.

The Locomotive Manufacturers Association of Great Britain has set up a code of standard practice in respect of limits and fits recommended for use in locomotives built by them. Through this code a greater measure of interchangeability can be effected by enabling spare parts to be designed in detail as well as manufactured in an identical manner at individual factories.

The code departs from British Standard Specification 164 for 'Limits and Fits for Engineering' in that it is based partly on the 'hole basis' and partly on the 'shaft basis'; it is termed by the Association a 'locomotive basis.' In addition to dealing with the sizes and tolerances for steam locomotive details of all descriptions, recommendations are made as to the forms and dimensions of rivets, mild steel sections and bars to be used.

MOTION WORK, ETC.

ALLOWANCES USED IN FITTING THE PARTS.

		In.			In.
Gland and neck rings	+ piston rod	0·03125	Slipper flanges	+ width of bar	0·03125
Eccentric straps	+ sheaves	0·015	Axle-box flanges	+ horn	0·03125
Side play of do.		0·03125	Brake gear holes	+ pin dia.	0·0156
Slide blocks	− bar opening	0·006	Valve gear pins	− holes	0·004

(F. Thompson, 'Journal of Inst. of Loco. Engineers.')

Coupling and Connecting Rods.

In the case of outside cylinder engines the throw of coupling rods is usually the same as that of the connecting rods, namely, 12 ins. to 15 ins., but in a few cases the crank pins are turned eccentrically on their outer bearing, so that the throw of the coupling rod may be shortened a little. For inside cylinder engines the throws are from 9 ins. to 11 ins. Small throws require rods to be stiff laterally, in order to resist crippling loads, while large throws need a deep rod on account of the bending stresses set up by centrifugal force.

Where a fire-box comes between two coupled axles, some railways allow a little for expansion by heat of the frames by shortening the centres between axles by $\frac{1}{32}$ to $\frac{3}{64}$ in. When steam is raised the frames lengthen, so that the distance between centres of the axles is equal to the length of the coupling rods.

Most coupling rods have plain bushed ends, as have the solid-ended connecting rods of outside cylinder engines. The gun-metal bushes are turned slightly larger than the hole by an allowance of 0·002 inch per inch of diameter. This requires a tonnage of 12 tons to press a 7-inch bush into place. A running clearance on the crank pin of 0·002 inch per inch of diameter is specified in one case, $\frac{1}{64}$ inch being a common figure. Another railway presses the bushes in with a load of 20 to 25 tons, and allows $\frac{1}{32}$ in. to $\frac{3}{64}$ in. clearance on the pin.

Valve Gear.

With inside cylinders Stephenson valve gear (see also Sec. XXVII, Part III) is general. Outside cylinder engines, with the valves inside the frames, also have the Stephenson gear; but, when valves are outside, the Walschaerts valve gear is now preferred.

The outside cylinder engines on the former Great Western Railway have 10-in. piston valves placed above the cylinders worked by Stephenson gear from the inside of the frames. The maximum valve travel is $6\frac{1}{4}$ ins., the lap being $1\frac{5}{8}$ ins., and the port opening $1\frac{1}{2}$ ins., although the steam ports are $1\frac{3}{4}$ ins. wide. The eccentrics are set to give $\frac{1}{8}$ in. lead at 25 per cent. cut off, resulting in the valves being about $\frac{1}{8}$ in. blind in full gear. This arrangement gives a sharp cut off, prolonged expansion and a free exhaust, resulting in large mean effective pressure at high speeds.

Walschaerts Valve Gear.

The Walschaerts valve gear, figs. 4 and 5, is mainly used on outside cylinder engines. The travel of the valve is derived from two movements, the crosshead of the engine and a return

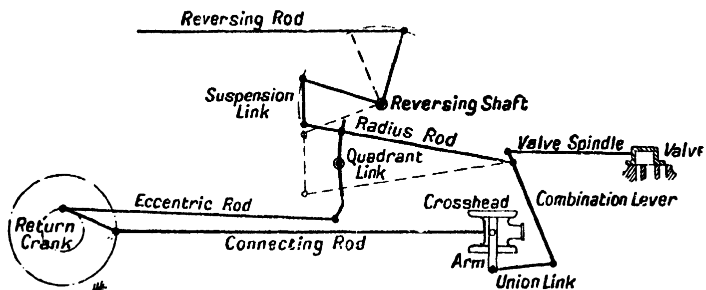

FIG. 4.

crank attached to the main crank pin, or, in the case of inside cylinder engines, from an eccentric on the crank shaft. The first movement is a reproduction of the travel of the crosshead to a reduced scale, the reduction being effected by a combination lever connected at its lower end to the crosshead through a link. In order that the angular movement of the lever shall not be too great by any restriction of length an arm is rigidly attached to the crosshead so that the lever may be suitably lengthened. The combination lever is also attached to the valve spindle and to the radius rod which forms its fulcrum. With an outside admission valve the valve spindle is attached above the radius rod and with inside admission of steam the positions are reversed (see figs. 4 and 5). The function of the combination lever is to give the mid-gear travel, equal to twice 'lap + lead,' and the lever is so proportioned that the stroke is reduced to this amount. The lead is constant for any length of travel.

The second movement, derived from the return crank, is transmitted to a quadrant link rocking on fixed bearings. The maximum angle through which this link swings should be kept

within 45°. The radius rod is attached to the link through a die block and communicates its motion to the valve by way of the combination lever. This second movement is at a phase of 90° with the first, and its magnitude can be varied and its direction reversed by altering the position of the radius rod on the quadrant link. In mid-gear the second movement is nil, only the first movement being communicated to the valve. The position of the radius rod in the link is regulated by the reversing shaft, the attachment being either a vibrating suspension link (see fig. 4) or a slider consisting of a die block working in a long slot, as in fig. 5. In the latter case it is

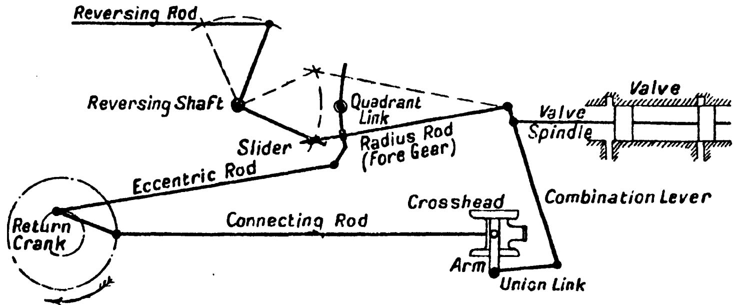

FIG. 5.

more convenient to use the bottom of the link for fore-gear running, while in the former either top or bottom can be used, since it is only necessary to alter the position of the return crank, which is nominally 90° ahead or behind the main crank. For convenience of design the quadrant link is usually raised so that the eccentric rod is inclined, and this angle of inclination should be taken into account when setting the return crank, being added to or subtracted from the main angle of 90°. The setting of the return crank is as follows :—

Valve.	Fore Gear.	Return Crank.
Outside admission	At top of link	90° behind main crank
" "	At bottom of link	90° in advance of main crank
Inside "	At top "	90° in advance of "
" "	At bottom "	90° behind "

BAKER VALVE GEAR.

The Baker valve gear is extensively used in America, and has been successfully adopted in New Zealand and elsewhere. It is similar to the Walschaerts gear as far as that lap and lead are obtained from a crosshead-driven combination lever, but in place of the quadrant link and its die block, a form of Marshall gear is used. An eccentric rod operates a swing link whose point of suspension can be moved to vary travel and to reverse the motion. Longer valve travels are possible than given by Walschaerts gear.

LENTZ POPPET VALVE GEAR.

Each cylinder is fitted with 4 poppet valves. These are disposed in pairs, one for admission and one for exhaust, at each end of the cylinder casting. A central annular chamber is provided in the cylinder casting, through which a camshaft runs at right angles to the valve spindles, which camshaft has mounted on it 2 cams, one of which operates the steam valves and one the exhaust. The cams may come into direct contact with the valve spindles, which in such cases are fitted with a roller and pin, the former bearing upon the cam profile. Alternatively intermediate levers are fitted which are arranged on a suitable fulcrum support.

The fulcrum support is a special feature of the design in question; it carries the fulcrum pins and may be disposed above the cams or below them in the cam space, as may be most convenient. This fulcrum bar fits in the end of the cam space and also in the cam chamber cover, being securely held in order to prevent it from any possible movement. This arrangement permits of the withdrawal of the fulcrum bar, together with intermediate levers for inspection purposes, and also greatly facilitates the withdrawal of the cams and camshafts for a like purpose.

The intermediate levers are fulcrummed at one end; at the opposite end they bear against the valve spindles, and in the centre a special roller and pin is fixed, the roller bearing against the cams. The advantage that the intermediate lever system has over what is known as the direct

drive lies in the fact that better port openings are secured, as for any given cam profile the valve lift is doubled.

The valves are securely held on the spindles by an improved form of combined nut and inner spring cap, and the spindles, which are hardened and ground, work in cast-iron bushes pressed into the cylinder casting.

Each valve and spindle is fitted with a control spring and a control spring adjusting device fixed in the valve covers. The function of the springs is to keep the valves following the cams when the locomotive is running with steam shut off.

The poppet valve arrangement described is operated by one or other of the usual type of valve motion common in locomotive practice, and to this end the valve connecting-rod joins the upper part of the valve motion with a rocker arm securely keyed to the outer end of the camshafts. With the motion in full gear the camshaft has imparted to it a maximum angular movement corresponding to the greatest valve opening or travel. As the engine is linked up, the amount of motion imparted to the rocker arm becomes less, and likewise the valve opening, and in this manner the cut-off is made earlier or later, as may be desired.

With poppet valves more direct steam passages are obtainable than is possible with piston valves, and this is especially so for the exhaust. This together with the improved port openings possible with poppet valves, as against piston valves for any given degree of cut-off, are amongst the important advantages offered by a poppet valve gear as described as against piston valve gear.

One of the chief principles underlying the design of poppet valves as arranged in the above manner is a slow opening followed by a quick movement of the valve, a rapid closing followed by a slow movement at the actual time of closure, and also the fact that up to the actual seating of the valve on its face the valve spindle either directly or indirectly (through the intermediate system) is in contact with the cam profile. It is in this way that absolutely noiseless operation is assured, there being no drop action whatsoever.

Steam-tightness of the valve is at all times assured through the special design of the inner and outer valve face.

The Lentz valves have also been constructed to work with a rotary cam drive instead of the usual valve gear.

Caprotti Valve Gear.

This is somewhat similar to the Lentz, but the valves are vertical instead of working in a horizontal direction. The valves are lifted by cams on a rotating shaft, which derives its motion from bevel wheels on one of the main axles. Variation in cut-off and reverse is arranged by altering the angular advance of the admission cams on their shafts by an ingenious mechanism. The exhaust cams are operatated independently and give a fixed point of exhaust.

In the U.S.A. the Franklin poppet valve gear has been fitted to a few engines.

CRANK AXLES.

If W = weight of engine in tons, when in working order; D = diameter of driving wheels in inches; then

$$d = K\sqrt[3]{WD}.$$

For the best modern practice, K = ·522. (*Wolff.*)

Dimensions taken from the crank axles of a number of modern British locomotives, with cylinders ranging from 17 to 21 ins. diameter, give the following rule:—

$$d = 0{\cdot}375C + 1,$$

d being the diameter of main bearings and C the diameter of cylinders.

The crank-pin journals are usually the same diameter as the main bearings, the barrel or centre portion about ½ in. less and the wheel seat 1 in. more. Thickness of webs varies from 4 to 4½ ins.

Built-up crank axles are common. The advantages over a forged axle are cheapness, more effective bearing surfaces due to absence of radii, fractured parts may be replaced without scrapping the whole axle. By extending the webs a balanced axle is obtained. Special steels may be used.

The parts are assembled by shrinkage fits, the webs being heated in a gas furnace and shrunk on to the shaft and pins in special fixtures to set the throws in their correct positions. Holes are drilled between web and shaft, into which screwed dowel pins are fitted as keys.

The shrinkage allowance, or the amount by which the hole is smaller than the pin, depends on the tensile strength of the crank webs. For steel to B.S.S. 8c this is 0·025 in. in Horwich practice for axles about 8 ins. diameter.

AXLE-BOXES AND BEARING SURFACES.

In modern practice the straight axles of coupled wheels have no collars. Lateral thrust on axle-boxes is taken on wheel hubs only.

The simplest axle-box is one of solid bronze or gun-metal, with a keep of the same material. The crown is recessed to form pockets for a white-metal lining over the bearing surface. The sides of the box slide against steel or cast-iron horns.

Boxes forged from steel are fitted with a bronze or gun-metal bush, white metal lined, and the sides lined with the same metal as the bush.

Cast-steel boxes have a bronze or gun-metal crown pressed in with a load of 8 to 9 tons. The bearing surfaces are covered with a thin layer of white metal. Latest practice is to face the horn surfaces with thin plates of manganese steel (11 to 14 per cent. Mn.). The plates are bedded to the sides of the axle-box and welded to it. The horns have a compound assembly consisting of a manganese steel plate riveted and welded to a mild steel backing plate. The final machining of the mild steel surface affords an easy method of adjusting the horn gap.

Angle included at centre of journal by arc of contact is usually for coupled wheels, 160° to 170°, for bogie, carrying, or trailing wheels, 60° to 80°. The maximum bearing pressures are approximately 250 lbs. per sq. in. of projected area for coupled wheels, 350 lbs. for bogie, and 450 lbs. for tenders. Bearing brasses are commonly of gun-metal to Admiralty specification and the white-metal lining of Babbitt. In some cases alloys having a lead base are used. Maximum crown wear of brasses or axle-boxes is ⅛ in.

Lubrication is introduced either at a transverse slot at top centre, or at two slots at 30° each side of the vertical centre line.

Lubrication of bearings is by top feed from crown of box or from auxiliary oil boxes, and underpad of wool on spring frame. In case of bogie and tender wheels lubrication is often by underpad only.

The 'Isothermos' axle-box is used on the Continent for tenders. A disc or thrower dipping into a reservoir of oil raises the lubricant by centrifugal force to an upper chamber, whence it flows to the bearing and returns.

The lubricating oil is a medium mineral oil mixed with about 10 per cent. of rape oil. An average oil consumption is 6 to 7 oz. per bearing per 100 miles.

In U.S.A. cakes of hard grease are used in place of oil: these are placed in the keeps and pressed under strong spring action through a perforated metal plate against the journals. The cakes last for some time and obviate the frequent attention necessary in the case of oil lubrication. In some cases grease lubrication is extended to coupling and connecting rods, and even to valve motion.

Roller bearings are being adopted to an increasing extent for axles of carrying wheels and for tenders. In the case of inside bearings of coupled wheels it is usual to house the two bearings in a cannon box embracing the axle. A roller-bearing box has, however, been produced for bearings of crank axles, where the cannon box cannot be adopted.

For crank-pin journals and coupling-rod pins, the pressure may be as much as 1,500 lb. per sq. in., the load on connecting rod being taken as full boiler pressure on piston area.

For crosshead pins 4,000 lb. per sq. in. is allowable on account of the small angular movement. Crosshead slippers should be about 60 lb. per sq. in., a low pressure being advisable on account of the exposure of slide bars to sand and grit.

WHEELS AND TYRES.

Cast-steel wheels are general. The method of securing tyres by means of set screws through the rim of the wheel is the most common, but this practice is not favoured to-day. The alternative is to depend on the shrinkage of the tyre to grip the wheel, a retaining ring being inserted to lock the tyre in place laterally. This is a cheap and satisfactory fastening, but there is a tendency for tyres to become loose as they wear thin.

The shrinkage allowance for tyres is usually between 1/750th and 1/1000th of the diameter of wheel centre.

In W.R. practice the total shrinkage is given as $\frac{1\cdot0625\,D + 10}{1{,}000}$**, D being the diameter of wheel in inches.**

Driving wheels have tyres with flanges about ⅛ in. thinner than the other wheels. This eases the engine on curves and protects the crank axle to some extent. Blind or flangeless tyres are uncommon in England, although often resorted to in America.

Of modern types the 4–4–0 engine is the most economical in tyre wear. The flanges of the leading bogie wheels which guide the engine wear much faster than the second pair. Bogie wheels wear less than radial truck wheels, as a bogie sets itself tangentially to any curve. In engines of the 0–6–0 and 0–8–0 types mileage is determined by the flange wear of the leading coupled wheels.

Tyres with treads worn hollow are detrimental to points and crossings. A flange worn sharp is liable to cause derailment. Tyres are turned down to 1⅝ ins. on tread and allowed to wear to 1½ ins. before they are scrapped, except in case of large driving wheels, where 1¾ ins. or 2 ins. is the limit. The thickness of new tyres is usually 3 ins.

Wheels are forced on axles by hydraulic pressure. A minimum of 10 tons per inch diameter of wheel seat should be allowed when rape oil is used as a lubricant, 100 tons being a usual amount for large axles; or, if D is the diameter of wheel seat in inches, the load = 10D tons.

The wheel is bored slightly less in diameter than the axle, the difference expressed as a fraction of an inch being from $\frac{2D + 3 \cdot 5}{1,000}$ to $\frac{4D + 2}{1,000}$, depending on rigidity of the boss, quality of steel, etc.

In some cases the wheel and wheel seat are slightly tapered, the difference in diameter in the length of the wheel seat being $\frac{1}{32}$ in. The W.R. practice is to bore the hub parallel to and smaller than the axle by an allowance varying from 0·0015 to 0·002 per inch of diameter. Tonnage for pressing on the wheels by hydraulic press is from 8 to 12 tons per inch of diameter, the intensity of the grip depending to a large extent on the thickness of the hub. The best results are obtained when this is not less than half the diameter of the axle in thickness.

If the tyre is on the wheel, it takes 25 per cent. more pressure to force the wheel on the axle for the same allowance.

Keys should be tapered $\frac{3}{64}$ in. per foot and fitted to within $\frac{3}{4}$ in. before being driven home.

Crank pins should be forced in with a minimum pressure of 13 tons for each inch of diameter and the ends of the pins riveted over inside the wheels.

BRITISH STANDARD CONTOURS FOR LOCOMOTIVE TYRES.*

(FOR BRITISH RAILWAYS 4 FT. 8½ IN. GAUGE.)

(No. 276—1927.) (*Abstract.*)

Contour A recommended for the leading and trailing wheels of bogies, the wheels of pony trucks and radial axles, or any pair of wheels which constitute the leading or trailing wheels of a locomotive, whether tender or tank engine.

Contour A or G recommended for the leading wheels of a set of coupled wheels, when led by a bogie, pony truck, radial axle, or any pair of carrying wheels.

Contour A or G recommended for the trailing wheels of a set of coupled wheels, when followed by a bogie, pony truck, radial axle, or any pair of carrying wheels.

Contour G or B recommended for coupled wheels, other than the leading and trailing coupled wheels of groups 6, 8, and 10 coupled.

(In practice, the use of the G Contour is being given up in favour of A or B.)

FLEXIBLE WHEEL BASE.

Main-line engines should be capable of traversing a curve of 5 chains radius, and sufficient side-play is given to bogies and radial wheels for this. The theoretical amount required is not attained in practice, as engine frames and track spring a little on sharp curves.

There is a small amount of side-play allowed between flanges of wheel and rail. With new tyres on new rails, this is about $\frac{5}{16}$ in. each side, or a total of $\frac{5}{8}$ in. The flanges of driving wheels are thinned down to give about $\frac{3}{4}$ in. to $\frac{7}{8}$ in. total. Additional side-play is sometimes given by allowing a little clearance between axle-boxes and guides. It is very exceptional to give any side-play between journal and bearings.

Baldry's rule for the radius of pony trucks and radial axleboxes is

$$R = \tfrac{1}{2}\left(B - \frac{A^2}{B}\right),$$

where B is horizontal distance from truck wheels to centre of rigid wheel base and A is half rigid wheel base.

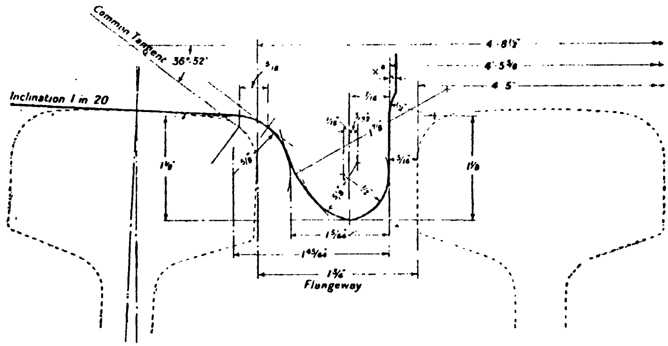
Bogies, in addition to turning on the pin, are allowed a certain amount of transverse movement. This is controlled by springs, suspension links, or inclined slides. Some bogies have curved slides giving radial instead of transverse movement. Fixed centre bogies are now but little used.

Counterbalancing Locomotive Driving Wheels.

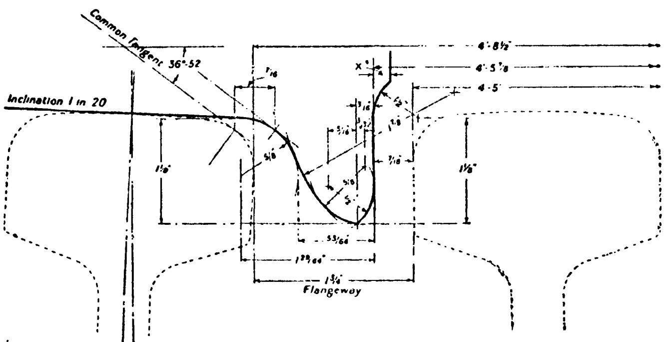
The revolving and about 60 per cent. (this figure varies considerably) of the reciprocating parts should be counterbalanced. The tendency at the present time is to reduce this figure, and in three- and four-cylinder engines it has been as low as 40 per cent. In some recent three-cylinder engines the counterbalance for reciprocating masses has been omitted altogether, so that no 'hammer blow' is exerted on the rails.

* By permission of the British Standards Institution.

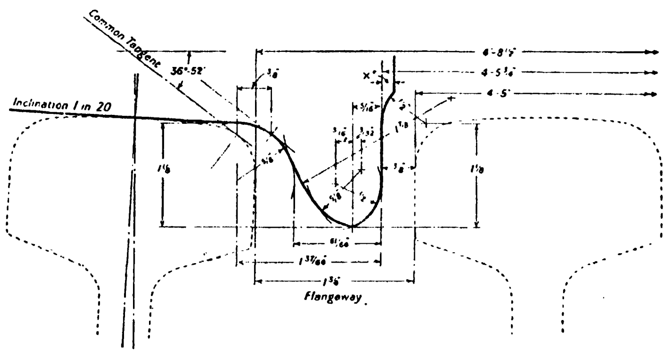
British Standard Contours for Locomotive Tyres for British Railways.



B.S. CONTOUR A.



B S CONTOUR E.



B.S. CONTOUR G.

The revolving parts develop centrifugal force, the horizontal component of which disturbs the engine longitudinally, to which must be added that due to the momentum of the reciprocating parts: also, these two forces produce a sinuous motion by acting first upon one side of the engine and then on the other. The vertical component of the centrifugal force generates a rolling motion by acting alternately upon each side of the engine. A peculiar effect is also produced by the obliquity of the connecting-rod to the slide bars, a turning upon a horizontal axis, together with an up-and-down movement at the crank axle. The horizontal forces are the most injurious, although some American engineers consider the vertical to be so; but English practice is to take a medium course between excessive horizontal and vertical disturbing influences. It has been clearly demonstrated that high centres of gravity are advantageous.

The balance weights in the wheels do not revolve in the same vertical plane as the parts to be balanced, and it is therefore necessary to balance moments as well as forces. The weights for each part must be split into two, and their proportions will vary with the distance of the part away from the balance weight plane. If this distance is a and the distance between weights in left and right wheels is b, a primary weight of $(a + b)/b$ times the weight of the part must be placed in the near wheel, diametrically opposite to the crank pin, and a secondary one of a/b times in the far wheel, on the same side as the crank pin, if the part revolves outside the wheels. If the part is between the wheels a primary weight of $(b - a)/b$ is placed in the near wheel and a secondary of a/b in the further one, both opposite to the crank pin. There will, therefore, be as many primary and secondary weights as there are vertical planes of revolving and reciprocating parts. These are summed up and the weights combined in each wheel to form a single weight at an angle to the crank pin. This is calculated at crank pin radius and reduced afterwards in accordance with the distance of the centre of gravity of the weight when placed at the rim of the wheel. This weight is usually made of crescent shape.

American practice has been to allow 1/400th part of the engine weight to remain unbalanced in the reciprocating parts on each side. The remainder is then divided amongst the coupled wheels;

$$r = \left(R - \frac{W}{400}\right)/N,$$

where,

r = reciprocating weight in each wheel at crank pin radius; R = total weight of reciprocating parts; W = weight of engine in working order; and N the number of coupled axles.

The Association of American Railroads has recently investigated the effects of balancing in locomotives upon the track and upon the riding of locomotives. Tests were carried out within the limits of 56 per cent. to zero reciprocating compensation, that is, from 4·6 to 12·8 lb. per ton (of 2,000 lb.) reciprocating unbalance. The disturbing effect of reciprocating compensation was judged to be unduly high when the reciprocating unbalance was more than 8 lb. per side per ton of total locomotive weight in working order. An overbalance of 100 lb. per wheel for all drivers showed a low hammer-blow effect on the track, and this was increased to 200 lb. per wheel without causing excessive hammer blow. Over 200 lb. it became undesirably high. Because of the disturbing effect of the vertical component of the connecting rod thrust some advantage is to be obtained by placing 50 lb. less overbalance in the main driving wheels than in the coupled wheels.

The English method of cross balancing is being taken up in America.

Cast steel wheels have the balance weights cast solid with them; occasionally the weights have pockets cored out for the reception of lead. Another practice is to cast the wheels without weights and to rivet steel plates to the spokes. Molten lead is then run into the pockets formed between the spokes.

In order to obtain uniformity of results, some railways make use of a wheel-balancing machine. The pair of wheels to be tested is mounted on bearings supported by springs set radially round them. Weights are attached to the crank pins to represent the revolving and a proportion of the reciprocating parts. The wheels are then spun round at high speed and the counterbalance adjusted until steady running is obtained.

BOILERS.

Locomotive boilers should have a factor of safety of 5: considerations of weight make a larger factor undesirable. The copper fire-box stays should not be stressed greatly in excess of 4,000 lbs. per sq. inch, as copper loses much of its tensile strength at the steam temperature, while steel is not greatly affected.

Coned boiler barrels, although more costly, are adopted by some railways in order to obtain the most powerful boiler for a given weight, by the reduction in diameter at the front end, while allowing ample space by reason of the larger diameter in the region of the fire-box tube plate, where steam generation is at a maximum.

Some railways prefer the 'Belpaire' type of fire-box, while others adopt the round top with direct crown stays. In British practice the long narrow grate is almost universal for lengths up to 10 ft. 6 ins. and areas up to 33 sq. ft., but as this is insufficient for engines working the heaviest main line trains to the North, the wide type of fire-box has been introduced with grate areas up to 50 sq. ft.

This practice necessitates a carrying axle under the fire-box.

In America the wide fire-box is almost universal due to the large grates required, up to about 110 sq. ft., and to the use of bar frames which allow less width of fire-box than with the plate frames employed in British practice.

Most American fire-boxes of over 50 sq. ft. area are fitted with a mechanical stoker or are oil-fired.

Steel or Monel metal fire-box stays are now being extensively used in place of copper.

Steel fire-boxes are being more extensively used owing to the ease with which they can be constructed and repaired by arc welding. Tube ends can be seal welded to them after being expanded by rolling.

The all-welded boiler is under trial in many countries. The barrel and shell is stress relieved and all seams subjected to X-ray examination. Caution is being observed until more experience is gained with the boilers in service.

Boiler Capacity.—The maximum evaporation per sq. ft. of firebox (including combustion chamber, thermo-syphons or water-tubes) is about 55 lb. per hour. Evaporation from fire tubes is approximately 10 lb. per sq. ft. per hour, depending on length, diameter and spacing, and from superheater flue tubes about 11½ lb.

The maximum continuous rate which it is desirable to maintain in service is 12 to 13 lb. per sq. ft. of total heating surface per hour.

Grate Area and Heating Surface.

$$\text{Grate area in sq. ft.} = \frac{\text{average I.H.P.}}{25 \text{ to } 45}$$ the smaller denominator being used for small, low-pressure engines, and the larger one for the latest type of high-power, high-pressure engines.

The ratios giving the best results are as follows: Grate to total heating surface, 1 : 55 to 65; grate to fire-box heating surface, 1 : 5 to 5·5; and fire-box heating surface to total heating surface, 1 : 11 to 12.

Bituminous coals require space in the fire-box for the proper combustion of their gases before entering tubes. The fire-box volume should be 6 or 7 cub. ft. for every square foot of grate. Under these conditions 15 lb. of air are needed for each pound of coal burnt. The air spaces through fire-bars should not be less than 33 per cent. of grate area, and the damper opening not less than 15 per cent. Air spaces of 50 per cent. and damper opening 20 per cent. are not too large. In coupled engines, where an axle comes close under the grate, the slope of pan over it should be not less than 45°; and the restricted space for air between pan and fire-bars must have an area of at least 15 per cent. of the part of the grate which it supplies.

Fire-bars are of wrought iron or cast iron, and usually ⅞ inch wide at top. Gaps of ⅜ inch to ½ inch between these give an air space of 30 per cent. to 40 per cent. of the grate area.

Boiler Tubes.

Diameter and Length of Tubes.—The diameter of tubes varies with the length of barrel. Short barrels require 1¼ in. to 1⅝ in. outside diameter tubes; those over 10 ft. long, 1¾ in. to 1⅞ in. tubes. Long barrels, 13 ft. and upwards, require tubes 2 ins. to 2¼ ins. diameter. The internal diameter of a tube should be approximately 1/100th of its length.

Usual Thickness of locomotive boiler tubes, 5-in. superheater flue tubes, No. 8 W.G.; 1¾-in. tubes, No. 11 W.G.

British Standard.—For 1⅝ in. outside diameter, 13, 12 or 11 s.w.g.; for 1¾ in., 1⅞ in., and 2 ins., 12, 11 or 10 s.w.g.; for 2¼ ins., 11 or 10 s.w.g.

Water space between tubes should not be less than ⅝ in. for 1¾ in. diameter tubes, and ¾ in. for 2¼ in. tubes at the fire-box end, but may be pitched 1/16 in. closer at the smoke-box end.

Life of Boiler Tubes.

The life of copper and steel tubes in locomotive boilers, taken over a period of eight years is as follows:—

	Miles.
Copper 1st period (new)	110,000
„ 2nd period (drawn)	80,000
„ 3rd period (pieced)	50,000
Total	240,000

Subsequently 30 to 40 per cent. of those pieced are treated so again.

	Miles.
Steel 1st period (new)	70,000 to 80,000
„ 2nd period (pieced)	30,000 to 40,000

(*G. Hughes.*)

After withdrawal from the boiler steel tubes are de-scaled and the ends cut off. The tubes are safe-ended by butt welding on a short piece of new tube, the joint being ground flush. They are then swaged and belled in readiness for a further period of service.

Alternatively, the shortened tubes are used in boilers having shorter barrels than those from which they were withdrawn.

Calculation of the Heating Surface of Boilers for Locomotives.

The Association of Railway Locomotive Engineers' method of calculating the heating surfaces of locomotives is as follows:—

Fire-box.—The outside (wetted surface) of inner fire-box plates to be taken to top of foundation ring. Areas of tube-holes and sectional area to wetted side of fire-hole ring, or flanged plate, as the case may be, to be deducted; section of fire-hole being taken close up to the inner fire-box plate.

No deductions to be made for copper stays or roof stays. If the boiler has fire-box water tubes the surface to be taken on the inside (wet side) of tube.

Tubes.—The outside surface of tubes (wet side) to be taken, calculated on uniform diameters for both ordinary and superheater tubes; the length of tube being taken between tube-plates.

Elements.—The inside surface (steam side) of elements to be taken, the effective length of tube being from and to smoke-box end of large flue tube.

Smoke-box tube-plate.—No allowance to be made.

Equivalent heating surface of superheaters.—In order to compare the steaming capacities of superheater and non-superheater boilers, an equivalent heating surface is sometimes given for the superheater boiler, as owing to the lesser evaporative surface of the tubes, it appears less powerful. If 1·5 times the superheater surface is added to the evaporative heating surface, an equivalent heating surface is formed, which may be compared with that of a non-superheater boiler. Thus, a non-superheater boiler has 2,455 sq. ft. of heating surface, but when converted to superheater has 2,031 sq. ft. of evaporative heating surface and 460 sq. ft. of superheating surface. The addition of 1·5 times the superheating surface to the evaporative gives a total of 2,721 sq. ft., and indicates that the boiler is 11 per cent. more powerful when superheated.

Fire-Boxes.

Many attempts have been made in the past to substitute steel for copper plates in fire-boxes of British locomotives. Electric arc welding now offers improved facilities for the construction and repair of steel boxes, and their number is increasing. Steel fire-boxes are universal in America, where conditions favour their adoption. Greater success had attended the introduction of steel side stays for copper fire-boxes. Owing to the higher tensile strength the diameter over threads is about ⅝ in. for a pitch of 3½ ins. The stay projects through the fire-box casing plate about ¼ in., but the projection through the copper plate is furnished with a hexagon nut of reduced thickness. This forms a renewable head for the stay and protects it from injury by the fire. Similar stays are also made in Monel metal.

In locomotive practice a pitch of about 4 ins. is almost invariably adopted for the screwed stud stays in the fire-box. Theoretically this is much closer than is necessary, but the practice is good, as it provides a substantial margin of wear in the copper plates.

Life of Fire-Boxes.

The life of fire-boxes depends more upon the tons hauled than the actual miles run. Copper fire-boxes on the Lancashire and Yorkshire section of the L.M.R. have a life of from 10 to 16½ years. The older engines with 140 lbs. pressure are found to run their fire-boxes up to as much as 500,000 miles: an average figure for 70 engines being 310,000 before replacement by new ones. In standard engines, such as the radial tank and 6-wheeled coupled goods classes, working at 160 lbs. pressure, the average life of a copper fire-box is eleven years, with average mileages of 272,000 and 235,000 respectively. These figures are based upon records of 120 locomotives. Individual copper tube-plates in the fire-boxes above named require renewing during the life of the box. In the radial tank class, records of 53 tube-plates show an average life of seven and three-quarter years with 205,000 miles before renewing, whilst the 6-wheeled goods average 135,000 miles for 144 tube-plates. The remaining plates, viz., door and wrapper plates, practically do not require replacing during the life of the fire-box, but certain repairs and patches are fitted if necessary.

Smoke-Boxes.

In superheater engines the blast pipe is set some 30 ins. forward of the tube-plate, to allow ample room for the superheater header, and the orifice is about 7 ins. below the centre line of the boiler, but this figure varies considerably. The blast pipe should not be too low or there is risk of cinders being drawn into it. The diameter of the orifice should be as large as possible consistent with good steaming. For cylinders 16 ins. to 22 ins. diameter, the orifice varies from

4½ ins. to 5½ ins., 5 ins. being usual with a 19-in. cylinder, but a good deal depends on class of coal, work performed, and other conditions.

Chimneys are made as high as load gauge permits, and are extended downwards into the smoke-box. The main consideration as to dimensions is that a cone of steam diverging from the blast pipe orifice with a total angle of 1 in 6, should just pass clear through the top of the chimney, leaving a small annulus for the gases. The chimney should be slightly tapered and terminate in a bell, so that gases may be gradually entrained and increased in velocity.

In American practice a diaphragm is fitted across the smoke-box above the top row of tubes and carried down just below the blast-pipe orifice, terminating a little in front of it. By this means the draught on the tubes is equalised and the emission of sparks prevented. Some British engines are also fitted with this device.

The smoke-box vacuum obtained in modern superheater engines varies with the horse-power developed, and is about 5 in. of water, with a maximum of 7 in., in heavy passenger work, and about half these amounts for superheater goods engines.

Superheaters.

The superheater of a locomotive boiler performs two functions. In the first place, it acts as a steam drier by evaporating the moisture carried over with the steam to the cylinders. Secondly, the dried steam is heated some 200°–400° F. above its normal temperature at the working pressure, and a volumetric increase occurs. By superheating the steam, not only is the loss due to moisture avoided, but initial condensation in the cylinders is eliminated or greatly reduced. Losses due to leakage are also less. The expansion line of indicator diagrams taken from cylinders using superheated steam show a more rapid fall of pressure than with saturated steam. On the other hand, the compression line is also lower, showing less back pressure, so that there is little difference in the mean effective pressure to that of cylinders using saturated steam at the same initial pressure and cut-off. The orifice of the blast pipe with a superheater engine needs to be about ¼ in. smaller as the weight of steam discharged in a given time is less than in saturated steam engines. The chief gain due to superheating the steam to a final temperature of about 650° F. results in a saving of from 15 to 25 per cent. in fuel and 20 to 30 per cent. in water. The steam consumption of saturated engines is approximately 27 lb. and coal consumption 4 lb. per i.h.p. The corresponding consumptions of engines superheated about 200° F. are reduced to 19 lb. of steam and 3·0 lb. of coal per i.h.p.

Boiler repairs are also less, due to smaller demand for steam and lower rate of combustion of fuel. Engines fitted with superheaters can run longer distances without replenishing water and fuel supply. This is particularly advantageous in the case of tank engines, where the supplies of both are limited. The superheater adds little or nothing to the starting power of an engine, but it enables a larger horse-power output to be maintained, and consequently the hauling power is increased when running. Engines which had become obsolete on account of the growth of train loads have been given a new lease of useful life by the addition of a superheater. In some cases it has been successfully applied to engines with flat unbalanced slide valves between the cylinders, the only alteration being the provision of new tube plates for the superheater flues. A moderate degree of superheat does not appear to affect bronze valves provided great care is taken with the lubrication. Either a mechanical force-feed or a sight-feed displacement lubricator can be used, but the lubricant must be of first-class quality. With piston valve engines, the chief trouble is the formation of carbon deposit. This clogs the packing rings, chokes the ports and coats pistons, covers valve heads and spindles, etc. When steam is shut off, the pumping action of the main pistons, when running, draws smoke-box gases, dust, and ashes down the blast pipe, and solids adhere to the oily surfaces. Some decomposition of the oil also occurs. This action can be considerably lessened by (1) putting the reversing lever into full gear when steam is shut off; (2) by the provision of air valves to automatically admit air to the steam chests and destroy any vacuum created; (3) by automatic by-pass valves which put the opposite ends of the cylinder in communication when steam is shut off. Another practice is to admit a very small quantity of steam, either through the regulator or by means of a special valve. By filling the spaces with steam instead of air, decomposition of the oil is prevented.

Fire-tube Superheaters are principally employed. Several rows of large fire tubes are fitted in the boiler, and into these superheating tubes extend from a header or headers in the smoke-box towards the fire-box and back again. The construction of the header varies, as well as the arrangement of tubes, but the object in all designs is to direct steam through small tubes exposed to hot gases direct from the furnace and supplying an extended steam path, so that while travelling at a high velocity a considerable degree of heat is taken up by the steam.

The 'Swindon' (used only on the Western Region) design has its own constructional features, being designed for a moderate degree of superheat. The Schmidt design aims at a high superheat – from 250° to 530° F. above the temperature of saturated steam. It consists of a suitable header or steam collector, to which are attached four-fold elements. This provides a long steam path, and in virtue of the high steam velocity it is able to take up the required heat.

To obtain superheated steam of from 625° to 675°, the net gas area through flue tubes should be approximately 51 per cent. of the whole.

Most locomotives designed in recent years have relatively large superheating surface, as it has been found that a high degree of superheat is more economical as regards consumption of steam than a low degree, despite the fact that the exhaust steam from the blast-pipe still retains some degrees of superheat.

Some railways fit snifting or anti-vacuum valves on the top of the smoke-box. When an engine is drifting with steam shut off, air is drawn from the valves through the superheater elements, and prevents overheating. At the same time the air is heated before coming into contact with the valves, and thus reduces the risk of the valve liners becoming loose by contraction from sudden cooling.

Feed-water Heating.

For many years attempts have been made to recover some of the losses that occur in the locomotive by returning waste heat to the boiler through the medium of the feed water. To devise a method—or methods—however, of feeding continuously with water preheated to a degree high enough to render the means worth while, has taken years of development, research and experiment.

Locomotive feed heaters may be classified as:

1. Surface or closed type, incorporating in their construction water tubes deriving heat from either exhaust steam or from flue and smoke-box gases.
2. Direct contact, mixture or open type embodying either steam-jet pumps (injectors), steam-driven, direct-acting pumps and jet condenser chambers, or mechanically-driven pumps, comprising jet condensers and surface economisers in series.

It is generally recognised that if the temperature of the feed water be raised by heat from waste sources, a saving in fuel of 1 per cent. for every 11° F. rise will be obtained.

This may be expressed simply by:

$$S = \frac{100\,(t_2 - t_1)}{H + 32 - t_1}$$

where S = percentage of fuel saved:
t_1 = inlet feed temperature before heating in F°;
t_2 = outlet or final feed temperature in F°;
H = total heat of steam.

The principle of the tubular surface equipment has been in use at sea for many years, but one of the first successful applications to locomotives was made by Trevithick on the Egyptian State Railways, and the exhaustive experiments made are fully described in *Proc. Inst. Mech. Eng.*, 1913. This class of heater is probably the simplest in existence, and consists essentially of a nest or group of tubes through which passes the feed water from the pump delivery on its way to the boiler and around which tubes a quantity of exhaust steam from the blast-pipe is condensed. This heater is, in effect, a surface condenser open to atmosphere by means of the drain through which passes to waste or back to the tender the water of condensation.

Modifications of this arrangement involve the placing of the heater, usually of cylindrical form, across the smokebox forward of the chimney, and either attached by brackets to the shell or set in a recess formed by cutting away or shaping the smoke-box plating to suit. Both dispositions are widely used in the U.S.A. and in Germany, and this positioning of the heater has the advantages of an extremely short exhaust lead, and of providing a ready and simple means of returning by gravity the condensed exhaust steam to the tender tank, which is reached after the condensate has passed through an oil filter or separator. The tender capacity is thus increased by the amount of exhaust condensed.

An ingenious form of water raiser, for use on closed heaters situated below tank-top level, comprises a drain receiver fitted with a ball float and trip valve. The upper part of the tank is connected with the air-brake reservoir, and the system is so arranged that when a sufficient quantity of condensate is received from the heater drain the ball lifts, opens the trip valve, which admits high-pressure air to the tank, and the water is thus forced back into the tender.

The surface or closed type heater, while being undoubtedly simple, has the inherent disadvantage of being quickly rendered inoperative when used on engines working in districts with 'bad' water.

A large French railway determined the relative economies rendered by three classes of feed heaters as follows:

(*a*) *Fuel.*

Mixture heater	.	10 to 12 per cent. saving.
Surface heater	.	7 per cent. saving.
Exhaust Injector	.	4 to 5 per cent. saving.

(*b*) *Water.*

Mixture heater	.	15 per cent. saving.
Surface heater	.	Nil.
Exhaust injector	.	5 to 6 per cent. saving.

In the early days of locomotive engineering, before sufficient experience had been obtained with the effects of high temperatures on tubes containing impure water, much costly experimentation was made with tubular feed-water heaters fitted in the smoke-box. The high temperature obtaining in this compartment formed a very tempting bait to designers, and there is no doubt that given sufficient surface and the right materials the effect of the smoke-box gases can be a useful one. The difficulty is that, although a high temperature of 600° or 650° F. is normal to a smoke-box in full operation, its heat is what may be termed comparatively static, and it is difficult to impart this heat through a tube wall to the water.

One of the first contact or mixture heaters to be applied to locomotives was the exhaust steam injector which, by reason of its low first cost, light weight and small bulk, has enjoyed considerable favour. The exhaust injector is, perhaps, one of the best examples of finesse in modern steam locomotive practice, and while its returns in the way of fuel economies are not so high as those rendered by some of the more modern pump and heater systems, there would seem to be circumstances where it is considered of value, especially where weight is a vital question. It is much used on British railways. It appears to be the consensus of opinion of most locomotive engineers that an average fuel economy of 5 to 6 per cent. is as high as can reasonably be expected.

An early form of direct-contact heater was the tender tank itself, to which was led a branch from the engine blast-pipe. Owing to a number of reasons, the chief being the long lead of exhaust pipe, the unwieldy connections between engine and tender, undue heating of the water causing trouble with the injector, the arrangement did not find universal favour; it has, therefore, not become one of the recognised feed-water heaters. It may be further added that the maintaining of water at a temperature at which it would be acceptable to the injector in cases of pump failure, viz., 120° F., scarcely justified the means adopted.

Mixture or open type heaters are further subdivided into those using a mechanically-operated pump and those incorporating the steam-driven auxiliary.

An example of the former system is the Dabeg.

The Worthington arrangement, used in the U.S.A., employs a small turbine-driven centrifugal pump situated as near as possible to the tender, and which delivers water at constant speed to the heater. A practically constant, low-delivery pressure is thus maintained, and the pump, therefore, supplies as much water as is permitted by the opening of the control valve in the heater.

The feed having been pre-heated in the exhaust chamber, passes then to the feed pump proper, which is an ordinary direct-acting reciprocating pump.

Undoubtedly, one of the simplest mixture systems so far evolved is the A.C.F.I., employing a pair of cylindrical chambers or drums placed in parallel across the top of the boiler and combined with a small direct-acting steam-operated feed pump of the horizontal pattern. It is much used on French railways, and the L.N.E.R. have a number of engines fitted with it.

Water from the tender is drawn through a fine mesh strainer contained in the feed well by a cold water pump, which discharges it through a spray pipe into the mixing chamber. Here exhaust steam from the blast-pipe is met with, having just previously traversed an oil separator, and the mixture passes over through an inter-connecting pipe to the settling chamber, where dissolved oxygen and CO_2 are liberated, which gases are discharged through a vent in the top of the chamber. The feed, now heated practically to exhaust temperature, reaches the suction of the hot pump, and is delivered to the boiler. Any excess hot water collecting in the settling compartment is returned to the feed well.

(Abstracts of paper read before Inst. Loco. Eng.)

Injectors.

TABLE SHOWING MAXIMUM DELIVERY OF COMBINATION INJECTORS.

(Gallons per hour working on dry steam, with feed water at 60° F., lifting 3 ft. and delivering against pressure equal to steam at back of nozzle.)

BRITISH STANDARD SPECIFICATIONS FOR MATERIAL USED IN THE CONSTRUCTION OF RAILWAY ROLLING STOCK.

(Report No. 24—Parts I.–VI.). (*Abstracts.**)

LOCOMOTIVE CRANK AXLES—B.S.S. 1—1941 (of Report No. 24, Part I.).

The crank axles shall be manufactured from high quality steel made by the acid open-hearth or electric process, and shall not show on analysis more than 0·05 per cent. of sulphur or of phosphorus.

A standard test-piece C or a subsidiary test-piece 0·798 in. diameter shall show an ultimate tensile stress of not less than 28 tons nor more than 33 tons (62,720 to 73,920 lb.) per sq. in. (44·10 to 52 kg. per mm.²), with an elongation of not less than 25 per cent. The yield stress in either case shall be not less than 50 per cent. of the ultimate tensile stress.

A test-piece 9 ins. (230 mm.) long, 1¼ in. (32 mm.) square, with $\frac{1}{16}$ in. (1·6 mm.) radius at the edges, machined from the crank axles, shall withstand being bent cold by direct pressure from a tool 2 in. (51 mm.) wide, the end having a radius of 1 in. (25 mm.), until the sides of the test-piece are parallel. The ends of the test-piece are then to be brought together, without fracture, by direct pressure.

As an alternative to the cold bend test, the test-piece may be placed upon bearings having a clear span of 6 in. (152 mm.), resting on a solid foundation, and shall withstand, without fracture, 20 blows from a weight of 1,120 lb. (508 kg.), having a rounded end of 1¼ in. (32 mm.) radius, falling 6 in. (152 mm.). The test-piece shall be reversed after the first and every alternate blow. The fall shall then be increased to 12 in. (305 mm.), and the test continued until fracture occurs.

All crank axles shall be oil-hardened, and tempered.

LOCOMOTIVE STRAIGHT AXLES—B.S.S. 2—1941 (of Report No. 24, Part I.).

Quality of material same as for locomotive crank axles. Use of basic open-hearth stee permitted.

The axle shall be placed upon bearings resting on a block of metal of not less than 5 tons (11,200 lb. = 5,080 kg.) weight supported on a concrete or other solid foundation, and shall withstand, without fracture, five blows from a weight of 1 ton (2,240 lb. = 1,016 kg.) falling 16 to 35 ft., according as the diameter is under 4 or over 6 in., the distance apart of the bearings being from 3 to 5 ft., as shown by table.

The axle shall be turned after the first and third blow, and shall be broken after testing, both in the centre and at the journals.

A standard test-piece C or a subsidiary test-piece 0·798 in. diameter shall show an ultimate tensile stress of not less than 35 nor more than 40 tons (78,400 to 89,600 lb.) per sq. in. (55·1 to 63 kg. per mm.²), with an elongation of not less than 25 per cent. with 35 tons and 20 per cent. with 40 tons; the sums of the intermediate tensile breaking strengths and corresponding elongations being not less than 60. The yield stress shall be not less than 50 per cent. of the ultimate tensile stress.

A test-piece 9 in. (230 mm.) long and 1¼ in. (32 mm.) sq., with $\frac{1}{16}$ in. (1·6 mm.) radius at the edges, shall withstand being bent cold by direct pressure from a tool 2 in. (51 mm.) wide, the end having a radius of 1 in. (25 mm.), until the sides of the test-piece are parallel. The ends of the test-piece shall then be brought together, without fracture, by direct pressure.

N.B.—This test shall be taken only when a less number than 15 axles is ordered and the falling weight test has not been carried out.

All axles shall be either normalised or oil-treated.

LOCOMOTIVE STRAIGHT AXLES—B.S.S. 2A—1941 (of Report No. 24, Part I.).

The axles shall be manufactured from high quality steel made by the acid or basic open-hearth, acid Bessemer or electric process. In the event of the basic open-hearth process being employed, the maximum percentage of sulphur or of phosphorus shall not exceed 0·06 per cent.

Tests and treatment as for B.S.S. 2.

CARRIAGE AND WAGON AXLES—B.S.S.3—1941 (of Report No. 24, Part I.).

Same as for locomotive straight axles, B.S.S. 2, except that sulphur or phosphorus shall not exceed 0·06 per cent. and that range of falling weight test is from 15 to 35 ft. for axles under 3¾ in. to over 6 ins.; distance between bearings, 3 to 5 ft.

CARRIAGE AND WAGON AXLES—B.S.S. 3A—1941 (of Report No. 24, Part I.).

Same as for locomotive straight axles, B.S.S. 2A, except that range of falling weight test, etc., is as specified in B.S.S. 3.

LOCOMOTIVE TYRES—B.S.S 4—1942 (of Report No. 24, Part II.).

Quality of material same as for locomotive axles—B.S.S. 2.

* **By permission of the British Standards Institution.**

The tyre shall be placed in a running position with the tread resting on a block of metal of not less than 5 tons weight supported on a concrete or other solid foundation, and shall withstand, without fracture, blows from a falling weight of 1 ton. The weight shall be allowed to fall freely on to the tread from heights of 10 ft., 15 ft., 20 ft., and upwards, until the deflection of the tyre corresponds to that given in the following formula, in which d is the internal diameter of the tyre as rolled, in inches, and t is the thickness of the centre of the tread, as rolled, in inches, and s is the depth of the snip in inches.

Class C.—Tensile Breaking Strength 50 to 55 tons per square inch.

$$\frac{(d-3s)^2}{50t^2}$$

Class D.—Tensile Breaking Strength 56 to 62 tons per square inch.

$$\frac{(d-3s)^2}{55t^2}$$

Class E.—Tensile Breaking Strength 63 to 69 tons per square inch.

$$\frac{(d-3s)^2}{60t^2}$$

A standard test-piece C taken from the position indicated shall show the ultimate tensile stress and minimum elongations given in the table, the intermediate elongations being in proportion.

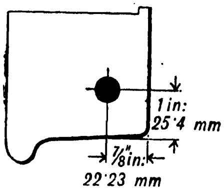

FIG. 6.

Class.	Tensile Strength. Tons per sq. in.	Minimum Elongation. Per cent
C	50–56	13 to 11
D	56–62	11 to 9
E	63–69	10 to 8

When so specified in the inquiry, each tyre shall be allowed to drop freely in a running position, from the height specified below, upon a rail fastened to an iron block of not less than 2 tons in weight. Each tyre shall then be turned round through an angle of 90 degrees, and dropped a second time.

Internal Diameter of Tyre.	Up to 3½ ft.	Over 3½ ft. and up to 4½ ft.	Over 4½ ft. and up to 5½ ft.	Over 5½ ft. and up to 6½ ft.	Over 6½ ft.
	ft.	ft.	ft.	ft.	ft.
Height of fall	5	4	3½	3	2½

CARRIAGE AND WAGON TYRES—B.S.S. 5—1942 (of Report No. 24, Part II.).

The specification is the same as for locomotive tyres, with the addition of Class B tyres, tensile breaking strength 42 to 48 tons per sq. in. and minimum elongation 18 to 15 per cent. Basic open-hearth process permitted, and limit of sulphur and phosphorus raised to 0·06 per cent for Classes B, C and D. For Class E tyres it is 0·05 per cent. Formula for deflection, Class B— $\frac{(d-3s)^2}{45t^2}$. Height of fall for diameters over 3½ ft. is 4 ft., and up to 3½ ft. it is 5 ft.

CARRIAGE AND WAGON TYRES—B.S.S. 5A—1942 (of Report No. 24, Part I.).

Material as for axles B.S.S. 2A. Class E omitted.

CARBON STEEL LAMINATED SPRINGS—B.S.S. 6X—1942 (of Report No. 24, Part III.).
With Analysis.

The spring plates shall be manufactured from high quality steel made from the best selected material by the acid or basic open-hearth or electric process, and shall show on analysis not more than 0·05 per cent. of sulphur or of phosphorus, nor more than 0·9 per cent. nor less than 0·65 per cent. of carbon in the case of plates which are to be oil hardened, nor more than 0·65 per cent. nor less than 0·45 per cent. of carbon in the case of plates which are to be water hardened. The engineer (or purchaser) may, however, specify the range of carbon which he requires, within the limits given above, when placing the order.

All springs shall be tested by being deflected by a quick-acting scrag before the buckle is put on, to an amount equal to $\frac{L^2}{900t}$, where L is the length of the top plate in inches measured along the arc as shown in fig. 7, and t is the thickness of the thickest plate in inches. They must then stand being deflected again three times in quick succession without showing any permanent set. The required deflections are shown in the table and must not be exceeded at any time during manufacture by more than 15 per cent.

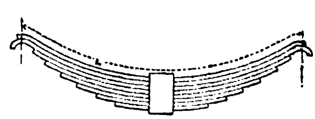

FIG. 7.

All plates shall be carefully hardened and tempered.

The buckles shall be made of good fibrous iron having a tensile breaking strength of from 20 to 24 tons per sq. in. or of suitable steel having a tensile breaking strength of not less than 24 nor more than 30 tons per sq. in. The elongation in each case shall not be less

L	Required Deflection under Scrag, in Inches.				
In.	$\frac{3}{8}$ in. plate.	$\frac{7}{16}$ in. plate.	$\frac{1}{2}$ in. plate.	$\frac{9}{16}$ in. plate.	$\frac{5}{8}$ in. plate.

54	$8\frac{3}{8}$	$7\frac{3}{8}$	$6\frac{1}{2}$	$5\frac{3}{4}$	$5\frac{1}{8}$
48	$6\frac{7}{8}$	$5\frac{7}{8}$	$5\frac{1}{8}$	$4\frac{1}{2}$	$4\frac{1}{8}$
42	$5\frac{1}{4}$	$4\frac{1}{2}$	$3\frac{7}{8}$	$3\frac{1}{2}$	$3\frac{1}{8}$
36	$3\frac{7}{8}$	$3\frac{1}{4}$	$2\frac{7}{8}$	$2\frac{1}{2}$	$2\frac{1}{4}$
30	$2\frac{5}{8}$	$2\frac{1}{4}$	2	$1\frac{3}{4}$	$1\frac{5}{8}$

than 20 per cent. (standard test-piece A), and in the case of buckles made from the solid, the elongation (standard test-piece C or subsidiary test-piece 0·798 in. diameter) shall not be less than 25 per cent., and the material shall admit of bending, when cold without showing crack or flaw, as follows :—

For iron, $\frac{3}{4}$-inch thick through an angle of 120 degrees.
" $\frac{5}{8}$-inch " " 130 "
" $\frac{1}{2}$-inch " " 140 "
For steel, all thicknesses, through an angle of 180 degrees.

In all cases the inside radius of the bend shall be not greater than $1\frac{1}{2}$ times the thickness of he test-piece.

SILICO-MANGANESE STEEL LAMINATED SPRINGS—B.S.S. 6Y—1942 (of Report No. 24, Part III.).

The spring plates shall be manufactured from high quality steel made by the acid open-hearth or the electric process and shall show on analysis the following composition :—

Quality.	Carbon. Per cent.	Silicon. Per cent.	Manganese. Per cent.	Sulphur. Per cent.	Phosphorus. Per cent.
Oil-hardening . .	0·50 to 0·60	1·50 to 2·0	0·60 to 1·0	0·05 max.	0·05 max.
Water-hardening .	0·33 to 0·50	1·50 to 2·0	0·60 to 1·0	0·05 max.	0·05 max.

The engineer (or purchaser) must specify whether he requires oil- or water-hardening.
Scragging test as for B.S.S. 6X.
All plates shall be carefully hardened and tempered.
Buckles as for B.S.S. 6X.

CARBON STEEL LAMINATED SPRINGS—B.S.S. 6A—1942 (of Report No. 24, Part III.).

Without Analysis.

Same as specification B.S.S. 6X, except that spring plates shall be manufactured from steel made from selected material by the acid or basic open-hearth, the acid Bessemer, or electric process. In the event of the basic open-hearth process being employed, the maximum percentage of sulphur and phosphorus must not exceed 0·05 per cent. The manufacturer shall supply a certificate of the carbon determination when required to do so.

CARBON SPRING STEEL FOR LAMINATED SPRINGS—B.S.S. 6B—1942 (of Report No. 24, Part III.).

With Analysis.

The spring bars shall be manufactured from high quality steel made from the best selected material by the acid open-hearth or electric process, and shall show on analysis not more than 0·05 per cent. of sulphur or of phosphorus, nor more than 0·9 per cent. nor less than 0·65 per cent. of carbon in the case of material which is to be oil hardened, nor more than 0·65 per cent. nor less than 0·45 per cent. of carbon in the case of material which is to be water hardened. The

engineer (or purchaser) may, however, specify the range of carbon which he requires, within the limits given above, when placing the order.

The test-piece shall be 60 T long, where T is the thickness of the steel and shall be cambered to a radius of 80 T, hardened and tempered. The required camber should then be 5·5 T. Any adjustment of camber shall be made at tempering heat. The test-piece shall be pressed straight between straight parallel surfaces and the camber noted after release which shall not be less than 5 T. The test-piece shall then be pressed straight again six times in quick succession without showing any permanent set.

	In.	In.	In.	In.	In.	In.	In.
Thickness of bar T . . . . Length of test-piece 60 T . .	$\frac{1}{4}$ 15	$\frac{5}{16}$ $18\frac{3}{4}$	$\frac{3}{8}$ $22\frac{1}{2}$	$\frac{7}{16}$ $26\frac{1}{4}$	$\frac{1}{2}$ 30	$\frac{9}{16}$ $33\frac{3}{4}$	$\frac{5}{8}$ $37\frac{1}{2}$
Initial camber 5·5 T . . .	$1\frac{3}{8}$	$1\frac{3}{4}$	$2\frac{1}{16}$	$2\frac{7}{16}$	$2\frac{3}{4}$	$3\frac{1}{8}$	$3\frac{7}{16}$
Minimum camber after first blow and next six consecutive blows, 5 T	$1\frac{1}{4}$	$1\frac{9}{16}$	$1\frac{7}{8}$	$2\frac{3}{16}$	$2\frac{1}{2}$	$2\frac{13}{16}$	$3\frac{1}{8}$

CARBON SPRING STEEL FOR LAMINATED SPRINGS—B.S.S. 6C—1942 (or Report No. 24, Part III.). Without Analysis.

Material for spring bars same as B.S.S. 6A. Tests same as B.S.S. 6B.

SILICO-MANGANESE SPRING STEEL FOR LAMINATED SPRINGS—
B.S.S. 6D—1942 (of Report No. 24, Part III.).

Material for spring bars same as B.S.S. 6Y. Tests same as for B.S.S. 6B.

CARBON STEEL VOLUTE AND HELICAL SPRINGS—B.S.S. 7X—1942 (of Report No. 24, Part III.).

The springs shall be manufactured from high quality steel made by the acid open-hearth or the electric process and shall show on analysis the following composition:—

	Not less than	Not more than
Carbon . . .	0·9 per cent.	1·2 per cent.
Manganese . .	0·45 „	0·70 „
Silicon . . .	—	0·30 „
Sulphur . . .	—	0·05 „
Phosphorus . .	—	0·05 „

Each spring shall be tested by being pressed home three times by a quick-acting scrag, the free height shall then not exceed that specified by more than $\frac{1}{4}$-inch or $1\frac{1}{2}$ per cent., whichever is the greater, and it shall not be less than that specified by more than one half of this tolerance.

Up to 5 per cent. of the springs may also be tested under varying loads to determine the range and deflection per ton.

All springs shall be hardened in oil and suitably tempered.

CARBON STEEL VOLUTE AND HELICAL SPRINGS—B.S.S. 7A—1942 (of Report No. 24, Part III.).

The springs shall be manufactured from the highest quality of steel made from the best selected material by the acid open-hearth, the acid Bessemer, or the electric process, and shall not contain more than 1·2 per cent. nor less than 0·9 per cent. of carbon.

Test and treatment same as B.S.S. 7X.

SILICO-MANGANESE STEEL VOLUTE AND HELICAL SPRINGS—
B.S.S. 7Y—1942 (of Report No. 24, Part III.).

The springs shall be manufactured from high quality steel made by the acid open-hearth or the electric process and shall show on analysis the following composition:—

	Not less than	Not more than
Carbon . . .	0·50 per cent.	0·60 per cent.
Silicon . . .	1·50 „	2·00 „
Manganese . .	0·60 „	1·00 „
Sulphur . . .	—	0·05 „
Phosphorus . .	—	0·05 „

Test and treatment same as for B.S.S. 7X.

CARBON SPRING STEEL FOR VOLUTE AND HELICAL SPRINGS—
B.S.S. 7B—1942 (of Report No. 24, Part III.).

Material same as B.S.S. 7X above.

SILICO-MANGANESE SPRING STEEL FOR VOLUTE AND HELICAL SPRINGS—B.S.S. 7C—1942 (of Report No. 24, Part III.).

Material for spring steel same as B.S.S. 7Y.

STEEL FORGINGS AND CLASS 'C' AND CLASS 'D' ROLLED BARS FOR LOCOMOTIVES—B.S.S. 8—1941 (of Report No. 24, Part IV.).

The forgings and Class 'C' and Class 'D' rolled bars shall be manufactured from steel made as given below.

The tensile breaking strength and minimum elongation on standard test-piece C or subsidiary test-piece 0·798 in. diameter to be as follows :—

Class.	Description of Forging.	Process of Manufacture.	Maximum Manganese Content per cent.	Maximum Sulphur or Phosphorus Content per cent.	Tensile Breaking Strength in tons per sq. in.	Elongation Minimum per cent.
A	Special forgings which will be case-hardened	Acid or basic open-hearth, Acid Bessemer or electric	0·70	0·05	24 to 28	29 to 25
B	Ordinary and boiler forgings	Do.	—	0·05	26 to 32	28 to 22
C	Special forgings without wearing surfaces, and bars	Acid open-hearth or electric	—	0·05	23* to 38	26 to 20
D	Special forgings with wearing surfaces and bars	Do.	—	0·05	40* to 45	20 to 15

The sums of the tensile breaking strengths and corresponding elongations must be not less than 53 for Classes A, 54 for Class B, 58 for Class C, 60 for Class D. In the case of Classes C and D the yield stress shall be not less than 50 per cent. of the ultimate tensile strength.

A test-piece, 9 inches long and 1¼ inch square, or as near this size as the forging or forgings selected will permit, with 1/16 inch radius at the edges, machined cold, must, without any reheating, withstand being bent cold by direct pressure from a tool 1½ in. wide in the case of Classes A, and B, 1¾ in. wide in the case of Class C, and 2½ in. wide in the case of Class D, the ends having a radius respectively of ¾ in., ⅞ in., and 1¼ in., until the sides of the test-pieces are parallel. The ends of the test-pieces of all classes of forgings, except Class D, shall then be brought together without fracture by direct pressure.

Forgings in Classes A and B may be, and those in Classes C and D shall be, either normalised or otherwise heat treated.

STEEL BLOOMS FOR LOCOMOTIVE FORGINGS—B.S.S. 9—1941 (of Report No. 24, Part IV.).

Specification and tests for Classes A, B, C, and D same as for B.S.S. 8.

One bloom selected by the representative of the engineer (or of the purchaser) from each cast shall be tested at the works of the manufacturer, as follows :—

Blooms for Classes A and B forgings shall comply with the tests without any forging down or heat treatment.

For blooms Classes C and D forgings a portion of full section shall be cut and normalised or a portion may be forged down to not less than 5 in. diameter or thickness and then normalised before testing.

STEEL CASTINGS—B.S.S. 10—1941 (of Report No. 24, Part IV.).

The castings shall be manufactured from steel produced by such process as may be agreed between the manufacturer and the customer, and shall show on analysis not more than 0·06 per cent. of sulphur or of phosphorus.

All castings shall be heat-treated by heating to a uniform temperature not less than the normalising temperature and allowing to cool slowly from the maximum temperature in a practically uniform manner, or alternatively, normalised by heating in a similar manner and allowing to cool in air.

* Yield stress shall not be less than 50 per cent. of the ultimate tensile stress.

The minimum tensile breaking strength and elongation on standard test-piece C or subsidiary test-piece 0·798 in. diameter to be as follows:—

Grade.	Description of Casting	Minimum Tensile Breaking Strength per sq. in.	Minimum Elongation per cent.
1	Castings with wearing surfaces	35	15
2	Other General Castings and Wheel Centres . .	26	20

In the case of wheel centres the yield stress shall be determined and shall be not less than 13 tons per sq. in.

Cold bend tests shall be made upon machined test-pieces 9 in. long and having either a diameter of 1 in. or a rectangular section of 1 in. wide by ¾ in. thick. In the case of rectangular test-pieces the edges shall be rounded to a radius of $\frac{1}{16}$ in., and the test shall be made by bending the test-piece over the thinnest section.

Bend tests may be made by pressure or by blows and the test-piece shall without fracture withstand being bent cold round a former having a radius of 1 in. through an angle not less than 60° for castings of Grade 1 and 90° in the case of Grade 2.

Each wheel centre shall be suspended in a suitable position and struck with a 4 lb. hammer on the rim and spokes (where such exist) and an examination made for any signs of blowholes or other defects.

When wheel centres are tested to destruction, the test shall be made by dropping the wheel centre on to a block of metal of not less than 5 tons weight, supported upon a rigid concrete or other solid foundation. The wheel centre shall be raised and allowed to fall freely in a running position through distances of 5 ft. and 10 ft. on the end of a spoke (where such exists), and then turned through 90 degrees and again raised and allowed to fall freely in a running position through distances of 5 ft. and 10 ft. on the end of a spoke (where such exists). Coupled wheels having balance weights shall be dropped with the weights at the bottom. Any sign of failure under this test will render the wheel centres liable to rejection. The test shall then be continued, the fall being increased 5 ft. each time until fracture results or the wheel centre is doubled up.

Copper Plates for Locomotive Fire-boxes—
B.S.S. 11—1943 (of Report No. 24, Part V.).

The plates shall contain not less than 99·20 per cent. of copper, and shall contain not less than 0·30 per cent. nor more than 0·50 per cent. of arsenic. Antimony shall not exceed 0·05 per cent. Bismuth shall not exceed 0·01 per cent.

Tensile breaking strength to be not less than 14 tons per square inch, with an elongation of not less than 35 per cent. on standard test-piece A.

Pieces of the plate shall be tested both cold and at a red heat by the ends being bent through an angle of 180 degrees in opposite directions and doubled up close, without showing either crack or flaw on the outside of either bend.

Rolled Copper Rods for Locomotive Stay Bolts, Rivets, etc.—
B.S.S. 12—1943 (of Report No. 24, Part V.).

The rods shall contain not less than 99·20 per cent. of copper, and shall contain not less than 0·30 per cent. nor more than 0·50 per cent. of arsenic. Antimony shall not exceed 0·05 per cent. Bismuth shall not exceed 0·01 per cent.

Tensile strength to be not less than 14·50 tons per square inch, with an elongation of not less than 40 per cent. on standard test-piece B. For rods up to 1¼ inch diameter, the test shall be made upon the unturned rod. For rods above 1¼ inch diameter, the rod may be turned down, when a subsidiary standard test-piece 0·798 in. or 0·977 in. in diameter shall be used, in which case the elongation shall be not less than 45 per cent.

The rod shall, both when cold and at a red heat, withstand, without machining, being doubled up close without cracking.

A piece of rod 1 inch long shall be placed on end and hammered or crushed down when cold to a thickness of ⅜ inch without showing either crack or flaw on the circumference of the resulting disc.

Extruded Copper Rods for Locomotive Stay Bolts, Rivets, etc.—
B.S.S. 12a—1943 (of Report No. 24, Part V.).

Tests the same as for B.S.S. 12.

Copper Tubes for Locomotive Boilers—
B.S.S. 13—1943 (of Report No. 24, Part V.).

The tubes shall contain not less than 99·20 per cent. of copper, and shall contain not less than 0·30 per cent. nor more than 0·50 per cent. of arsenic. Antimony shall not exceed 0·05 per cent. Bismuth shall not exceed 0·01 per cent.

Tensile tests shall be made on pieces of tube or strips cut from the tube. If the test is made on a piece of tube, the tensile strength shall be not less than 14·50 tons per square inch, with an elongation of not less than 50 per cent. on 2 inches. If the test is made on a strip, the tensile strength shall be not less than 14 tons per square inch, with an elongation of not less than 40 per cent. on a test piece having a gauge length of four times the square root of the area.

The test-piece shall stand bulging or drifting cold without showing either crack or flaw until the outside diameter of the bulged or drifted end measures not less than 25 per cent. more than the original diameter of the tube.

The test-piece shall stand flanging cold without showing either crack or flaw until the diameter of the flange measures not less than 40 per cent. more than the original diameter of the tube.

The test-piece shall stand the following test, both cold and at a red heat, without showing either crack or flaw. The test-piece shall be flattened down until the interior surfaces meet, and be doubled on itself, that is, bent through an angle of 180 degrees, the bend being at right angles to the direction of the length of the tube.

Each tube shall be tested by an internal hydraulic pressure of 750 lb. per square inch, or by such internal pressure as may have been specified.

BRASS TUBES FOR LOCOMOTIVE BOILERS—
B.S.S. 14—1943 (of Report No. 24, Part V.).

Brass for locomotive tubes may be of either 70/30 alloy or 2/1 alloy of copper and zinc.

The tubes shall consist of an alloy of copper and zinc, and shall contain :—

70/30 Alloy.—Not less than 70 per cent. of metallic copper and not more than a total of 0·75 per cent. of materials other than copper and zinc.

2/1 Alloy.—Not less than 66·70 per cent. of metallic copper and not more than a total of 0·75 per cent. of materials other than copper and zinc.

The tubes shall be carefully annealed at both ends.

The test-piece shall stand bulging or drifting cold without showing either crack or flaw until the diameter of the bulged or drifted end measures not less than 25 per cent. more than the original diameter of the tube.

The test-piece shall stand flanging cold without showing crack or flaw until the diameter of the flange measures not less than 25 per cent. more than the original diameter of the tube.

The test-piece when cold shall stand the flattening and doubling-over test applied to copper tubes, B.S.S. 13. Tubes to be tested by an internal hydraulic pressure as may have been specified.

WELDLESS STEEL TUBES FOR LOCOMOTIVE BOILERS.*
(B.S.S. No. 53—1927.)

The tubes shall be cold-drawn and weldless, and shall be manufactured from steel of the best quality made by the open-hearth process. They shall not show on analysis more than 0·035 per cent. of sulphur or more than 0·030 per cent. of phosphorus.

The tubes or strips cut from the tubes shall, without further annealing, show a tensile strength of not less than 20 tons per sq. in., nor more than 26 tons per sq. in., with an elongation of not less than 28 per cent. in 8 in. for tubes, and not less than 22 per cent. in 8 in. for strips cut from the

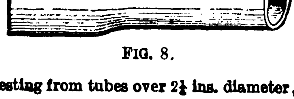

FIG. 8.

tubes. If strips are cut for testing from tubes over 2½ ins. diameter, they may be annealed before testing.

The tubes shall, when cold, stand bulging with a parallel drift (see fig. 8) without showing either crack or flaw, until the diameter of the bulged end exceeds the original diameter of the tube by not less than 15 per cent. for tubes under 11 s.w.g. in thickness and 12½ per cent for tubes from 11 s.w.g. to 6 s.w.g. inclusive.

A piece of tube 2 in. long shall be placed on end and shall, when cold, stand hammering down until it is reduced to 1¼ in. high without showing either crack or flaw.

Tubes up to 2½ in. external diameter and 10 S.W.G. shall be flattened by pressure between two parallel flat surfaces, the width of which shall be not less than three times the diameter of the tube, until the interior surfaces meet at the middle and remain in contact when the pressure is released.

Other tubes shall be flattened in a similar manner until the interior surfaces are, at the middle, brought out to a distance apart equal to the thickness of the wall of the tube.

Every tube shall be tested by an internal pressure of at least 1,000 lb. per sq. in.

*** Pending revision of this Specification B.S.S. 494 is at present quoted. Limits for sulphur and phosphorus 0·05 per cent.**

SEAMLESS COPPER PIPES FOR LOCOMOTIVES—

B.S.S. 15—1943 (of Report No. 24, Part V.).

The pipes shall contain not less than 99·20 per cent. of copper, and shall contain not less than 0·30 per cent. nor more than 0·50 per cent. of arsenic. Antimony shall not exceed 0·05 per cent. Bismuth shall not exceed 0·01 per cent.

Tensile tests shall be made on pieces of pipe or strips cut from the pipe. If the tensile test is made on a piece of pipe, the tensile strength shall be not less than 14·50 tons per square inch, with an elongation of not less than 50 per cent. on 2 inches for pipes of cross-section greater than 0·3 sq. in. and 50 per cent. on a gauge length of 1 in. for pipes of 0·3 sq. in. or less cross-sectional area.

If the tensile test is made on a strip cut from the pipe, the tensile strength shall be not less than 14 tons per square inch, with an elongation of not less than 40 per cent. on a test-piece having a gauge length of four times the square root of the area.

The test piece shall stand drifting cold without showing either crack or flaw until the diameter of the drifted end measures not less than 25 per cent. more than the original diameter of the pipe.

Flattening and doubling-over test the same as for copper tubes, B.S.S. 13.

Tubes to be tested by such internal hydraulic pressure as may have been specified.

STEEL PLATES (INCLUDING FIREBOX PLATES), SECTIONS, BARS AND RIVETS FOR LOCOMOTIVE BOILERS *—B.S.S. 16—1942 (of Report No. 24, Part VI.).

The plates, sections and bars shall be manufactured from steel made from selected material by the acid or basic open-hearth or the electric processes. The steel must not show on analysis more than 0·05 per cent. of sulphur or of phosphorus.

In the case of plates for fireboxes the steel must be made from the acid open-hearth or electric process and sulphur and phosphorus must not exceed 0·03 per cent.

When plates are required for flanging purposes it shall be so stated at the time of inquiry.

Test-pieces shall be cut or sheared crosswise from rolled material in case of plates, and lengthwise in case of sectional material. When material is annealed or otherwise treated, the test-pieces shall be similarly and simultaneously treated with the material before testing, except in the case of drawn steel wire when the test-pieces only shall always be annealed before testing. Any straightening of test-pieces shall be done cold.

Material.	Tensile Strength. Tons per sq. in.	Minimum Elongation. Per cent. On Test-Piece A.	On Test-Piece B.	On Test-Piece B.1.
Plates (other than firebox).	25–30	23	—	—
Firebox plates †	23–28	25	—	—
Sections and flats	28–33	20	—	—
Round and square bars (up to and including 1-in. diameter or thick)	28–33	—	20	—
Round and square bars (above 1-in. diameter or thick)	28–33	—	—	24
Rivet bars	25–30	—	26	30
Cold drawn material for rivets below ⅞-in. diameter	20–25	—	26	—

Test-pieces for the cold-bend test shall be cut or sheared crosswise from plates and lengthwise from sections and bars, and shall be not less than 1½ in. wide, but for small material the whole section may be used. In all bend tests the rough edges of the test-pieces may be removed by filing, grinding or machining. The edges of the test-piece may be ground or draw filed to remove sharpness and roughness.

* This Specification also applies to drawn steel wire under ⅞ in. diameter for the manufacture of cold forged rivets.

† Firebox Plates shall have a yield stress of not less than 55 per cent. of the ultimate tensile stress.

The test-pieces shall not be annealed or otherwise heat-treated unless the material from which it is cut is similarly annealed or heat treated, in which case the test pieces shall be similarly and simultaneously heat-treated before testing, except in the case of drawn steel wire, when the test-pieces only shall be annealed before testing.

The test-pieces shall withstand without fracture the bend test described in the following table.

The bend tests may be made either by pressure or by blows.

Material.	Max. Internal Radius of Bend.	Description of Bend Test.
Firebox plates	The thickness of test-piece	Doubled over until sides are parallel
Plates (other than firebox plates)	Twice the thickness of the test-piece	Do.
Sections and bars	Twice the thickness of the test-piece	Do.
Rivet bars	—	Doubled over and flattened on itself.

Tests for Manufactured Rivets.—The rivet shanks shall be bent cold, and hammered until the two parts of the shank touch, without fracture, on the outside of the bend. The rivet heads shall be flattened while hot without cracking at the edges until the diameter of the head is 2½ times the diameter of the shank.

Dump Test for Rivet Bars.—Short lengths equal to twice the diameter cut from the rivet bars shall, when cold, withstand without fracture being compressed to half their length.

Reverse Torsion Test for Rivet Bars.—Alternatively for material under ⅜-in. diameter the reverse torsion test may, at the option of the manufacturer, be substituted for the dump test. A length of material 8 in. between grips of the machine shall withstand without showing splits or frills being axially twisted four complete turns in one direction, then from this position four complete turns in the reverse direction.

STEEL PLATES, SECTIONS, BARS, AND RIVETS FOR LOCOMOTIVES*—

B.S.S. 17—1942 (of Report No. 24, Part VI.). With Analysis.

The plates (other than locomotive frame plates), sections, and bars shall be manufactured from steel made from selected material by the acid or basic open-hearth, acid Bessemer, or the electric process. Locomotive frame plates shall be made by either the acid or basic open-hearth process only.

The material shall, on analysis, contain not more than 0·06 per cent. of sulphur or phosphorus.

The tensile test-pieces shall be cut or sheared lengthwise or crosswise from the rolled material in the case of plates, and lengthwise in the case of sections and bars. The edges of the flat test-pieces shall be ground or draw filed to remove roughness and sharpness.

The test-pieces shall not be annealed or otherwise heat treated unless the material from which they are cut is similarly annealed or heat treated. In the case of drawn steel wire the test-pieces shall always be annealed before testing. For all material, other than rivet bars, under $\frac{1}{16}$-in. thick, bend tests only are required.

Cold-Bend Tests.—Test-pieces shall be cut or sheared crosswise from plates and lengthwise from sections and bars, and shall be not less than 1½ in. wide, but for small material the whole section may be used. In all bend-tests the rough edges of the test-pieces may be removed by filing, grinding or machining. The edges of the test-pieces may be ground or draw filed to remove sharpness and roughness.

The test-pieces shall not be annealed or otherwise heat-treated unless the material from which they are cut is similarly annealed or heat treated, in which case the test-pieces shall be similarly and simultaneously heat treated before testing.

For small sections these bend tests may be made from the flattened section.

Bend tests may be made by pressure or by blows.

---

* When material is required for cold flanging, cold pressing, welding or cold working, this shall be so stated at the time of the enquiry or order. This specification shall apply also to drawn steel wire under ⅜-in. diameter for the manufacture of cold forged rivets.

TABLE OF BEND TESTS.

Material.	Dimensions.	Max. Internal Radius of Bend.	Description of Bend Test.
Plates—for other than cold-flanging or cold-pressing	All thicknesses	3 times the thickness of test-piece	Doubled over until sides are parallel
Do. for cold-flanging or cold-pressing	$\frac{5}{16}$ in. thick and above	Twice the thickness of test-piece	Do. Do.
Do. Do.	Below $\frac{5}{16}$ in. thick	—	Doubled over and flattened on itself
Sections, flats, and bars—for other than welding or cold-working	All thicknesses or diameters	3 times the diameter or thickness of test-piece	Doubled over until sides are parallel
Do. for welding or cold-working	$\frac{5}{16}$ in. in diameter or thickness and above	Twice the thickness of test-piece	Do. Do.
Do. Do.	Below $\frac{5}{16}$ in. in diameter or thickness	—	Doubled over and flattened on itself
Rivet Bars	All diameters	—	Do. Do.

Tests for Manufactured Rivets.—Same as for B.S.S. 16.

TABLE OF TENSILE TESTS.

Material.	Dimensions.	Ultimate Tensile Strength. Tons per sq. in.	Minimum Elongation. Per cent. On Test-Piece A.	On Test-Piece B.	On Test-Piece B.1.

STEEL PLATES, SECTIONS, BARS, AND RIVETS FOR LOCOMOTIVES—
B.S.S. 17A—1942 (of Report No. 24, Part VI.).

Same as B.S.S. 17, but without analysis. No special provision is made in the case of locomotive frame plates.

STEEL PLATES, SECTIONS, BARS, AND RIVETS FOR CARRIAGES AND WAGONS—
B.S.S. 18, B.S.S. 18A—1942 (of Report No. 24, Part VI.).

Specifications same as for locomotives, B.S.S. 17, B.S.S. 17A.

WROUGHT IRON.

(B.S.S. No. 51—1939.)

Specifications are given for wrought iron, Grades A, B, and C. The tensile tests, etc., vary with the sizes of the different sections rolled. Manganese shall not exceed 0·10 per cent. in the case of Grade A and 0·15 per cent. in the case of Grades B and C.

(B.S.S. 858–1939.)

Specification given for best Yorkshire wrought iron. The tensile tests, etc., vary with the sizes of the different sections rolled.

Manganese shall not exceed 0·06 per cent. and phosphorus shall not exceed 0·16 per cent.

Other Materials used in Locomotive Construction.

Iron Castings.—The tensile test is the most trustworthy; 7 tons per sq. in. is the usual specification; 8 and 9 tons may be demanded in reason and expected. General foundry iron up to 11½ and 12½ tons per sq. in. and cylinder iron up to 13½ and 14 tons per sq. in. are not unknown, each having good fractures, and being good workable foundry metal. The usual commercial test is generally made transversely upon bars 3 ft. long, 2 in. deep, and 1 in. thick, without being machined, 25 to 32 cwt. being the specified central breaking load. The test bars should be cast by means of an attachment to the casting, and the specified ultimate loads should not vary more than 1 per cent. Special irons such as Meehanite have tensile strengths of 20 tons or more.

Alloy steels are now used to some extent for the motion parts of fast-running locomotives in order to minimise the weight of the revolving and reciprocating parts.

Connecting and coupling rods are the most important items.

Nickel-chrome steel has been used on the E.R., and a manganese-molybdenum steel is used to a large extent on the L.M.R.; the Southern Region has used 'Vibrac' steel.

Nickel steel has been used for boilers to effect saving in weight by its higher tensile strength.

(For further details see Section XXIII., Part I., Vol. I. 'METALLURGY.')

For *Bronze, Brass, White Metals, and other Alloys*, see Section XXIII., Part I., Vol I.

Use of Materials made to British Standard Specifications.

(Report No. 24—Parts I.–VI.)

No. 1.—Crank axles.

Nos. 2 *and* 2A.—Straight axles, locomotive and tender.

Nos. 3 *and* 3A.—Carriage and wagon axles.

No. 4.—Tyres for locomotive and tender. Class C or D is usually specified. Class E is used for motor bogies of electric stock.

Nos. 5 *and* 5*a*.—Carriage and wagon tyres. Class C for carriages and Class B for wagons are the most commonly specified.

Nos. 6X, 6Y, *and* 6A.—Laminated springs, purchased complete.

Nos. 6B, 6C *and* 6D.—Plates and bars for manufacturing laminated springs, spring wearing plates, flat springs.

Nos. 7X, 7Y *and* 7A.—Manufactured volute and helical springs.

No. 7B *and* 7C.—Spring steel for volute and helical springs.

No. 8.—Steel forgings of Classes A to D (as below).

No. 9.—Steel blooms for making forgings. *Class A* is used for motion work and pins and other parts requiring to be case-hardened; spring hangers and links, brake work, draw bar, and safety links and pins, coupling screw and shackle, regulator rod, fire hole ring, foundation ring, and other parts requiring a weld. *Class B* for ordinary forgings, valve spindles, motion work not requiring case-hardening, reversing shaft and rod, reversing screw, buffer heads, regulator handle, roof slings, safety valve, and other seatings, wash-out doors and bridges, etc. *Class C*, connecting and coupling rods, crossheads, keys and cotters. *Class D*, piston rods, slide bars, crosshead cotters.

No. 10.—Steel castings. Wheel centres form one class; castings with wearing surfaces another, and this includes axle boxes and guides, bogie centres, bogie slide, brake shaft brackets, spring brackets, buffer plungers and guides. General castings without wearing surfaces include motion plate or slide bar brackets, smoke-box saddle, etc.

No. 11.—Copper fire-box plates.

Nos. 12 *and* 12A.—Copper stays and studs.

No. 13.—Copper boiler tubes.

No. 14.—Brass boiler tubes.

No. 15.—Copper pipes for feed water and steam. Steel fire-box plates.

No. 16.—Boiler barrel and fire-box shell plates, front tube plate, rivets, stays, nuts, angles, rods, etc., for boiler work. Expansion brackets, roof stays, palm stays.

Nos. 17 *and* 17A.—Locomotive and tender frame plates and cross stays, angles, bolts, rivets, plating, ash pan and doors, fire door, smoke-box and door, cab, tender tank plates, etc.

Nos. 18 *and* 18A.—Steel plates, angles, and other sectional material for carriage and wagon underframes.

No. 53 (1927).—Weldless steel tubes for boilers. (B.S.S. 494 used in lieu.)

Contract Specification for Locomotive Construction.

The *Contract Specification* should provide for delivery and payment after running a guaranteed mileage (about 3,000 to 5,000). That all parts shall be constructed exactly to the drawings supplied, and no deviation made whatever without consulting those responsible for letting the contract, and that lack of information shall be no excuse for discrepancies in material or construction. The price quoted must be inclusive, and no responsibility shall devolve upon the purchaser for royalties and patent rights. The quotation should also include drawings (2 complete sets), photographs (12), lists of details, weights, etc., to be furnished with the (3rd or 5th) engine.

The specification should also stipulate that the workmanship should be accurate and well finished.

Liquid Fuel.

In oil-burning locomotives the ashpan is replaced by a brick lined floor to the fire-box in which are openings to admit air. Admission is governed by doors or else there is a false bottom into which air is admitted through a damper. The weir type burner about 2 in. wide permits the flow of oil fuel to fall on to a ribbon of steam issuing below from a slot $2\frac{1}{4}$ in. wide by $\frac{3}{16}$th in. deep. The fuel is pulverised and burns as a long flame directed towards a flash wall built below the fire-hole door. The lower part of the fire-box is also lined with firebrick. The burner is fixed below the front of the foundation ring and is housed in a small chamber communicating with the combustion space. Some 1,800 gal. of oil are carried in a reservoir on the tender and heating coils are arranged to facilitate the flow of fuel both there and at the burner.

On the Buenos Aires Pacific Railway the control arrangement has atomiser, auxiliary blower, oil-firing valve and damper combined in one operation.

The Laidlaw-Drew burning equipment used on the G.N.R. of Ireland has a vertical burner in centre of fire-box base. The advantages of this system include controlled steam raising, automatic supply of correct amount of air and minimum amount of brickwork. The train-heating pipe line is utilised to supply steam when starting up from cold.

Liquid fuel burning is seldom resorted to on British railways except at times of coal shortage resulting from prolonged strikes at the collieries. A temporary conversion to oil burning is readily made. A burner is inserted in the fire-hole, and is fed from the tanks placed on the tender, each of which holds from 400 to 500 gal. of oil. The flame is directed under the brick arch, no alteration being made to the fire-box except by bricking up the portion of the tube plate under the brick arch; the top portion of the fire-hole is closed by a special door, which can be opened if it is necessary to use coal.

The fire-bars are covered with a layer of broken fire-brick, and if it is at any time necessary to use a little coal, it is put at the back of the fire-box. The fire can be started with wood, and as soon as the steam pressure reaches about 40 lb. the burner can be used. In many cases no coal whatever is burnt for long periods, the engine steaming freely and the fire requiring very little attention. The best steaming results are, of course, obtained when there is a slight amount of smoke given off at the chimney. The locomotives fitted with this arrangement are able to deal easily with their accustomed loads. The advantage of the system is the ease with which it can be fitted up, and the simplicity in handling.

Oil is extensively burned in the South-Western States of America, Mexico, and the Argentine Republic, as coal has to be imported and oil is nearer at hand or is more cheaply transported.

See also Section XXV., Vol. I. 'FUELS.'

Mechanical Stokers.

Mechanical stokers are used in the United States, Canada and South Africa. They are adopted not for reasons of economy but because the locomotives had become too large for their full capacity to be maintained by hand firing. The consumption per unit of power developed is approximately the same with either hand or stoker firing. The same grade of fuel is used with mechanical stokers as is fired by hand, but in combination with a shaking grade it is possible to make use of a lower grade of fuel. The proper use of these stokers to obtain best results calls for as much skill on the part of the fireman as hand firing, but the labour is reduced.

Mechanical stokers can be justified only on locomotives too large to be fired to full capacity by hand. The minimum economical size of engine for them are those of a rated tractive effort of 50,000 lb., and then only when operating on long heavy grades. Engines having a rated tractive effort of 55,000 lb. or over justify the use of mechanical stokers on any territory in freight service, as also engines of 50,000 lb. tractive effort in passenger service.

The mechanical stoker for locomotives is a development in response to the necessity of securing greater capacity from single power units. Mechanical stoking permits more tonnage to be handled at a higher sustained speed, and gives greater average dependability than would be practicable with hand stoking. Its development has rendered it possible to design locomotives capable of burning coal continuously at a rate much in excess of the capacity of any fireman to supply it by hand. It is generally considered that a tractive capacity of 50,000 lb., or a coal consumption of 4,000 lb. per hour, will justify the use of a mechanical stoker. The present commercial production of mechanical stokers in the United States is confined to the overfeed or 'scatter' type, made by four companies. According to information supplied by those companies, 7,856 mechanical stokers were in service or on order on November 1, 1923, but their use has been considerably extended since then.

Mechanical stokers are under trial on British railways with a view to the use of coal of a lower quality. The French railways have put a number into service for this purpose.

Coal Consumption.

The average rate of combustion in British express engines on heavy service is about 100 lb. per sq. ft. of grate area per hour, and about 50 lb. of coal per mile; the maximum rate may reach 160 lb. per sq. ft. of grate area per hour.

According to the Railway Returns for 1938, the lb. of coal consumed per engine-mile for the four British railway groups were: for passenger service 49·38 lb., for freight service, including shunting, 55·69 lb.

In 1918 average consumption of coal for all purposes was approximately 60·0 lb. per mile. The increase in consumption is mainly attributed to a decline in the quality of the fuel.

The consumption of fuel in a locomotive engine at rest, as when standing in a station or at a signal, is about one-fifth of that consumed when the engine is in motion. When standing at a shed with fire banked the consumption is very much less.

In a modern engine about 3¼ cwt. of coal is actually consumed in raising steam in a boiler from cold water, and about 2¼ cwt. from hot water. Some 10 cwt. is required for making up the fire before working a heavy train.

Water Consumption.

With a piston speed of 900 ft. per minute and a boiler pressure of 175 lb. per sq. in., locomotives using saturated steam require about 24 lb. per i.h.p. hour. The evaporation is approximately 8 lb. of water per pound of coal, or 9½ lb. from and at 212°F. The coal consumption is therefore 3 lb. per i.h.p. hour. Locomotives using superheated steam require 25 per cent. less, or about 18 lb. of steam per i.h.p. hour. The coal per i.h.p. is 12½ per cent. less, or roughly 2½ lb. per i.h.p. hour, the evaporation being 7 lb. of water per pound of coal.

Lubricating Oil Consumption.

The oil consumption of different railways varies considerably, but under favourable conditions 1 lb. of cylinder oil and 4 lb. of engine oil are required per 100 miles. Superheater engines use rather more cylinder oil than non-superheater, and the quality of the oil is more expensive.

The oil consumption of the 4-6-0 on the Western Region engines averages 5 lb. per 100 miles.

According to the Railway Returns for 1938, the consumption of lubricating oil per 100 running miles for the four British railway groups was 6·41 pints for all services.

Sight feed lubricators on the hydrostatic principle, delivering oil to the steam pipes, are used on both superheater and non-superheater engines. It is more usual on superheater engines to employ a mechanical force feed lubricator driven by an attachment to some part of the engine motion.

The practice of feeding oil to the crowns of axle boxes by mechanical lubricators is also extending, more particularly in the case of heavy eight wheels coupled mineral engines.

For LUBRICATION AND LUBRICATORS, see Section XX, Part II., Vol. I.

Brakes.

In addition to hand brakes the majority of engines and tenders are fitted with power brakes, usually the Westinghouse or Automatic Vacuum apparatus (page 2113). Goods engines not fitted with a continuous brake have a simple steam brake. Many engines are fitted with a steam brake working automatically with the vacuum by means of a valve of simple construction which can either be controlled by the vacuum in the train pipe or by hand. This is found to be a convenience, and the brake cylinders being of small diameter occupy but little space under the engine. The arrangement is extensively used and gives very satisfactory results.

Instead of a small ejector for maintaining the vacuum in the train pipe, a vacuum pump about 5 in. bore directly driven from one of the crossheads of the engine can be used instead. As the pump is capable of creating a high vacuum, a relief valve is provided to limit the vacuity. On the Western Region this is set for 25 in., but other railways set the valve for the standard 20-inch vacuum.

Under average conditions as to load, leakage, and number of stops, the steam required by a vacuum ejector in maintaining a 20-in. vacuum results in the consumption of 42½ lb. of coal per hour. The power absorbed by a vacuum pump coupled to the cross-head of the engine is equivalent to a consumption of 15 lb. of coal per hour with a 20-in. vacuum, and 17½ lb. per hour with a 25-in. vacuum. (*J. N. Gresham*, '*Journal of Inst. of Loco. Engineers.*')

The percentage of brake power—that is, pressure on brake blocks in relation to load on wheels—should not exceed 75 per cent. for coupled wheels and 100 per cent. of weight when empty for tenders. If bogie wheels of engine are braked the percentage should not exceed 50 in order to minimise any chance of skidding.

To avoid frequent taking up of blocks brake leverage should not be too great. With steam and air brakes leverage is about 7 to 1; vacuum brakes are sometimes as much as 14 to 1 on account of difficulty of finding room for large cylinders. With this ratio a 7-in. piston travel allows ½-in. clearance for blocks and ½ in. wear.

Tenders.

On the British Railways each of the main line companies has evolved one or two standard designs of tenders to meet all their requirements.

The L.M.R. now build six-wheeled tenders exclusively, the larger holding 9 or 10 tons of coal and 4,000 gal. of water. Smaller tenders carry 5 tons of coal and 3,500 gal. of water.

On the E.R. there are two types in general use, one being of the six-wheeled type to carry 7½ tons of coal and 4,200 gal. of water; the other is of the eight-wheeled rigid axle type with a capacity of 8 tons and 5,000 gal.

The standard tenders on the W.R. are of the six-wheeled type and the largest carry six tons of coal and 4,000 gal. of water. Others are of 3,500 and 3,000 gal. capacity with 6 and 5 tons of coal respectively.

Each of the above companies has water troughs so that very large tank capacities are unnecessary.

The Southern Region has no troughs and uses large tenders for long distance runs. These are of the bogie type and have eight wheels; the water capacity is 5,000 gal., and there is a space for 5 tons of coal. This railway also has a six-wheeled tender of the same capacity.

The second standard tender design of the Southern Region is a six-wheeled one to carry 4,000 gal. and 5 tons of coal.

The connection between engine and tender in modern designs usually consists of a substantial eye-bolt pinned to the engine and fitted with a helical or rubber spring and nut on the tender.

It is also desirable to fit rubbing blocks between the engine and tender so that the tendency for side oscillation is resisted. Two safety links or bars are also provided in case the main drawbar should break.

Side buffers have been used to reduce oscillation, but the central block is better when curves are encountered.

In order that long non-stop runs may be made on the E.R., some of their eight-wheeled tenders have gangways through the tank on one side and which are coupled to the vestibule on the train to enable a change of enginemen to be made on the journey.

Tanks are now generally of welded construction instead of being riveted; a small saving in weight and less liability to leakage being the main advantages.

In the U.S.A. where water capacities of 9,000 to 14,000 gal. and 15 tons of coal are common, the six-wheeled bogie is used, and sometimes the tanks are cylindrical or round-bottomed.

Tender journals are almost invariably situated outside the wheels. The bogies are generally of the plain pivoted type without side play, but in the case of very long engines having a trailing truck or bogie, it is common to allow side play on the leading tender bogie to facilitate the motion of the locomotive round a curve. Roller bearings are gradually being adopted on tenders.

Water Troughs.

Effective length is from 440 to 560 yards. Theoretically a quantity of about 1,000 gallons can be picked up, the mouth of the scoop being at rail level and $1\frac{1}{2}$ in. below water level. In practice considerably more is obtained owing to the heaping up of the water in front of scoop, the maximum being obtained at 45 miles per hour with some 1,700 galls. At higher speeds there is a considerable loss by spray. The lowest speed at which water can be picked up is 15 miles per hour.

When running at 60 miles an hour over a water trough $\frac{1}{4}$ mile long, a locomotive tender will pick up about 1,000 gallons or 10,000 lb. of water.

Examination of Locomotives at Running Sheds.

A failure on the road is a serious matter, and the best way of reducing breakdowns to a minimum is by periodical examinations. The following is a list of the usual examinations of the L.N.E.R. (G.N. Section):—

Slide valves:—		Small ends	6 months
Piston valves	2 months	Vacuum regulating valves	1 month
Richardson's	2 "	Water scoops	1 "
'D' valves, $\frac{7}{8}$ in. thickness	4 "	Fire-boxes	1 week
'D' " $\frac{3}{4}$ and $\frac{11}{16}$ in. "	3 "	Axle-box pads	3 months
'D' " $\frac{5}{8}$ and $\frac{9}{16}$ ins. "	2 "	Injectors	1 month
'D' " $\frac{1}{2}$	1 month	Main steam pipes on superheated engines	1 "
Pistons	3 months	Tender wheels gauged	1 "
Tender tanks	1 month	Leading wheels of 2–4–0 type gauged	1 "
Drip valves	1 "	Engine and tender tyres gauged	1 "
Safety valves	6 weeks	Mechanical lubricators to slide valves and pistons	2 months
Ball valves in water gauge frames (dependent upon quality of water in district)	2 months	Mechanical lubricators to axle-boxes	1 month
Lead plugs	1 month		
Large ends	3 months		

Cracked frames, flaws in connecting and coupling rods, or any part of motion, loose tyres, etc., should also be watched for. (*G. A. Musgrave, 'Proceedings, Inst. Loco. Engrs.'*)

Engine and Tender Tools and Equipment.

Carried in Tool Boxes.

Flat chisel.
Pin punches (large and small).
Chipping hammer.
Wrench for union nuts.
Complete set of spanners.
Adjustable wrench.
Tommy bar.
Large can for engine oil (6 to 8 quarts).
Large can for cylinder oil (6 to 8 quarts).
Small can for paraffin (about 1 quart).
Spring valve oil feeder, long spout.
Spring valve oil feeder, short spout.
Flare lamp.
Case of fog signals.
Rod flag.
Hand sweeping brush.
Packing drawer } (if required).
Tallow pot } (if required).
Spare glasses for water gauge.
Spare glasses for sight feed lubricator (if fitted).
Spare packing rings for glasses.
Copper wire for trimmings.
Worsted for trimmings.
Spare cotter pins.
Spare nuts.

Carried on Tender.

Fire rake, Pricker, Dart, Tube scraper, Clinker shovel } (length to suit firebox).
Slice (to suit depth of firebox at back).
Coal hammer.
Coal pick.
Pinch bar.
Bucket.
Fireman's shovel.
Screw-lifting and traversing jack (if specified).

OTHER EQUIPMENT.

Full set of head and tail lamps.
Full set of head boards or discs (when used).
Water gauge lamp.
Sight feed lubricator lamp (if required).

SPECIAL EQUIPMENT AT SHED FOR CLASS OF ENGINE.

Spanner for brake screw adjusting nuts.
Box spanner for fusible plugs.
Ashpan rake.

RAIL MOTOR CARS AND TRAINS.

For certain feeder services to points on the main line or for branch-line working, it is more economical or more convenient to use either rail-motor trains or self-propelled railcars, which can be driven from either end.

The practice on the L.M.R. and S.R. is to use up obsolete locomotives and carriages by suitably converting them for motor services. A small tank engine is attached to one or more trailer cars to form a unit which can be driven from either end. When pushing the car, the locomotive is controlled by the driver from the opposite end of the train by means of levers and rods with universal joints connected to the regulator. A brake valve and whistle cord are provided and an electric bell signal enables the driver to communicate with the fireman on the footplate. In some cases control of the regulator is by means of compressed air or vacuum.

For their suburban traffic round Paris the French railways have developed this plan by building trains of nine coaches each. A powerful tank engine is attached at one end, and this can be controlled from a driving compartment at the opposite end.

The W.R. steam railcars built many years ago have been replaced by push-and-pull trains with steam locomotives of the 0–4–2 and 0–6–0 types, and partly by oil-engined cars.

During the past few years almost all new railcars have been built with internal combustion engines, the oil engine being used to a much greater extent than the petrol engine.

In England, where progress in this direction has been on a smaller scale than in Europe generally, the former L.N.E.R. put into service three oil-electric motor coaches of 250 b.h.p. each, and one oil-electric railbus of 110 b.h.p.; the former are of the heavy engine type, and the latter has an engine similar to those in road vehicles.

The former L.M. & S.R. experimented with small petrol-engined vehicles of the road-railer type **for running on the road or the rails; in France pneumatic tyred cars of very light weight and capable of high acceleration are being used. These cars with pneumatic tyres have to be built extremely light as the maximum load that can be carried under a pair of wheels is about 1½ tons; consequently a car of normal length requires two eight-wheeled bogies.**

The W.R. is the greatest user of oil-engined cars in this country. It has standardised on **A.E.C. oil engines of 130 b.h.p. and the Wilson pre-selective gear-box with hydraulic clutch. Its first car has one engine which is mounted outside the main frame and below the floor and drives on to the end of an axle. The seventeen subsequent cars have two engines each, and the latest ones have had improvements made to the engine as a result of experience with the original one which was standard with those of road vehicles. All these cars are for passenger carrying except one for parcel traffic.**

On the Continent there are railcars for all purposes, ranging from four-wheeled ones for slow branch lines to high-speed long distance cars, either running as single units or in two and three car sets. In Norway three-car sets include a compartment for diners.

The engines are generally of the high-speed type developed from road and aviation experience, and are mainly of the four-stroke airless injection design. The usual position for them is either on the bogies or underneath the floor; in the latter case the flat opposed cylinder engine is gaining ground and several manufacturers have developed this design.

Transmission systems have passed through many stages as the mechanical transmissions of road vehicles were quite unsuitable for railway working, and existing electric systems were heavy and of low efficiency.

Mechanical change-speed systems are almost entirely of the constant-mesh type where the drive is taken up gradually through slipping clutches or by hydraulic clutches, but above 150–200 h.p. the mechanical system has not been developed to any extent, therefore electric transmission is used for higher powers; its objection for small powers is its high cost and heavy weight.

Hydraulic transmission of the rotor type is being developed for all powers now, but is expensive in first cost and usually requires a change-up gear between itself and the engine. It is much lighter than electric transmission but has not the same wide range of torque variation, although this can be increased by the inclusion of a two-speed gear or two converters.

The efficiencies of the three transmission systems are all different from each other and are apt to lead to wrong conceptions of the tractive power at the rails.

A well designed mechanical transmission will give up to 92 per cent. efficiency, but it requires a variable speed engine and precludes a constant h.p. output.

The electric transmission has a comparatively low efficiency, ranging from about 65 per cent. at starting to a maximum of about 80 per cent.; it permits the engine to give almost constant maximum h.p. at all speeds if required.

The hydraulic transmission has a starting efficiency similar to that of the electric, but it soon rises and attains a figure between that of the mechanical and electric transmissions; its torque range is limited.

The electric transmission is unique in that the location of the driving axles is independent of the position of the engine, thereby permitting the motors to be situated in any convenient part of the car or train. The motors are either of the axle-suspended type or of the frame mounted type with a cardan shaft drive on to a worm or bevel gearbox.

Generally, when oil-engined cars are being built, advantage has been taken of new methods to build light-weight stock, thereby saving on the initial cost of the engine and on running costs.

In some recent designs the articulated type of car has been adopted. This has a driver's cab integral with a power bogie. The front of the car body is carried by the power bogie bolster and the other end by a trailing bogie. The passenger compartment is thus insulated from the noise and heat of the engine compartment, and the body can be readily detached from the power bogie.

In Italy an articulated set has a central power unit with a passenger coach at each end.

Super-charged engines now being manufactured have improved the power/weight ratio of railcars.

Some cars have been built to run on producer gas made from such fuels as charcoal.

In the U.S.A. the railway oil-engine has been developed mainly in large powers for trains of three to twelve cars, and electric transmission is used exclusively. These trains are usually run at timings faster than the ordinary trains and are popular for long distance as they enable journeys to be made during more convenient periods of the day than formerly.

Some of these trains are being purchased on long-term payments.

High Speed Services.

The competition of road transport, and in some cases of air transport as well, has led to the demand for increased speed in both passenger and freight services on railways all over the world. This has been met on branch lines by single cars of light weight and capable of high acceleration, propelled by oil engines. On main lines these have been developed into articulated train sets, consisting of two, three or more stream-lined cars, capable of speeds of 80 to 100 miles per hour.

As an alternative, specially built steam locomotives, partly or fully stream-lined, and capable of speeds in excess of 100 miles per hour, have appeared in Great Britain, Germany and the United States, and they draw lightweight stream-lined cars. The advantage of this arrangement over the articulated train set is that the number of cars can be varied to suit fluctuations in traffic.

OIL-ENGINED LOCOMOTIVES.

The application of the oil engine to railway locomotives has been given much consideration throughout the world.

In America most of the locomotives now being constructed are diesel-electric. It is claimed that owing to greater availability one diesel-electric can replace at least two steam locomotives.

Its adoption in any particular country depends largely upon the natural fuel resources of that country and its economics.

In England the cheapness of coal and the fact that over 90 per cent. of oil has to be imported, coupled with the cost of an oil-engined locomotive being more than twice that of a steam locomotive, has caused little progress to be made with the former except in small sizes for industrial work, and for railway shunting where the locomotive can be given a high load factor and be worked by one man.

On British railways two diesel-electric locomotives for passenger service have been put to work on the London Midland Region. Each has a 1,600 h.p. diesel engine of the 16-cylinder, Vee type, four-cycle construction running at 750 r.p.m. The locomotives are of the C_0-C_0 type with three motors per bogie. By coupling the two units together the heaviest and fastest trains can be operated.

* See p. 522.

The London Midland Region has tried about eight small shunting locomotives ranging up to 200 b.h.p. with mechanical transmission, and larger locomotives of 350–400 b.h.p. with electric transmission; results have shown that electric transmission is the better for the larger powers. This company has in service a number of oil-electric shunters of 350 b.h.p.; these locomotives have six wheels, and some of them have a single motor driving a jackshaft through double reduction gearing and which is coupled to the wheels by rods, whilst the others have two axle-suspended motors with single reduction gearing and the three axles coupled by rods.

Similar locomotives are in use on the other Regions.

Where there is a demand for high tractive effort at slow speed, such as at hump yards, double-reduction gearing is of benefit. It saves some space and weight in the motors.

On the Continent there is no standardised design and orders have been usually for single units, excepting small shunting locomotives. Experiments have been made there with large powered locomotives having mechanical or fluid transmission, or direct drive, but none has had the success of the electric transmission.

In Siam the State Railway has embarked largely on oil-engined locomotives for future renewals, also the South American Railways have made considerable experiments in this direction, but owing to financial difficulties they have concentrated on the cheaper light railcar in preference to heavy locomotives.

Almost all large locomotives are fitted with the four-stroke airless injection engine as this is considered the most reliable and simplest for railway work. In the U.S.A. the two-stroke engine has been tried in the large sizes, but has not met with the same success as the four-stroke engine.

Super-chargers driven by exhaust gas turbines are now in use and are capable of increasing an engine output by 30 to 40 per cent.

Various transmission systems have been tried out as with railcars but the electric one has proved the most successful despite its high initial cost and low efficiency; the hydraulic transmission is making progress and may surpass the electric before long.

Railway oil engines usually run on light Diesel oil of about 0·87 or 0·88 specific gravity.

The general method of starting the engine is by electricity or compressed air. In the former case if the engine is small in cylinder capacity an electric motor is geared to the engine; with large engines having electric transmission the main generator has a starting winding and is motored by current from a battery to start the engine.

Where compressed air is used there are several ways available. For a small engine an air motor may be geared to it, or an air impulse starter may be fitted. With large engines the compressed air is admitted direct by special cams into some or all of the cylinders.

The fuel capacity of oil-engined locomotives is greater than that of steam ones; shunting locomotives can carry conveniently a week's supply, and main line locomotives and railcars can usually carry two or three days' supply.

Automatic control is a common feature of oil-engined rolling stock, such items as oil and water temperatures and pressures being governed within pre-determined limits by apparatus which can stop the main engine if the limits are exceeded.

Filtration of engine inlet air is very important as cylinder wear is increased by particles of dust in the engine.

One big advantage of electric transmission and of other types and engines electrically controlled, is the ease with which multiple unit running and remote control can be arranged. The Scharfenberg coupler is suitable for this purpose as it comprises one head which automatically couples the draw and buffing gear, brake pipes and electrical connections.

GAS TURBINE LOCOMOTIVES.

A gas turbine locomotive built by Brown Boveri has been running on the Swiss Federal and French National Railways since 1941. The turbine develops 8,200 h.p. of which 6,000 h.p. is absorbed by the compressor, leaving 2,200 h.p. for driving the electric generators which supply current to the traction motors. The locomotive is arranged for one-man operation. By substituting bunker oil for diesel oil the cost of operation has been reduced below that of a diesel-electric locomotive. Thermal efficiency of the gas turbine locomotive has been raised to 20 per cent.

The Western Region of British Railways has a similar but larger locomotive on order with Brown Boveri, and a second locomotive is to be supplied by Metropolitan Vickers.

Much development work is in hand in America on gas turbine plants destined for locomotives. Experimental work is being carried out on coal-burning gas turbines, the fuel being burnt in pulverised form. Fly ash is the main problem to be overcome.

ROLLING STOCK.

Recent Developments in Carriage and Wagon Stock.

Electric arc welding is being applied to the construction of underframes for carriages and wagons and for bogie frames. Some reduction in weight is brought about in dispensing with riveted connections.

On British railways galvanised steel plates of about $\frac{1}{16}$-in. thickness are used for panels of carriages in conjunction with a wooden framework. Plastic material is being tried for panels There is a trend, however, towards all-steel welded bodies.

Plastic materials have also been introduced for interior panels and upholstery, and some trial is being made of fluorescent lighting, mainly in America and France.

Air conditioning is used on the more important trains in America. Power requirements are such that there is a tendency to replace axle-driven generators by diesel-driven auxiliary plants to supply current for lighting, air conditioning, etc.

The Eastern and Southern Regions of British Railways use the American type of automatic coupling and vestibule for many of their main-line trains. In order that these vehicles can be attached to ordinary stock, the coupler is hinged and can be dropped down, exposing a hook for screw coupling. Side buffers are provided, and these have a loose sleeve which can be removed to allow the buffers to be pushed back when the automatic coupling and vestibule with central buffers are in use.

Articulated twin coaches consist of a pair of bodies hinged together. The outer ends rest on bogies in the usual way, but there is only one bogie for the inner ends, the bogie pin being at the hinge between the coaches. A flexible gangway connects the two bodies. This system has been extended to complete trains, so that a set train of five coaches has only six bogies.

In France and Switzerland trial is being made of light coaches carried on rubber-tyred wheels. As not more than about 1 ton can be carried per wheel the number of wheels per coach is increased to 20. They give improved riding comfort, reduced wear and tear, and greatly improved braking.

The high-capacity bogie wagon makes but slow progress on British railways, owing to the lack of terminal facilities. The tendency is to build 4-wheel wagons of 12, 15, or 20 tons capacity

Electric welding is now much used for underframes and in some cases for bodies.

The fitting of power brakes to goods vehicles is being slowly extended. Its more general application is retarded by the presence of a large number of private owners' wagons and the high capital costs involved. Braked freight trains are, however, a feature of all the main line companies to-day; they are made up entirely of vacuum braked stock and are hauled by the highest powered engines at scheduled speeds of 50 m.p.h. and enable overnight delivery of goods to be made between most of the large towns in the country. Other goods trains are arranged so that as many as possible braked wagons are connected to the engine brake.

The container system of transporting goods is much used on British railways. Large boxes fitted with doors are filled at the factories, transported by road and then placed on railway wagons by a crane.

A new type of wagon is available for the transport of fragile goods, in which the body is not rigidly fixed to the underframe but is connected to it through four slides which allow of some longitudinal movement but prevent lateral or vertical movement relative to the underframe. The shock-absorbing element consists of four sets of rubber buffing springs which are attached to the underframe and two horizontal sets attached to the body. The effect of any longitudinal shocks delivered to the wagon are largely absorbed by these springs and do not reach the body. The wagons are also fitted with special shock-absorbing buffers on the headstocks.

General utility vans have been introduced by the Southern Region. These are 4-wheeled **vehicles, with a wheel base of 21 ft., and they have end as well as side doors. By means of special fittings they are adaptable for a number of purposes besides passengers' luggage, such as milk cans, motor-cars, road vehicles, fruit baskets, theatrical scenery, aeroplane parts, etc.**

One of these vans has been experimentally constructed with panels of reinforced plastic material. The underframe is of the cantilever type.

In England and in France some trial is being made with aluminium alloys for bodywork in order to save weight. Much more extensive use of this metal is being made in America for bodies and in some cases for underframes as well. It gives reduction in weight consistent with exceptional strength, durability, high corrosive resistance and low centre of gravity. Low carbon high strength steels are an alternative means of saving weight, as also copper-bearing steels, as thinner plates and sections can be used owing to reduction of rusting in service. The light tare weight of these wagons necessitates the use of load-compensating brakes.

In Germany some pre-stressed reinforced concrete wagons are being made.

Rolling Stock for Southern Railway Electrified Lines.

Extensive electrification of suburban and main lines for passenger train working has been carried out on 600 volt d.c. third-rail system. Rolling stock takes the form of set trains of two, three, four, five or six coaches, permanently coupled together to form the various units. Two or more units are joined together to form longer trains, as required. Motor bogie has two nose-suspended traction motors, each driving an axle through gear wheels.

***Two-Coach Set.*—For branch and light traffic. One motor coach with motor bogie at outer end; one trailer coach with driving compartment. Non-corridor sets, 62 ft. 6 in. long by 8 ft. ¾ in. wide bodies, 129 ft. 5½ in. over buffers, 70¾ tons tare. Seats, 24 first class, 135 third. Corridor sets, 62 ft. 6 in. long by 9 ft. bodies, 129 ft. 5½ in. over buffers, 74¾ tons tare. Seats 24 first class and 88 third. Two 275 b.h.p. motors, geared 1 to 2·8.**

***Three-coach Set.*—For suburban services. Two motor coaches with trailer between them. Non-corridor, 62 ft. 6 in. by 8 ft. ¾ in. bodies, 193 ft. 10½ in. over buffers, 109·6 tons tare. Seats 56 first and 180 third. Four 275 b.h.p. (or 300 b.h.p.) motors, geared 1 to 2·8. Motor bogies at outer ends.**

In conjunction with these sets, two-coach trailer sets are used to form eight-coach trains with another driving unit, when traffic is heavy. In some cases three three-coach sets are used to form trains of nine coaches. Two-coach trailer units have bodies 50 ft. by 8 ft are 107 ft. 1 in. over buffers, and weigh 43·7 tons. They provide 180 third-class seats.

***Four-coach Set.*—For semi-fast services. Two motor coaches with two trailers between them, one trailer being a corridor coach with lavatories for first and third class. Other vehicles are non-corridor. Bodies, 62 ft. 6 in. by 9 ft., 256 ft. 11 in. over buffers, 139 tons tare. Seats 70 first class and 204 third. Four motors of 275 b.h.p., geared 1 to 2·8. Motor bogies at outer ends. Two sets are joined to form eight-coach trains when required.**

***Six-coach Set.*—For express services. Two all-steel open saloon-type motor coaches with four trailers between them. Two motor bogies per motor coach, each with two 225 b.h.p. traction motors, gear ratio 1 to 2·5, total 1,800 b.h.p. per set. All bodies are 62 ft. 6 in. by 9 ft.**

Sets with Pullman car:

Motor coach	59 tons.	Seats 52 third class		
Compo.	35½ „	„ 24 „ „	and 30 first.	
Pullman	40 „	„ 16 „ „	„ 12 „	
Compo.	35½ „	„ 24 „ „	„ 30 „	
Corridor (third)	31½ „	„ 68		
Motor coach	59 „	„ 52		
Total	260½ „	„ 236 „ „	72 „	

Sets without Pullman:

Motor coach	59 tons.	Seats 52 third class,	
Corridor (third)	31½ „	„ 68 „ „	
Buffet and first	32 „	„ — „ „	30 first class.
Corridor (first)	31 „	„ — „ „	42 „ „
Corridor (third)	31½ „	„ 68 „ „	
Motor coach	59 „	„ 52 „ „	
Total	244 „	„ 240 „ „	72 „ „

When required, two sets are joined to form twelve-coach trains.

***Five-coach Pullman Sets.*—For express services. Two motor coaches, each equipped with four 225 b.h.p. motors, with three trailers between. All Pullmans, first and third class. When required, two sets all joined to form ten-coach trains.**

Axle Boxes.

These are usually of cast iron, but a welded axle box fabricated from ¼-in. plates and a ½-in. backplate is now being introduced for wagons; for carriages oil boxes are universal, and a large number of new wagons are now being fitted with them instead of grease boxes. An oil reservoir in the bottom of the box conveys oil by capillary attraction, either by cotton-waste packing or by means of a worsted pad with tail trimmings supported on springs. The bearing or 'brass' is of gun-metal, or gun-metal lined with white metal. Some white metals have a tin base and contain about 60 per cent. tin and 25 per cent. of lead, with 10 per cent. antimony and a little copper. The lead base alloys have about 76 per cent. of lead, 15 per cent. of antimony, 6 per cent. tin, and a small percentage of copper.

The oil used is a mineral oil, and sometimes contains a trace of fatty oil.

A leather-faced dust shield prevents dirt or water creeping in at the back of the box.

In India axle guards for containing the axle boxes are being successfully replaced by radius links. Wear is found to be reduced.

Roller Bearings.

In some countries roller-bearing axle boxes are being increasingly used for passenger and freight vehicles, notably in U.S.A.

Experiments made on British railways seem to indicate that the friction of a plain bearing lubricated by an underpad is even less while running than a roller bearing, although the starting effort required with the latter is reduced, as also the oil consumption.

Owing to the higher capital cost there is, however, little or no inducement to adopt the roller bearing on British railways. On railways abroad, where the workmanship, maintenance, and materials are not so high-class, so that friction is greater, some advantage is gained by the adoption of roller bearings, and a small saving in fuel is found, sufficient with the other advantages realised to justify the adoption, this tendency being more marked in the Northern countries in Europe having cold winters. The bearings are also applied to trains de luxe in France and elsewhere on the Continent, such as the 'Blue Train' and the 'Golden Arrow.' Favourable conditions for the use of roller bearings are also found in North America, where some of the steel passenger coaches weigh as much as 70 to 80 tons each. Owing to the axle loading the journals are of large diameter, while the wheels are smaller than in England, so that the frictional resistance is high, and the risk of heating increased. The use of roller bearings reduces the friction, enables an easier and smoother start to be made, and obviates the risk of hot bearings, besides reducing oil consumption.

Wheels.

For carriages the wheel with wooden centre, once universal, has now been superseded to a large extent by a steel disc centre of slightly dished form, on which is shrunk a steel tyre having a lip on outside, and secured by retaining ring inside. Tyres are 5 ins. wide and are coned 1 in 20. In order to ensure smooth running, all carriage wheels are carefully balanced. Each pair of wheels is placed on a machine, the journals resting in bearings mounted on springs. When the wheels are revolved at high speed any irregularity in the running can be detected, and a correction made by fastening small plates to the inside of the wheel, near the circumference, so that smooth running results.

Wood centres must be bonded by a copper strip between tyre and hub, so as to conduct electric current from rail to rail for operating signalling appliances. Tyre shrinkages are $\frac{3}{16}$ in. for wood centres, and about $\frac{1}{64}$ in. for steel centres.

Wagon wheels are made in a variety of ways. The bossed spoke wheel consists of spokes made from flat bar bent into triangular shapes. These are assembled in position and the boss is formed on them by placing two steel discs brought to welding heat on either side of the spokes and forcing them together in a powerful press. The bossed spoke wheel was formerly made by casting a cast iron boss on them, but this practice is no longer in favour. Spoked wheels have also been made by forging spoke bars and building up a wheel. But this has been largely superseded by a cast-steel spoke wheel. A few wheels are being made with steel disc centres.

Solid disc wheels are sometimes used in the case of guards' brake vans where the heat generated by prolonged braking is liable to loosen tyres shrunk on wheel centres.

In Canada rubber-cushioned wheels are being produced. They give smoother riding and noise is reduced by over 80 per cent.

Journals of axles are sometimes case-hardened, but very good results can be obtained by the simple process of burnishing in the lathe or by grinding, after the journal is machined. In the case of the former, a tool having a small roller at the end is fixed in the slide rest and the journal is rolled all over with considerable pressure; this closes all the pores and leaves a hard, bright surface.

The maximum bearing pressure for journals varies from 500 to 700 lb. per sq. in. of projected area.

A reduction in diameter of journal by $\frac{1}{4}$ in. is allowed before axles are scrapped. In India worn axles are being given a longer life by turning down the journals and sleeving them with a steel bush.

Springs.

Laminated bearing springs are usually $3\frac{1}{2}$ ins. wide for carriages, and 4 ins. for wagons, with plates $\frac{3}{8}$ to $\frac{1}{2}$ in. thick, approximately.

If L = distance in inches between centres of bearings measured along top plate; b = breadth of plates in inches; t = thickness of plates in sixteenths of an inch; n = number of plates; W = safe load in tons; D = deflection in sixteenths of an inch per ton of load,

$$n = \frac{15LW}{bt^2};\quad W = \frac{bt^2n}{15L};\quad D = \frac{2L^3}{bt^3n}.$$

If there are different thicknesses of plates in one spring, it is necessary to find the equivalent number of plates of uniform thickness from the square (or cubes in the case of deflection) of the thickness, thus :—

$$n = \frac{n_1 t_1^2 + n_2 t_2^2}{t_1^2}.$$

See also p. 551.

Buffer springs are largely made of rubber, and are formed of rubber discs 2½ to 3 ins. thick placed between 6 or 8 metal discs.

For *Helical Springs* see p. 553.

Couplings.

Draw bars should be 1⅞ ins. diameter; they should be made from wrought iron, Grade A, or welding steel. Area of end of eye = area of two sides × 1·2.

Couplings should be made of wrought iron, Grade A, or welding steel. Standard diameter = 1½ in.

Screw couplings are of wrought iron, or sometimes of steel (B.S.S. 9B).

Draw hooks should be of wrought iron, Grade A, or welding steel. If stamped out, the grain of the iron should be kept running with the hook, an important point sometimes overlooked in second-rate work.

FOR BRITISH STANDARD SPECIFICATIONS FOR MATERIALS USED IN THE CONSTRUCTION OF RAILWAY ROLLING STOCK, see pp. 550 to 561.

Heating Railway Carriages by Steam.

Heating of trains is by steam from the locomotive boiler. The train piping consists of 1½ in. bore iron piping, and flexible rubber hose connections with universal couplings are provided between carriages. Automatic ball valves and thermostats are fitted for drainage of water. A pressure of 60 lb. per square inch is usually the maximum, but 30 lb. is quite an average pressure for ordinary working. The G.W.R. adopts a maximum pressure of 80 lb. per square inch.

Several systems are in use, but they may be classed under two headings, high-pressure and atmospheric. In the high-pressure systems, long cylindrical heaters, 4 ins. to 5 ins. diameter, are placed under one seat of a compartment. These are in direct communication with the train pipe, and steam under pressure fills them. As condensation takes place the water is drained away through a thermostatic valve. There are several modifications of this system.

In the atmospheric systems the heaters have an open outlet at one end, and a jet of steam entering at the opposite end expands to atmospheric pressure and condenses on the walls of the heater, the water draining away at the outlet. In some systems regulation of steam is by means of a thermostat, which automatically controls the steam. In others a choke plug in the branch pipe to the heater restricts the supply of steam to the necessary amount.

With coal of such a quality that it produces 7½ times its own weight of steam in the locomotive boiler, the average consumption of coal for the three coldest months should not exceed about 6½ lb. per axle per hour.

An approximation for the steam required for heating in Great Britain is 100–120 lb. per hour per coach.

American practice is different from that in Europe. External temperatures are lower and the internal temperature is higher, usually about 70° F., consequently the steam consumption is much greater and for a 70–80 ft. coach may be as much as 200–250 lb. per hour. The pressure in the train pipe is about 175–200 lb. per sq. in. maximum, and rigid pipes with ball joints and couplings are used instead of hoses.

On trains hauled by diesel traction the locomotive carries a boiler heated by exhaust gas, with oil-firing as auxiliary when required. A tank of water also has to be carried. A similar arrangement is provided on electric locomotives: the boiler in this case is electrically heated. It is more usual, however, for a boiler truck with a coal or oil-fired boiler to be attached at the rear of the train. In South Africa a special boiler vehicle is attached next to the locomotive where it is under the supervision of the driver. It has an electrically-heated boiler, current being drawn by a collector bow from the overhead conductor.

BRAKES.

Latest Developments.

The Westinghouse automatic empty and load brake with straight air control has been introduced for railways having long gradients necessitating prolonged braking periods. Straight air is used for normal application, while the automatic action is reserved for emergencies or breakaways. A change-over valve is provided on each vehicle; it has two positions—in one reduced pressure is obtained for empty to half-full vehicles. Full pressure is given by the other position for vehicles more than half-full. The control is set by hand.

The use of light-weight stock by reducing tare in relation to gross weight has called for a load compensating brake in U.S.A. Full force of each brake cylinder is reduced on empty and part-filled vehicles by the admission of air on the opposite side of the piston. Its pressure is governed by a weighing device which pre-sets a valve.

On passenger stock electrical control in parallel to the pneumatic system ensures simultaneous and quicker setting of the brake.

Some trains on high speed service have a 'Decelostat' connected to each axle. By this means greater brake block pressure can be applied. If a pair of wheels tends to skid the appliance momentarily reduces air pressure until the wheels are revolving normally.

Action of Brakes.

f = proportion which resistance produced by brakes bears to weight of train.

v = speed in feet per second.

V = speed in miles per hour.

Distance in feet in which the train is stopped on level $= \dfrac{v^2}{64 \cdot 4 f} = \dfrac{V^2}{30 f}$

Brakes self-acting on all the wheels, $f = \cdot 14$.

Ordinary brakes worked by hand in brake-vans, $f = \cdot 031$ to $\cdot 023$.

On gradient *ascending* 1 in n, resistance $= f + \dfrac{1}{n}$.

On gradient *descending* 1 in n, resistance $= f - \dfrac{1}{n}$.

Distance in feet for stopping $= \dfrac{f \times \text{distance on level}}{f \pm \frac{1}{n}}$

Power required by Brakes.

The following results have been obtained as regards consumption of energy with different kinds of air brakes :—1. On city lines, the consumption of energy for excentric compressors was 41·5 watt-hours per car kilom. (66·4 watt-hours per car mile); with geared compressors, 31·2 watt-hours per car kilom. (49·9 watt-hours per car mile); and with motor compressors, 16·16 watt-hours per car kilom. (25·86 watt-hours per car mile). 2. On suburban lines, the consumption for excentric compressors was 22·8 watt-hours per car kilom. (36·5 watt-hours per car mile); with geared compressors, 14·6 watt-hours per car kilom. (23·4 watt-hours per car mile); and with motor compressors, 6·32 watt-hours per car kilom. (10·11 watt-hours per car mile).

The Westinghouse Automatic Brake.

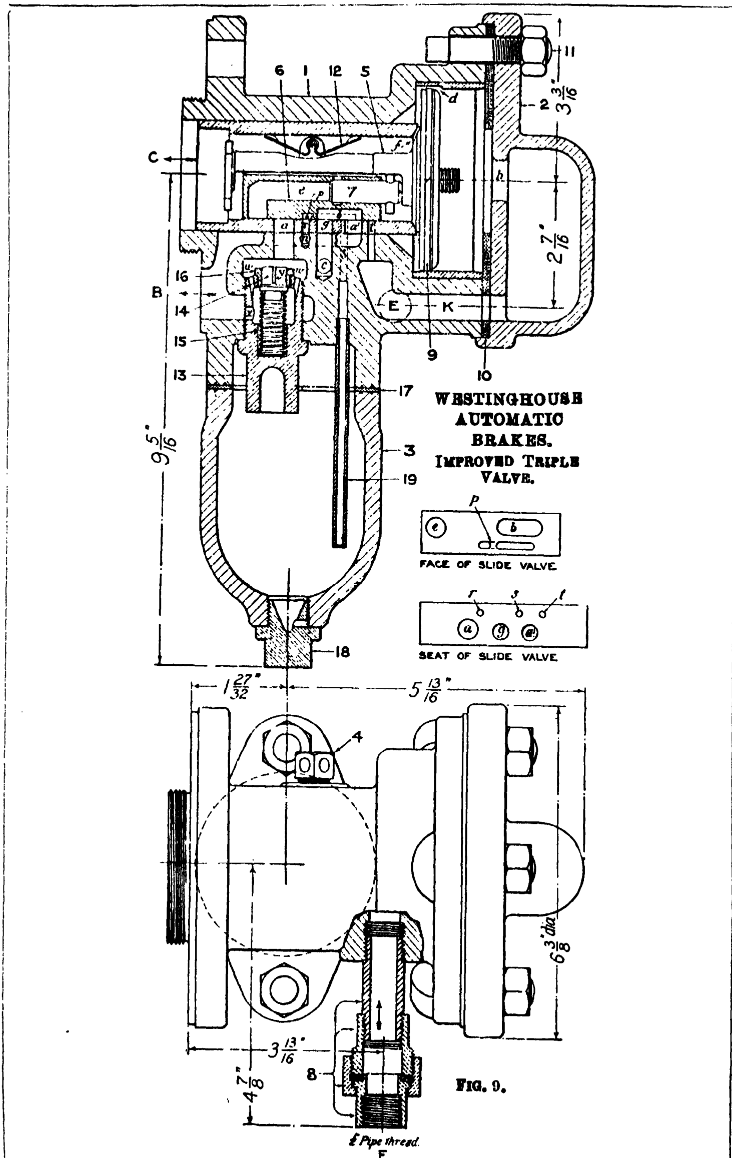
The Westinghouse automatic brake is continuous throughout the train and is operated by compressed air furnished by the compressor and stored in the main reservoir on the engine. This compressed air is fed by the driver's brake valve into the train pipe and, past the triple valves, into the auxiliary reservoir on each vehicle.

The brake is applied by reducing the pressure in the brake pipe, which causes the pistons of the triple valve to move and permit some of the compressed air stored in the auxiliary reservoirs to pass to the brake cylinders, the pistons of which are forced outwards, applying the brake blocks to the wheels.

The brake is released by restoring the air pressure in the train pipe, which causes the triple valves to close the communication between auxiliary reservoirs and brake cylinders and open a port from the brake cylinder to the atmosphere, through which the compressed air escapes from the cylinder. The spring in the cylinder can then push back the piston and withdraw the blocks from the wheels.

The brakes are usually applied by the driver, or in cases of emergency by the guard, but a break-away, or rupture of a hose coupling, or other accident causing an escape of air from the brake pipe, also immediately applies the brakes.

It is recommended that a pressure of 90 lb. per sq. in. be maintained in the main reservoir, and 70 lb. per sq. in. in the brake pipe.



WESTINGHOUSE AUTOMATIC BRAKES.
IMPROVED TRIPLE VALVE.

FIG. 9.

WESTINGHOUSE AUTOMATIC BRAKE.
DRIVER'S EQUALISING BRAKE VALVE.

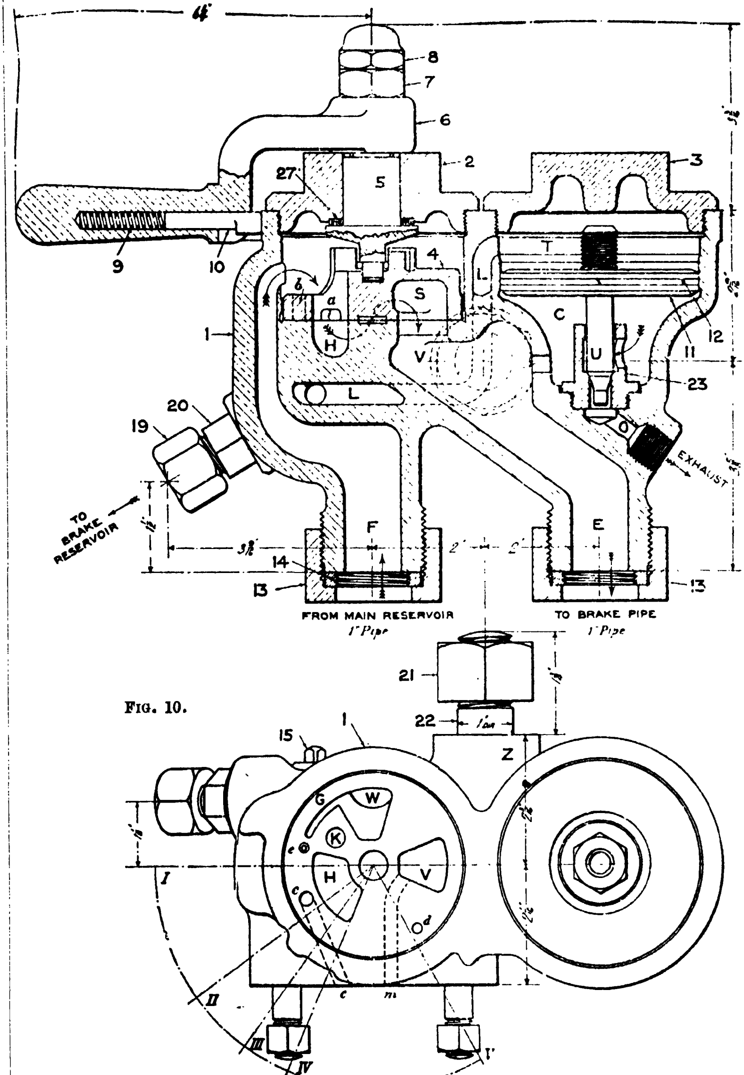


FIG. 10.

IMPROVED TRIPLE VALVE.

This valve has been designed to give a closer approach to simultaneous action of all the triple valves in a train than heretofore. As shown in fig. 9, p. 580, the valve is in the release position and the bulb is open to the atmosphere. When the slide valve 6 is moved in applying the brakes, the bulb 3 is closed to the atmosphere and opened to the brake pipe by the cavity *p* and port *s* shown in dotted lines. The local reductions of brake pipe pressure thereby produced by the forward triples in a train cause an earlier action of the rearward triple valves, which results in a more nearly simultaneous braking effect being produced throughout the train in every case of first setting the brakes than heretofore, with a smoother and more efficient brake service generally.

A further improvement, also tending to smooth and even action of all the brakes, is shown in the passage leading from port *a* in the seat of the slide valve 6 to the brake cylinder at B. It consists of a removable plug 13, perforated with holes *w* and *x*, which are always open, and an additional hole *y* carrying an automatic check valve 14, supported by a spring 15. It is so arranged that, when the brakes are first set, the automatic valve is opened against the spring resistance by the excess of air pressure above it, so that the hole *x* controls the rate of flow of air to the brake cylinder: as the air pressure on the under side of the valve increases, the spring closes the valve, when the smaller holes *w* control the rate of flow to the brake cylinder. The diameters of the regulating holes *w* and *x* are made proportional to the diameter of the brake cylinder with which the triple valve is to be used. By changing these perforated plugs, the same pattern of valve is thereby suited to cylinders of various sizes.

The bulb at the bottom of the triple valve is made in different sizes, proportioned in content to the volume of the brake pipe of the vehicle on which the valve is to be used.

A separate passage a^1 is provided in the triple valve body from brake cylinder to slide valve 6 for the air to escape from the brake cylinder on releasing the brakes. The rate of release is controlled as heretofore, by a nipple screwed into the outlet hole *c* in the triple valve body.

DRIVER'S EQUALISING BRAKE VALVE.

The principle of this brake valve, fig. 10, p. 581, is not to allow the driver in ordinary applications of the brakes to discharge air directly from the brake pipe, but from a small reservoir connected with chamber T of the valve. The reduction of air pressure, thus effected in the reservoir, is then at once automatically and properly repeated in the brake pipe by means of a small equalising piston, 11, placed between the air in the chamber T, and that in the brake pipe E. The piston moves in accordance with the variations in pressure above and below it, and governs an exhaust valve U in such a manner that the air pressure in the brake pipe must always equalise with that in the small reservoir connected with the valve chamber T. Even if the exhaust of air from the brake valve reservoir is abruptly stopped by the driver, the discharge valve U is always gradually closed by the piston, when equilibrium of pressure is established throughout the train. The equalising device, therefore, will under all circumstances provide for a uniform reduction of the pressure in the main brake pipe, thus ensuring a uniform application of the brakes to all the vehicles in the train.

The compression of air is effected by a Westinghouse compressor.

PIPE COUPLINGS.

In the connecting-pipe *coupling*, which is shown by fig. 11, the two halves of couplings, 1, are exactly alike, and an air-tight joint is formed by means of the rubber packing-ring, 3, 1 in each, which rings face each other when the couplings are united. The air-pressure in the

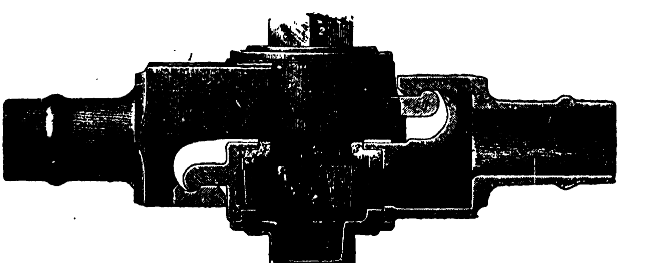

FIG. 11.

couplings tends to force these rings towards one another, so that the joint becomes tighter with increase of pressure. The tendency of the air-pressure in the couplings is also to force them apart in a direction at a right angle to the line of the india-rubber hose-pipes, and, consequently

the greater the pressure, the more firmly are the couplings held together by the projecting piece, *g*, of each coupling, which fits in a corresponding groove of the other coupling. No damage is done if the couplings be drawn apart forcibly by the separation of the train, as the rubber rings, 3, 3, are forced into their respective couplings far enough to permit the projections to disengage from their grooves. These couplings are united by simply placing them face to face at right angles, the stop-pins being on the under side, and then turning the projection of the one into the groove of the other.

The Vacuum Automatic Brake.

The Vacuum Automatic Brake is applied by admitting air to the brake cylinders through a continuous brake pipe, and released by withdrawing the air. To charge the brake cylinders, air from above the piston is withdrawn through a non-return ball valve to below the piston and thence direct through the brake pipe to a high-speed rotary exhauster in the case of an electric locomotive, or an ejector if a steam locomotive.

A service brake application is made by the driver admitting air to the brake pipe through a valve on the locomotive, and atmospheric pressure entering the brake cylinder below the piston acts against the vacuum above the piston and applies the brake at a pressure proportionate to the reduction of vacuum in the brake pipe. Air is prevented from entering the evacuated space above the piston by the non-return ball valve.

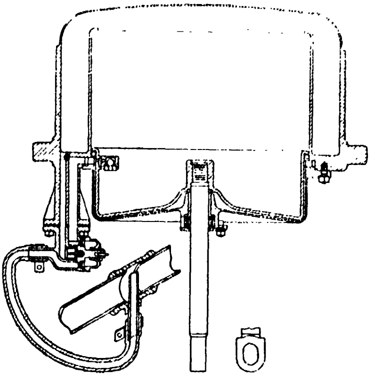

FIG. 12. 'Prestall' Wrought Steel Vacuum Brake Cylinder with internal ball valve and external release valve. Piston in release position. Air above piston is exhausted through the internal ball valve. The brake pipe connection to cylinder (shown in section) is provided with a siphon to prevent condensed moisture from being drawn into cylinder.

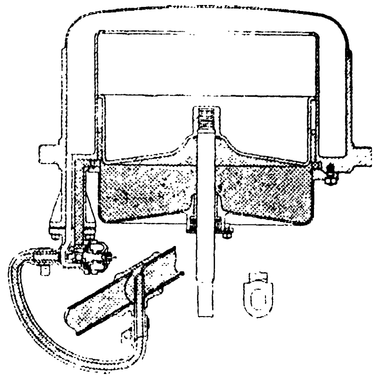

FIG. 13. 'Prestall' Wrought Steel Vacuum Brake Cylinder with external ball valve. Piston in 'brake on' position. A brake application is made by admitting air to the shaded portion below piston. The non-return ball valve prevents air entering the space above piston.

An emergency brake application may be made with the guard's van valve at rear of train, or a slow brake application by the passenger emergency valve fitted on each carriage. The brake is automatically applied throughout the train if an accident occurs sufficient to part the couplings.

Passenger trains are generally operated at 20-in. vacuum, but a few railways use 24-in. vacuum; and freight trains at 20-in. vacuum, or 16-in. vacuum on long trains where high vacuum is difficult to maintain.

Brake cylinders are either of the combined type with the vacuum chamber forming the outer casing of the cylinder (see figs. 12 and 13) or separate type with an independent vacuum chamber. In the former case, the cylinder is connected to the brake pipe by a single branch valve, and in the latter case a double branch is used, the second branch connecting the vacuum space above piston with an independent vacuum chamber.

The ball valve is housed either inside the piston as shown in fig. 12, or in the casing of a detachable valve as fig. 13. The former type of valve is less liable to leak through grit being drawn on to the valve seat, and it possesses a further advantage that when the piston moves upwards during a brake application the port in the wall of the piston (leading to the ball valve) passes to the

vacuum side of rolling ring, and thus isolates the valve and cuts off a possible source of leakage that might render the brake inoperative. The poppet type release valve (see fig. 13) used on cylinders with an internal ball valve, effects a more rapid manual release of the brake than is possible where the ball valve (see fig. 13) combines the functions of check valve and manual release valve as with the externally housed ball valve.

The tendency to reduce deadweight wherever possible, and the use of higher tensile materials in the construction of rolling stock has led to the introduction by the Westinghouse Brake & Saxby Signal Co., of brake cylinders made entirely from pressed steel. These are 30 to 40 per cent. lighter than cast-iron cylinders and possess greater resistance to fracture or breakage. These cylinders, known as the 'Prestall' wrought steel cylinders (figs. 12 and 13) have a detachable base for the easy renewal of the rubber rolling ring packing between cylinder and piston, the total detachable weight being 50 per cent. less than the cast-iron type in which it is necessary to remove the entire cylinder from casing in order to renew the rolling ring. The piston rod is guided by a gunmetal bush and rendered airtight by a rubber gland arranged so that atmospheric pressure acting

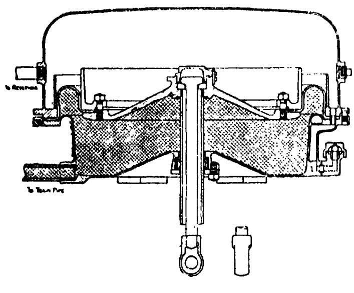

FIG. 14. 'Prestall' Wrought Steel Diaphragm Cylinder. The rolling action of the diaphragm between the vertical flanges is shown with the Piston at 'brake on' position; the shaded portion represents atmospheric pressure.

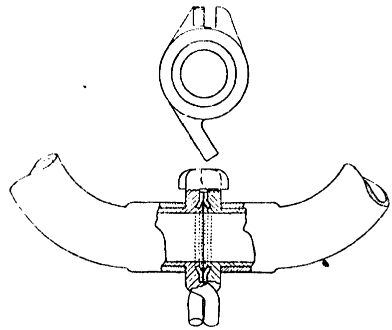

FIG. 15. Vacuum Hose Coupling. *Above*, End Elevation; *Below*, Sectional side Elevation.

on the outside diameter of the gland forces it with an even pressure around the piston rod. The rubber gland is easily renewed without dismantling the cylinder by simply unbolting the steel cover-plate forming the gland cap.

In all cylinders with rolling ring packing a certain amount of leakage is liable to occur after the rolling ring has become worn, and to avoid this, certain railways use a cylinder with a reinforced rubber diaphragm, since the vacuum can be maintained above piston for a longer period with a diaphragm than is possible with the rolling ring packing. This is an important feature for railways with long gradients, since it is impossible to recreate the vacuum above piston without first releasing the brake. The 'Prestall' wrought steel diaphragm cylinder, fig. 14, is provided with a vertical guide flange on the piston follower, and a corresponding flange in the dome of the cylinder, so that the diaphragm rolls between these two walls and the atmospheric pressure beneath the diaphragm is confined to a vertical path in the line of piston travel. This enables a longer and more powerful stroke than is possible when the diaphragm is not so guided.

The continuous brake pipe is generally 2-in. bore, but a few narrow-gauge railways use 1½-in. bore. The brake pipe is connected between vehicles by means of flexible internally armoured rubber hose, at the end of which is secured a metal coupling head with rubber jointing washer. These couplings when connected are held together by the horn at the bottom of coupling, which hooks on to a similar horn on the opposite coupling, whilst a lug and slot at the top of the coupling fits into a similar lug and slot on the opposite coupling, and keeps the bore of the two couplings in register. This coupling in the form approved by the Railway Clearing House is shown in fig. 15.

On their latest rolling stock the Southern Region is using one 30-in. Prestall cylinder instead of two of 22 in. as heretofore. Brake shafts can be dispensed with and much weight saved.

ELECTRIC RAIL TRACTION

(Revised by W. J. Arnold Sykes, A.M.I.Mech.E.)

British Standard Specifications relating to Electric Traction.

No.	Title.
2—1944.	Tramway Rails and Fishplates.
8—1939.	Tubular Traction Poles.
23—1933.	Trolley Groove and Wire.
68—1914.	Steel Conductor Rails (Resistance).
74—1937.	Charging Plugs and Sockets for Battery Traction.
24 (2)—1942.	Locomotive and Carriage Tyres.
101—1929.	Tramway Tyres.
102—1930.	Tramway Axles.
468—1932.	Rolled Steel Wheels and Wheel Centres.
150—1922.	Cast Steel Wheel Centres for Tramcars.
173—1941.	Electrical Performance of Traction Motors.

FORMS OF ELECTRIC TRACTION.

Forms Involving Electrification of Route.

These include long-distance and suburban railways, tramways, and trolley-bus routes, the electric energy being supplied to the vehicle from overhead lines or additional rails.

Forms not Involving Electrification of Route.

These include: (*a*) all forms of battery locomotives, road vehicles, trucks, etc., and entail charging stations and charging periods; (*b*) oil-electric traction, where the power of the internal combustion engine is conveyed electrically to the driving axles. Here the electric generator and motors merely form a transmission and so replace the gear box or other mechanical mode of speed change.

ELECTRIC TRACTION ON LONG-DISTANCE RAILWAYS.

There are at present four systems for electric traction on long-distance railways: (1) Direct-current, (2) Three-phase, (3) Single-phase, and (4) Split-phase—a combination of (2) and (3). The Three-phase system, although a complete success, has made considerable headway in but one country—Italy; its drawback is the double overhead conductor. The Direct-current, Single-phase, and Split-phase systems only are in active conflict to-day.

In most European countries the choice of system has been definitely decided by national commissions: these bodies, after weighing the facts, have set forth the details of the system most suited to their needs. Thus, in Great Britain the well-known report of the Electrification of Railways Advisory Committee has recommended the adoption of Direct-current at 1,500 volts. The same conclusion has been reached by the authorities in Holland, Belgium, Czecho-Slovakia, and France; whereas Switzerland, Germany, Austria, Sweden, and Norway have standardised the Single-phase system at low frequency. In the U.S.A. the electrification of the Chicago, Milwaukee, and St. Paul Railway, a large trans-continental route, on the Direct-current system at the high pressure of 3,000 volts, has had a considerable influence on some European decisions. The more recent adoption by the Virginia Railroad of the Split-phase arrangement for one of the heaviest freight services in the world has, however, again drawn attention to the capabilities of A.C. for electric train-haulage, while the Pennsylvania Railroad has adopted single-phase for a main line with heavy traffic.

The motors employed for Direct-current traction are universally of the Series type, yielding a torque which is greatest at starting, falling off as the speed rises. (See fig. 2, p. 590.) *Speed regulation*—a very important matter for locomotive work—is obtained by series-parallel grouping of the motors—the standard method employed in traction to vary the motor terminal voltage. Further speeds entail weakening of the motor field flux: a method, while economical, resulting in the reduction of the useful torque per ampere of armature current. Starting is effected by the insertion of resistance in the motor circuit. For passenger and express work the losses in the rheostats may well be insignificant, but for goods and shunting operation, or where stops are frequent, these losses may become important.

For Single-phase traction in Europe, the Single-phase neutralised series motor is used almost universally. The machine is similar in principle and performance to its D.C. counterpart; some inherent defects have been overcome by sound design and the use of a low frequency ($\frac{50}{3} = 16\frac{2}{3}$ periods). The decisive advantage, however, is the feasibility of a high contact line pressure; 20,000 volts has been successfully tried, and 16,000 volts is standard practice. Voltage reduction by tapped static transformer obviates the necessity for starting resistances by providing a simple means of regulating the current to the motors. Tappings are usually on the low-tension winding, but a later development in Sweden and Switzerland is the use of high tension control with the tappings on the high tension side, thereby avoiding the switching of the very heavy secondary currents. The tappings can be graded so as to allow of small and regular increases in starting tractive effort, thus making the maximum possible use of the adhesion without slipping the wheels. Experiments are being made in taking the supply from national Three-phase 50-cycle lines, either by using grid controlled mercury arc rectifiers to reduce the frequency or obtain D.C., or by the use of 50-cycle current in the traction motors.

In America the later developments in Single-phase train-haulage have been with the Split-phase arrangement. Here a higher frequency can be used on the lines with advantage. The high-voltage Single-phase energy taken from the trolley wire is transformed down on the locomotives and passed through a phase-converter, which supplies two- or three-phase energy to the induction motors used for traction. The use of these robust and efficient motors is a great advantage, and commutators are avoided. This is important in the U.S.A., where 25 cycles has become the standard frequency for A.C. traction. Polyphase induction motors are lighter than either D.C. or Single-phase machines, but speed regulation is difficult, complex pole-changing and cascading devices being required. Rheostatic starting is essential. The recuperation of energy by the motors when descending a grade is automatic, and this explains the adoption of the Split-phase system on lines dealing with heavy mineral trains on steep gradients; moreover, braking is positive; energy is returned to the line; tyres, brake blocks, and rails are subjected to less wear; and the high line-voltage makes the collection of large quantities of energy a simple matter. More recently the Single-phase-D.C. converter locomotive has been developed.

The straight Three-phase system possesses the disadvantage of requiring two overhead conductors, the track forming the third phase. The voltage between phases is thus limited, the load is always more or less unbalanced, and overhead work at junctions and termini is very complicated. Induction motors are used as for the Split-phase system.

The systems employed for electric traction which have proved to be technically sound are shown in the following table, which traces the connection from locomotive to power-station:—

Equipment of			Supply.
Locomotive.	Track.	Substation.	
D.C. motor . .	Overhead wire . / Third rail . .	Rotary converter . / Motor generator . / Mercury rectifier and transformer .	Three-phase at normal or low frequency.
Polyphase induction motor . .	Two overhead wires . .	Transformer . .	Three-phase at normal or low frequency.
Polyphase induction motor, with phase converter . .	Overhead wire .	Transformer . .	Three-phase at normal or low frequency.
Single-phase series motor and transformer . .	Overhead wire .	Motor generator and transformer . .	Three-phase at normal or low frequency.
		Transformer . .	Single-phase at mainly low frequency.

The choice of an electrification system in any specified case is first and foremost a matter of finance. In the main, the installation which is cheapest when taken from every standpoint

is the system to be installed. An important secondary matter is interference with communication circuits owing to the cost of essential safeguards. In total mileage the amount of Single-phase is about equal to Direct-current electrification.

The following summary shows the chief developments in long-distance and main-line electric traction.

SYSTEMS IN USE IN MAIN-LINE ELECTRIFICATION.

Single-phase System.—With overhead conductor, usually 15,000 volts at 16⅔ cycles—Austria, Germany, Scandinavia and Switzerland. In U.S.A., a voltage of 11,000 volts at 25 cycles is used. In Hungary, the frequency is 50 cycles with split-phase supply from phase-converters to the locomotives.

Direct-current System.—With overhead conductor or third rail—France (1,500 volts), Great Britain (1,500 to 600 volts), Holland (1,500 volts), Italy (3,000 volts), U.S.A. (3,000 to 600 volts).

Three-phase System.—With two overhead conductors, practically confined to original development in Northern Italy (3,700 volts, 16⅔ cycles).

GREAT BRITAIN.—Great Britain has comparatively little to show in the way of long-distance railway electrification, although there are numerous schemes and projects under consideration.

Standards for British Railway Electrification.—An attempt has been made to standardise the system, etc., for future developments, but a certain amount of latitude has been allowed, as the following will show:—

The Electrification of Railways Advisory Committee, appointed by the Minister of Transport in March 1920, issued its final report in September 1921, recommending that all new electrification should be on the direct-current system, and that the standard pressure should be 1,500 volts, except in the case of railways already operating at 600 or 1,200 volts D.C., or with alternating current. The adoption of 750 or 3,000 volts should be permitted where approved by the Minister. Both overhead and rail conductor collection were recommended, provided that the form and design of the conductors and structures were in accordance with specified regulations. Current should be generated on the Three-phase system, at the frequency in general use in the district concerned; 50 cycles could be used satisfactorily. Suggested regulations were given, with drawings, for the standardisation of contact rails.

The Railway Electrification Committee (1927) reviewed the 1921 recommendations in a report issued in 1928. It was found that extensions had been made to existing lines at 600 and 650 volts, making a total of 1,404 miles of track at low-voltage D.C., 77 miles of 1,500-volt D.C., and 19 miles of Single-phase, the Brighton section of the Southern Rly. having been converted to D.C. The Committee therefore recommended the adoption of D.C. working at 'maximum' standards of 750 and 1,500 volts, with third rail and overhead contact systems respectively, and with generation at 50 cycles, 3-phase. The Committee did not consider it necessary to provide for the inter-running of multiple-unit rolling stock between high- and low-voltage electrified sections. For locomotives, however, to enable inter-running to be effected, two maximum loading gauges were prepared. No. 1, with a maximum height of 12 ft. 8 ins. above rail level, will be suitable for inter-running on all British railways, except on certain short lines, such as light railways, tube lines, and goods branches, totalling 264 miles. Such locomotives will have a scope of practically the whole of the 20,000 route miles of railway. No. 2 takes advantage of the higher (13 ft. 2 ins.) loading gauges of the L.M. & S., L. & N.E., G.W., and Southern (central section main line) Railways, and locomotives constructed to this gauge will have a scope of rather more than 13,000 miles. A suitable overhead-contact current collector was suggested. To permit of inter-running electrically, locomotives should be equipped with 750-volt motors capable of being connected in series-pairs for operation on 1,500 volts, and both overhead and shoe collectors should be provided. The reservation was made that the electrical standardisation need not be effected by a railway company until one-third of its total locomotive stock has been replaced by electric engines. Details of third rail and overhead clearances were specified. The Committee considered it undesirable to set limits to the voltage drop and uninsulated return conductors, a decision with which representatives of the G.P.O. were in disagreement.

Report of the Ministry of Transport Committee on Main-Line Railway Electrification, 1931.

In 1929 a Committee on Main-Line Railway Electrification was appointed with Lord Weir as Chairman. The basis of the recommendation for an extensive conversion of British railways to electric working was the existence of the 'National Grid' network. At an estimated cost of £80 millions, the Central Electricity Board would construct and equip the necessary additional transmission lines and supply the railways with energy at 0·475*d.* per kWh., measured at the substation d.c. busbars.

The selected system was 1,500 volts d.c. with overhead contact line. The possibility of using oil-electric traction on branch lines with light traffic was also envisaged.

The advantages claimed for electrification were: increase of average speeds without increase of maxima; increased station capacity; absence of smoke; development of real estate sites over large stations; passenger amenities; increase of axle loads on account of the even torque; better conditions for train crews; flexibility to suit traffic demands; avoidance of fire from locomotive sparks. The concomitant disadvantages were: the heavy capital expenditure; possibility of

wholesale disorganisation by enemies, disaffected persons, or accident to supply; electrolysis, interference with communication circuits; possibility of fire after derailment; risk of shock.

The economic investigation showed that limited main-line schemes of electrification were not worth while. Only full and complete electrification was deemed to show sufficient financial advantage.

ESTIMATED CAPITAL COST OF ELECTRIFICATION OF ALL STANDARD GAUGE STEAM-OPERATED RAILWAYS IN GREAT BRITAIN.

Item.	£ millions.
Track equipment	129·7
Auxiliary power cable	13·5
Alterations to Way and Works. . .	13·7
Electric tractors	136·5
Running sheds, shops, stores, etc. . .	4·5
Spare parts	5·5
Auxiliary power supplies . . .	2·25
Interest during construction . . .	12·5
Engineering expenses	5 0
Total gross cost	£323·15
Total of credit items	62·28
Net capital cost	£260·87
Additional expenditure on generating plant, transmission lines and substations, to be incurred by the C.E.B. and other authorised undertakers, approximately, millions.	£80

The total mileage to be equipped is 36,000 track miles of running line and 15,500 miles of sidings. Average rates of £2,500 and £1,800 per mile were respectively taken for track equipment. About 10,400 electric locomotives and 4,800 three- or four-coach multiple-unit equipments were allowed for.

ESTIMATE OF COMPARATIVE WORKING COSTS, STEAM AND ELECTRIC.
(Including only items affected by electrification.)

	£ millions.		
	Steam.	Electric.	Saving.
Locomotive fuel or energy	12·31	11·28	1·03
Locomotive wages	20·93	10·78	10·15
Repairs to tractors	10·82	4·66	6·16
Water for locomotives	0·88	—	0·88
Stores, etc.	0·91	0·45	0·46
Lubrication	0·29	0·10	0·19
Maintenance of sheds and shops . . .	0·44	0·18	0·26
Guards' wages	4·30	3·65	0·65
Cleansing of vehicles	0·93	0·70	0·23
Insurance, pensions, etc.	0·79	0·40	0·39
Savings on maintenance of train lighting .	—	—	0·51
Savings on auxiliary power, etc. . . .	—	—	0·84
Totals .	52·60	32·20	21·75
Additional costs of electrification :—			
Maintenance and renewals of track		3·38	
Maintenance and operation of substations		1·05	
Increase in depreciation of electric tractors compared with steam		0·02	
		4·45	
Net saving due to electrification			17·30
Revenue on haulage of power station coal			0·25
Total .			£17·55

The saving represents 6·7 per cent. on the capital cost of £261 millions. The item for energy is the total at 50 Wh. per ton-mile of 114,000 million trailing ton-miles at 0·475*d*. per kWh.

The return is moderate, but it would be augmented by the revenue from suburban railways, which would in practice form the initial part of any scheme of large-scale conversion.

Electric Locomotives.

The first electric locomotives were developed directly from the street tramway, and had bogie trucks provided with nose-suspended motors. Progress in America has in general avoided mechanisms involving reciprocating motion, and the nose-suspension and the quill drives have been widely applied to passenger, freight and shunting locomotives. On the Continent of Europe there was a widespread tendency at first to apply the steam locomotive side-rod mechanism to the electric locomotive. Many difficulties were encountered and generally overcome, but the continuous torque of the electric motor was fundamentally unsuited to the reciprocating nature of the drive, whilst the effect of steam cushioning in the steam locomotive cylinders had no counterpart in the electric drive. Subsequent designs introduced springs and similar elastic members to provide for this, and to obviate the troublesome oscillatory phenomena in side-rod drives so damaging to the bearings. The present tendency in Europe is to return to individual-axle drives with nose-suspended motors or with some form of special gearing enabling the motors to be entirely spring-borne. Among these are the Westinghouse (geared-quill, with spring connection between gear wheel and driving wheel) and the Buchli (link connection) drives, and a later form of bevel drive in which the motors have vertical shafts. Individual-axle drives allow greater freedom in the running-gear design and are adaptable to most classes of service, tending to simplification of spare parts and maintenance. The locomotives built in Great Britain have been mostly fitted with nose-suspension drives. Various types of contactor control are used.

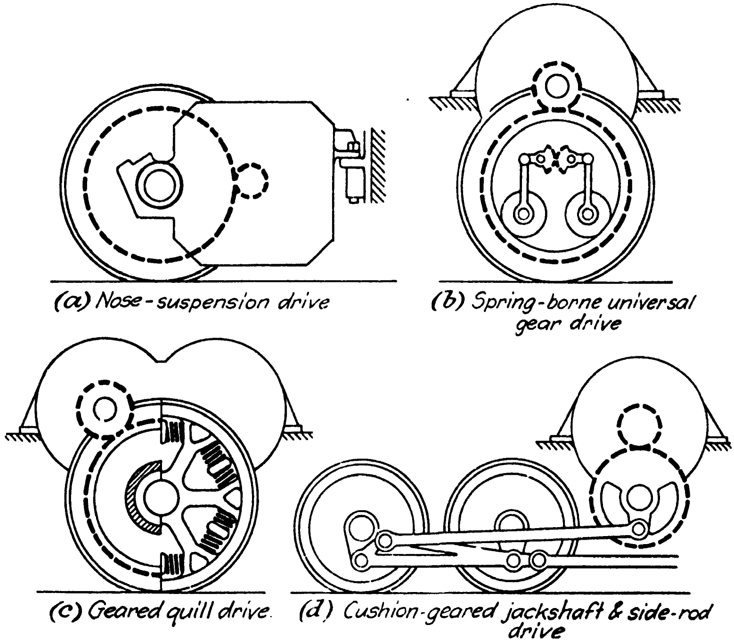

FIG. 1.—Typical Driving Mechanisms for Electric Locomotives.

Fig. 1 shows diagrammatically the arrangement of the more usual forms of individual-axle drive. (*a*) The nose-suspension (or tram) drive is extensively used for all classes of locomotives, as well as for all multiple-unit rolling stock and most tramway cars. The weight of the motor is divided between the frame and the driving axle, the former by means of a 'nose' (sometimes spring-loaded) and the latter by means of an outboard bearing. The weight is low and almost entirely non-spring borne, the gauge and the wheel diameter limit the motor output, and the motor is badly placed for maintenance; nevertheless the simplicity of the construction has led to its wide adoption even for some express locomotives. Improvements in output and design are continually being made. (*b*) The Buchli drive is typical of several devised to avoid the restrictions imposed by the nose-suspension drive particularly for high speeds. The motor is

completely spring-borne, together with its pinion and gear wheel. The essential elastic connection between the gear and driving wheels is obtained by means of a link mechanism. (*c*) The Westinghouse drive employs twin motors in a common housing, the two pinions engaging with a common gear wheel. The latter is within the driving wheels, and is carried on a 'quill' or hollow shaft, through which the driving axle is carried. The twin motors, pinion, gear and quill are all spring-borne. The drive is transmitted from the quill by means of a circular fork projection, which is attached to the ends of short, helical springs, the other ends of which are pinned to the driving-wheel spokes. (*d*) The jack-shaft drive with geared motor is still common. The gear-driven jack-shaft, carried on the frame, is coupled to the driving wheels by means of short side-rods. The gear wheel is provided with elastic connection between the toothed rim and the hub.

ELECTRIC TRACTION ON SUBURBAN RAILWAYS.

Much of the electrification work hitherto has been in connection with suburban railways around large cities like London, New York, and Paris. Such lines form a most promising field for the utilisation of electric power, as they usually carry heavy and dense traffic, a condition

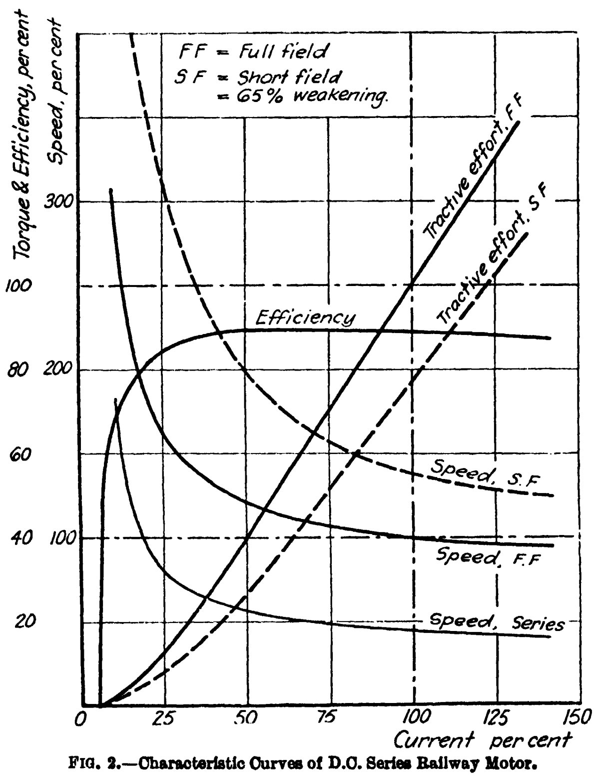

FIG. 2.—Characteristic Curves of D.C. Series Railway Motor.

very favourable to electric traction. Of course, on tube and similar underground railways anything but electric haulage in the light of modern requirements is unthinkable. For suburban and urban traffic the single-phase system is seldom considered unless some ulterior condition makes this advisable: in practically all cases the direct-current system is used, at voltages of 600 to 1,500, with third-rail collection. It is standard practice to generate three-phase energy

in the power stations, transforming to suitable pressures for transmission to the substations. Rotary converters have been widely used for A.C.-D.C. conversion, but are now being ousted by the mercury arc rectifier, often with grid control, and remotely controlled from a Central Supervisory Control Room.

For heavy electric traction on surburban lines using 600 volts and over, the tramway type of controller is replaced by 'multiple unit control,' consisting of small 'master-controllers' operating separate switches for establishing motor combinations and for cutting out resistances. Multicore cables between adjacent coaches enable any master controller to control the whole train. The great advantages of multiple unit control lie in the flexibility of train length, the provision of a motor capacity always proportioned to the load (for the maintenance of schedules under all load conditions), and the efficient utilisation of the available adhesion (for rapid acceleration).

For leading the current to the moving trains a third rail is provided for each track, the motor coaches being equipped with cast-iron contact shoes for current collection. In England, where the Board of Trade regulations require a very small drop in the earth return, it has been necessary on occasion to add an insulated fourth rail in order to avoid the drop in the running rails which elsewhere serve as a return. This may often be of considerable advantage in cases where track-circuiting is required for automatic train-signalling.

On most city and suburban electrified railways dealing with heavy traffic, automatic signalling is employed; indeed for many of the congested services it is essential. Where a fourth-rail return is used, the running rails are used to convey direct or alternating current for the track circuits. Where, however, the running rails carry the power current, alternating current alone may be employed for signalling. For automatic signalling the reader should consult Section XXXII, Part IV.

For lines with infrequent service the efficiency of the substations is comparatively low, while the running costs are high in consequence of the fact that the numerous substations must be capable of supplying the peak load. The transmission losses in the conductor rails are also considerable. In such cases automatic or semi-automatic substations, with higher line voltages, may be used.

Low-pressure traction motors are now standardised, as also is their control. Series-parallel arrangement of the motors of each bogie (of the motor coach) is universal practice. In special cases field-shunting is used, as, for instance, when trains make occasional runs to outlying districts.

Fig. 2 shows typical characteristic curves of a D.C. railway motor. Series-parallel control gives two economical speeds. By field weakening (usually by tappings) additional economical speeds can be obtained; the figures show the speed/current and torque/current characteristics for 50 per cent. field weakening.

Train units are usually made up of motor-coaches and trailer coaches. A common arrangement is one motor-coach semi-permanently coupled to one or more trailers. In such a case the end trailer is a driver trailer, and is provided with a driver's cabin with a master controller and the necessary apparatus for reversed operation. One, two, three, or more units may be coupled and controlled by one driver to form a train of any desired size according to traffic needs, and the same schedule may be maintained regardless of the train-length, since the power/weight ratio remains constant.

The following are brief details of some important suburban electrification systems:

Important Surburban Railway Electrification (All D.C.).

London.—(600 volts third or third and fourth rail.) Comprises a large network of surface and sub-surface and deep-level tubes; also main line termini. The Southern Region of British Railways has the largest suburban electrification in the world.

Manchester.—Bury line: 1,200 volts, third rail. Altrincham line: 1,500 volts, overhead conductor.

Paris.—(600 to 1,500 volts, third rail and overhead conductor.) City and suburban lines.

Berlin.—(750 volts, third rail.) Sub-surface and overhead railways.

New York.—(600 volts, third rail.) Tunnel, surface and elevated lines.

Melbourne and Sydney.—(1,500 volts, overhead line.) Suburban.

EQUIPMENT FOR MOTOR-COACH TRAINS.

Camshaft Control for Direct-Current Motors.

The main contactors in this system are operated by means of a camshaft under the control of a small pilot motor. The equipment includes the following essential features:—

(a) A camshaft composed of steel cams mounted on a mica-insulated steel shaft of square section. On rotating this shaft the cams close and open the main contactors in a definite predetermined sequence.

(b) A small pilot motor which drives the camshaft through suitable reduction gearing. This motor is controlled by the master controller and the position regulator, the latter being mounted on an extension to the camshaft itself.

(c) Two solenoid or cam-operated line breakers arranged in series to break the main circuit.

(d) All necessary auxiliary control gear, such as an electrically operated reverse, motor cut-out switch, overload relay, etc.

The closing of each contactor is effected against a strong spring by the rotation of the camshaft, so that the action is positive and the pressure constant, irrespective of the line voltage. Furthermore, the camshaft gives a definite mechanical interlock, controlling the sequence of operation of the contactors, and obviates the necessity for fitting electric interlocks. Since all current is broken on the line breakers, and the sequence of operation of all contactors is definite, the resistance contactors do not break any current, and are therefore not fitted with blowouts. The two contactors which deal with the operation of transition are called upon to break relatively small currents, and are fitted with blowouts. This arrangement effects a considerable reduction in the number of current-breaking contactors.

Electro-magnetic and Electro-pneumatic Control.

In the electro-magnetic system the contactors for effecting the motor and rheostat combinations are controlled electrically from the master controller by means of magnet coils energised from the line (if the voltage be below 600 volts), or from a low (*e.g.* 32-volt) circuit, comprising a dynamotor or motor-generator or battery. Interlocking is effected by auxiliary contacts on each contactor. After being closed the control of the contactor is transfered from a 'closing' to a 'holding' coil demanding less energy. Each contactor may require several pairs of interlock contacts, according to the system or design adopted. The direction of rotation of the motors is controlled by a separate reverser. The electro-pneumatic system embodies electrically-controlled needle valves for compressed air cylinders operating the contactors mechanically. Later developments involve the use of individually-operated pneumatic contactors effecting the motor combinations, the rheostats being cut out by means of a drum-type controller operated by a differential air motor. These systems are lighter, cheaper, and less complicated for automatic control. Pneumatic control has the advantage that the control voltage is low; a large mechanical force can be developed by a small and light compressed-air cylinder, and a spring relied upon for opening the contacts; the mechanical operations are performed independently of the line voltage, avoiding the tendency of electro-magnetic contactors (fed from the line voltage) to vibrate and weld together when the line voltage falls to a low value. The control is frequently automatic, the contactors being energised in sequence according to the operation of a current-limit relay.

The following details refer to typical motor-coach equipments with multiple unit control:

Details.	North-Eastern Region British Rlys.	London Transport Executive.	Bombay–Baroda Cent. Ind. Rly.	German State Rlys.
Motors per coach.	2	2	2	2
Line voltage	600	600	1,500	15,000 (1 ph.)
Motor h.p. (1 hr.)	145	235	275	330

* With automatic acceleration.

Metadyne Control.

A new method of traction motor control due to Pestarini and developed by Metropolitan-Vickers is the so-called *Metadyne* system,* employing a special rotating convertor interposed between the traction motors and the D.C. supply. This metadyne machine converts power at constant voltage, as obtained from the D.C. supply, to power at constant current as required by the traction motors. The advantage of the metadyne system lies in the maintenance of constant current in the motors throughout the accelerating period, so that the maximum possible use is

*** A good account of this novel system is given in the *Metropolitan-Vickers Gazette*, November 1938.**

made of the available adhesion. With standard rheostatic control the average torque during acceleration only reaches from 80 to 85 per cent. of the torque limit of adhesion. The metadyne system also dispenses with the use of heavy starting resistances and their associated control gear. Furthermore the equipment is readily adapted for regeneration and can be arranged to produce a retarding effort down to zero speed if required.

Control of Alternating-Current Traction Motors.

The majority of single-phase motors are of the neutralised series type, and the basic method of speed control is the variation of the motor terminal voltage. Since a main transformer is invariably used, the methods available are: (*a*) Transformer tappings, controlled by contactor gear. To avoid interrupting the motor supply, a second tapping must be closed before the first is opened. The section of the transformer between the two tappings is protected by an auxiliary choking or 'preventive' coil. (*b*) Transformer tappings with sliding contact switch, driven by a screwed shaft operated by a control motor from the master controller. (*c*) Transformer tappings with induction regulator. This allows of fewer tappings, but owing to its greater complication has found only a restricted application. The advantage is the absence of jerky control.

Polyphase induction motors with slip-ring rotors are controlled by means of rotor rheostats (usually of the liquid type) combined with cascade connection. Motors with cage rotors are started with reduced voltage (by auto-transformer), combined with pole-changing connections.

Direct-Current Traction Motors.

Direct-Current Series-Wound Traction Motors.

British Standard Specification for Traction Motors and Associated Rotating Electrical Machines. No. 173—1941 (Abstract).

Types of enclosure are: (1) Totally enclosed, there being no air circulation between inside and outside of case; (2) ventilated, having free circulation between inside and outside of case; (3) self-ventilated, having air-fan; and (4) forced ventilated (draught) type, in which air is forced through by external means.

Classes of Rating.—If excitation can be varied independently of armature current, the rating shall be associated with a stated condition of excitation and corresponding speed. (1) Nominal one-hour rating to be the h.p. output at motor shaft, at the rated voltage and constant current, which the motor can produce for one hour, the limit of temperature-rise measured by resistance being 100° C. for Class A and 120° C. for Class B insulation, and 90° C. on commutator. (2) Continuous rating is defined as the output at the motor shaft after working continuously with covers, etc., arranged as in service, the temperature-rise measured by thermometer not to exceed 85° C. on commutator, and on insulated windings measured by resistance 85° C. and 120° C. for Class A and Class B insulation respectively. Class A includes enamelled wire and cotton, silk, paper, etc., when impregnated or oil immersed. Class B, asbestos and built-up and cemented mica insulation. In ventilated motors, the rating shall be the output at rated motor voltage; in totally enclosed motors the output at half the rated motor voltage.

The motor must be run in both directions with fixed brush position under specified test conditions. The statement of efficiency to be made on result of direct measurement corrected to 75° C. and not on the basis of addition of losses. The new machine must withstand, at the conclusion of the one-hour test, an alternating voltage of 1,500 plus twice the line voltage applied for one minute, between the windings and frame. The insulation resistance in megohms, when the high-voltage test is applied, to be not less than line volts/(1,000 + Rated B.H.P.). The specification lays down methods of carrying out performance and voltage tests, and the information as regards type, voltage, speeds, weight, and characteristics, to be supplied by the maker.

SECTION XXXII

PART IV

RAILWAY SIGNALLING.

(By O. S. Nock, B.Sc., A.M.I.C.E., M.I.Mech.E., M.I.R.S.E.)

Rapid and far-reaching developments in this branch of railway engineering have taken place in recent years. The safety of train operation, once practically the sole consideration, has now been brought to such a degree as to be taken for granted in the study of any new signalling scheme. While safety in operation remains the basic and essential factor, signalling is now recognised as one of the principal aids towards the maintenance of a frequent service of fast trains in congested areas, and in all localities as a potent instrument for securing the maximum utilisation from any stretch of line. In Great Britain the signalling is still mechanically controlled and operated, except in a relatively few districts where the traffic is heavy; but in what may be termed mechanical territory the use of electrical apparatus to supplement existing plant is being greatly increased. Large terminal stations, and important centres of traffic have been equipped with complete installations of all-electric, or electro-pneumatic signalling, and it is in connection with these plants that rapid developments were taking place until the outbreak of war in 1939, when the likelihood of damage from aerial attack made it necessary to postpone the completion of certain schemes of signalling concentration, and to defer consideration of others.

It is now generally recognised that if control of train movements in a busy and complicated area is concentrated in one signal box better regulation of traffic is likely to be obtained than if a district superintendent has to co-ordinate the work of, maybe, five or six signal boxes, each of which is concerned with one particular section of the working. But while the principle of concentrating control in a single box can be readily accepted, very great care must be taken to relieve the signalmen, or traffic controllers, of all but the most essential duties. Manual work, and routine tasks, must be reduced to the very minimum so that the men are free to devote their time to the regulation of traffic movements. It is to this end that many recent developments in railway signalling practice have been directed. But, although the means that have lately been employed are in many cases novel, all, without exception, continue to be based upon the fundamental principles finally established some seventy years ago: the first of these—a principle of operation—is the use of the Block System; the second—a principle of engineering design—is that, in the event of any failure of mechanism or power supply, the signals immediately concerned shall display the danger indication.

THE BLOCK SYSTEM AND SIGNAL ASPECTS.

The principle of the block system is illustrated in fig. 1. A line of railway is divided into a number of block sections, and the dividing points between adjacent blocks, for example, the locations A, B and C, are known as block posts. The system is simply that only one train is permitted to be in a block at any one time. The diagram fig. 1 (*a*) relates to one direction of running, and it will be noted that there is a signal at the entrance to each block; such are termed 'absolute stop' signals, and must on no account be passed if displaying the danger indication. To permit of high speed running it is necessary to give the driver of a train ample warning that he is approaching an 'absolute stop' signal; accordingly what are termed 'distant' signals are installed, and these are so sited that there is full braking distance for the fastest trains between the 'distant' and the 'stop' signal. A 'distant' signal can be passed when it is displaying the warning indication, but a driver so doing must take immediate steps to reduce speed so as to be able to bring his train to a stand at the 'stop' signal. Semaphore 'distant' signals are distinguished from 'absolute stop' signals by having the blade painted yellow with a black chevron, instead of red with a white stripe; the ends of 'distant' signal arms are fishtailed.

To assist in the handling of traffic block posts are equipped with two or more 'stop' signals. The first one encountered by a train arriving at a block post is usually the 'home,' and the signalman is not permitted to accept a train from the preceding signal box unless the line is clear, not

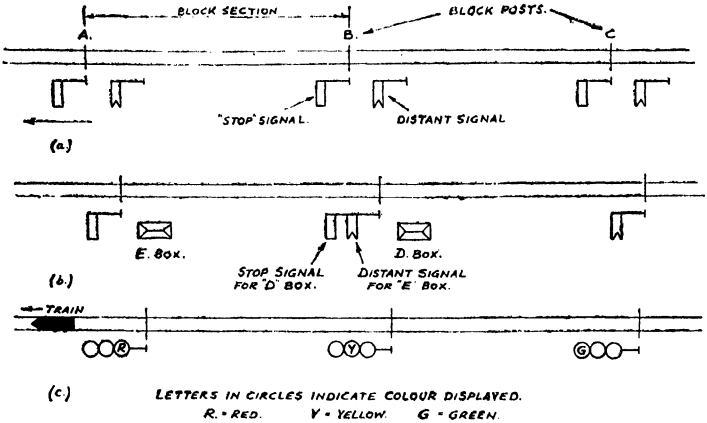

FIG. 1.—Principle of the Block System.

merely up to the home signal but for a distance of 440 yds. beyond it in addition. This rule affords a safeguard should an arriving train overrun the home signal. Supposing the block section ahead is occupied, if the block post in question is equipped with a second 'stop' signal, termed the starting signal, a train could be allowed to draw forward to that signal and await the clearance of the block ahead. If the starting signal is so located that the tail end of the train is more than 440 yds. from the 'home' signal, a second train can be accepted from the preceding block post before the first train has moved away, and traffic can thus be kept moving more freely. In larger and more complicated layouts there are outer and inner 'home' signals, followed by a 'starter,' and lastly an 'advanced starter'—four 'stop' signals in all. The 'distant' signal for the particular block post cannot be lowered unless all the 'stop' signals are in the clear position.

At larger stations equipped with mechanical signalling, there are usually two signal boxes, one controlling each end of the layout. In such cases, or any similar locations where two block posts are close together, it is often convenient to mount the 'distant' signal for the second box on the same mast as one of the 'stop' signals for the first, as shown in fig. 1 (*b*). The composite signal shown at D can then display any one of three indications: both arms 'on,' signifying stop; the upper arm 'off' and the lower arm 'on,' signifying 'caution'; both arms 'off,' signifying 'clear.' These indications, together with the corresponding lights for night working, are shown in fig. 2. The concurrent use, in different parts of Great Britain, of semaphore signals working

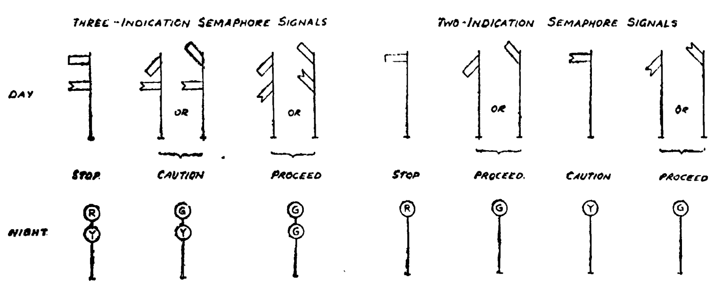

FIG. 2.—Semaphore Signal Aspects.

in the upper and the lower quadrant will be mentioned later. With semaphore signals having only two positions, 'on' and 'off,' it is necessary to use two arms in order to provide three indications from a single assembly, as shown in fig. 2; the day colour light signal, however, affords very simple means of providing three indications, each one of which consists of but one light—

red, yellow, green. Fig. 1 (c) shows the application of multi-aspect colour light signals to block working, where each of the signals constitutes, in effect, a block post, and each can display three indications. With signals arranged as in fig. 1 (c) the spacing requires to be designed to provide a uniform headway between succeeding trains; this problem, and the use of four-aspect colour light signals was discussed in *The Engineer*, December 8, 1939.

On routes where a few express passenger trains are run at average speeds considerably higher than that of the remaining passenger services, such as the 'Cheltenham Flyer' and the 'Bristolian' of the former G.W.R., and the streamlined trains of the former L.N.E.R., special attention has to be paid to the signalling arrangements to provide adequate braking distance before a signal displaying the danger indication is reached. These trains run at average speeds of over 80 m.p.h. for an hour on end, or more. In multi-aspect colour light territory the use of four indication signals provided a satisfactory solution, but over the long mileages equipped with manual block signalling the L.N.E.R. treated each individual location on its merits. In many places outer distant signals were installed. These were of the colour light type and displayed a 'double-yellow' when the ordinary semaphore distant was in the 'caution' position. Ordinary traffic could afford to ignore the outer distant signal and maintain full speed until the indication displayed by the inner distant was seen. On the G.W.R. special block regulations were in force for signalling the high speed trains, whereby a succession of block sections were required to be clear before the signals preceding such a group of sections was pulled to the clear position.

Apparatus for Block Working.

In the operation of the block system communication between adjacent signal boxes plays a very important part. Before the starting signal at one box can be 'cleared,' and a train allowed to proceed to the next box, messages must be exchanged between the two signalmen concerned to ascertain that the line is clear. These messages are conveyed through the use of a standardised code of bell signals. Thirty-two different messages are included in the Railway Clearing House standard code, and in addition to messages required for the ordinary working of traffic, describing the various classes of trains, the code includes messages for use in a variety of emergencies, such as a train becoming divided, runaway vehicles, obstruction on the line, and a call for fog signalmen. The bells, plungers or tapper keys are usually incorporated in the Block Instruments, which indicate the occupancy or otherwise of a particular block section. With manual block working, such as discussed so far, the line is normally closed, and requires to be opened for the passage of a train. A variety of block instruments is in use in Great Britain; one of the commonest forms used on double lines is the three-position, single needle instrument, and in this the needle normally points to the position LINE BLOCKED. These instruments are operated in pairs, one at each end of a block section. The signalman at the entering end, after giving the 'call attention' signal on the bell code, sends the code 'Is line clear for . . .'; the signalman at the leaving end switches his instrument so that the needle indicator points to LINE CLEAR, and this indication is repeated in the signal box at the entering end of the section. When the train passes the starting signal at the entering end the signalman there sends TRAIN ENTERING SECTION on the bell code; the signalman at the leaving end switches his instrument so that the needle points to the third position TRAIN ON LINE and this indication is repeated in the signal box at the entering end. On a double line of railway equipped with separate block instruments for each line working in the manner described, three line wires are required between adjacent signal boxes.

The above is a necessarily abbreviated description of the procedure taken prior to the lowering of the signals themselves, but it should be emphasised that the responsibility for correct operation of the instruments rests upon the individual signalman, just as the responsibility for correct interpretation of the signals rests upon the locomotive drivers. On some lines certain electrical apparatus has been introduced to safeguard against irregularities in block working by the signalmen, and where mechanical signalling is concerned the system of 'Lock and Block' has been widely used. In applying this system to meet particular requirements the practice of pre-grouping railway companies differed somewhat in detail; but the broad principle is the same, namely, that the starting signal for entering a block section is so interlocked with the block instrument that the signal lever cannot be pulled unless the signalman at the leaving end of the section has accepted the train. Once this has been done the accepting signalman cannot again give LINE CLEAR, and so accept a second train until the first one has arrived and cleared the controlling track circuit, or electric treadle, and the signals have been put to danger behind it. This electric inter-locking thus provides a positive safeguard against irregularities in the block working.

On single lines of railway the observance of correct block working is of vital importance, and on entering a single line block section the driver is handed a 'token,' without which he is not permitted to proceed, even though the starting signal might have been pulled to the 'clear' position. This 'token,' which on some railways takes the form of a steel tablet, and on others the form of a staff, is a positive assurance to the driver that the section is clear. The block instruments for single line working are of special construction and a number of tokens for a particular section are kept in the instruments at each end. Before a token can be extracted co-operative action between the signalmen at each end of the section is required, and once a token is 'out' both instruments are electrically locked until that token is inserted again in one or other of the instruments. This electric interlocking between the instruments prevents more than one token being out at a time, and thus the possession of a token by a driver is at the same time an assurance, as well as his authority to proceed. For ease in handling, the token is carried in a leather pouch,

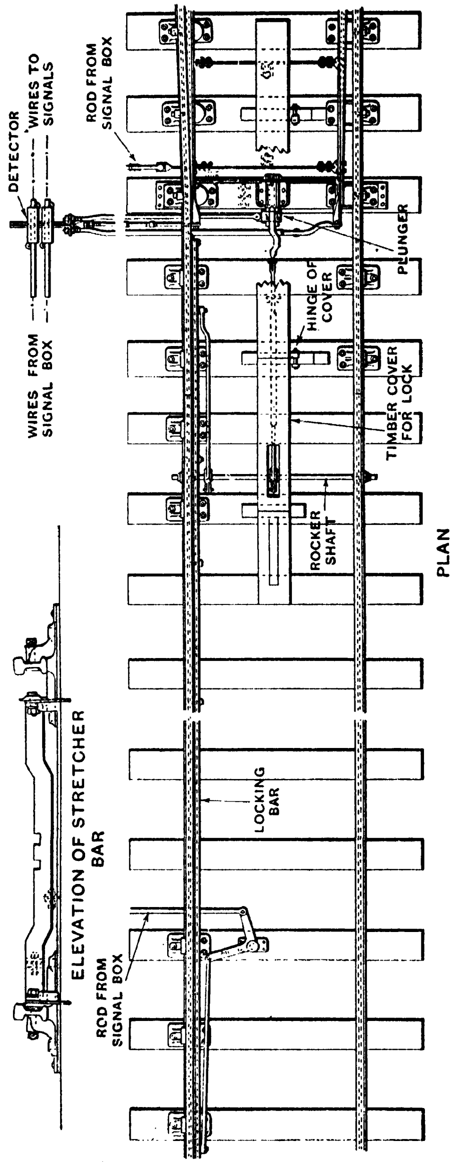

FIG. 3.—Standard Facing Point Layout.

fitted with a large diameter hoop; with this attachment the token can be collected from a lineside standard without the necessity for stopping. On lines where express services are operated over single-line sections mechanical token-exchanging apparatus is used, whereby the token for one section is released and that for the next section collected at speeds up to 60 m.p.h. In the ordinary way 15 m.p.h. is about the limit for hand exchanging of tokens.

Apparatus for Mechanical Signalling.

(a) *Signals.*—Two forms of semaphore signal are in use on the British Railways. The older form, working in the lower quadrant, is standard on the WESTERN REGION; but, while still widely used elsewhere it was in course of replacement by the newer form operating in the upper quadrant, on the former L.M.S.R., the L.N.E.R. and the S.R. Under nationalisation a standard will no doubt be decided upon, in due course, for the entire British railway system. While the indications displayed by these two forms is different the fundamental principle of operation is the same. In both the arm is normally in the horizontal position, denoting danger, and the wire leading from the signal to the cabin requires to be pulled in order to move the arm to the clear position. In the case of upper quadrant signals the weight of the blade itself restores the arm to the danger position when the wire is released; with lower quadrant signals the spectacle carrying the glasses is designed to provide a counter-weight so as to restore the arm to the horizontal position. The actuating wire in the case of a lower-quadrant signal is attached to a reversing lever, which translates the pull in the wire to an upward thrust in the signal down-rod, so pushing the arm into the familiar clear position, pointing downwards at about 45°. The wire between the cabin and the signal post is kept taut by the balance weight at the foot of the post.

The difference between 'absolute stop,' and 'distant' signals, both in function and appearance, has already been discussed. At diverging junctions it is the usual practice to instal a separate 'stop' signal for each route. The arms are grouped together on short posts, or 'dolls,' of varying heights, the tallest posts relating to the most important routes. At large centres of traffic the number of doll posts is such as to require structures of considerable size for their support, particularly where a number of running lines has to be spanned. In addition to the main running signals, the working of which has already been described, shorter arms with spectacle glasses of reduced size are used for the regulation of shunting movements, and, at large stations, for instructing drivers to draw ahead cautiously past a 'stop' signal at danger. These special arrangements are made to facilitate traffic working, as, for example, where a driver is instructed to draw into a long platform road, part of which is already occupied by another train.

(b) *Point Operation.*—The points at a diverging junction are termed 'facing,' and on passenger lines the blade on the closed switch side must be bolted against the stock rail before the signals can be lowered for the passage of a train. Fig. 3 illustrates a typical facing point layout. There are two rods from the signal box, one to operate the bolt, and the other to throw the switches themselves. The bolt lever stands normally pulled over in the cabin, so that the plunger is inserted and the points are locked. Before the points can be thrown the bolt lever must be restored to normal; this action moves the rod connected to the bell crank on the third sleeper from the left in fig. 3, and through the agency of the locking bar oscillates the rocker shaft and withdraws the plunger from one of the notches in the lock stretcher bar. The points can then be thrown, after which the bolt lever is pulled again and the plunger enters the second notch in the lock stretcher bar.

The locking bar is a member usually between 40 and 50 ft. long, of angle or tee section, and supported on a series of rocking arms. The level of the bar is normally just below the flanges of the wheels and in that position the arms are lying at an angle of approximately 45° to the vertical. As shown in fig. 3 the plunger is out, and the arms are towards the left. When the bolt lever is pulled the movement of the bell crank pulls the bar from the left to the right and the rocking arms move through an angle of 90°. In so doing the bar itself is moved from flange level up to rail level in passing from one extreme position to the other. This feature provides an important safeguard in that the bar cannot be raised when a vehicle is standing on, or a train is passing over, the particular piece of track. As the bar cannot be moved a signalman is prevented from inadvertently throwing the points under a train. The position of both switch blades, and the position of the locking plunger must be proved correct by the detector before the signal wires can be pulled. Fig. 3 shows two wires for signals; the lock notches in the detector blades are so arranged that only the wire to the signal relating to the right hand road is freed in the position shown. At converging junctions the points are termed 'trailing,' and there is no need for the switch blades to be locked.

(c) *Signal Box Equipment.*—The cross-section of a typical signal box interior is shown in fig. 4. The levers for point and signal operation are grouped in a frame supported on the cabin structure. Connections for both points and signals are shown. The points are operated direct from rodding coupled to the lever tail, whereas the signals may be operated by wire attached directly to the lever tail, or through the agency of a gain-stroke wheel as illustrated. This latter arrangement is used for signals that are at a very long distance from the box. In such cases a wire regulator is used to compensate for expansion or contraction of the wire due to atmospheric conditions. For signals located at shorter distances from the box a turnbuckle in the wire connection is usually all that is necessary for compensation. The necessary adjustments are made, as required, by the linesman. In the case of point operation automatic compensators are fitted in all lengths of rodding exceeding about 120 ft.

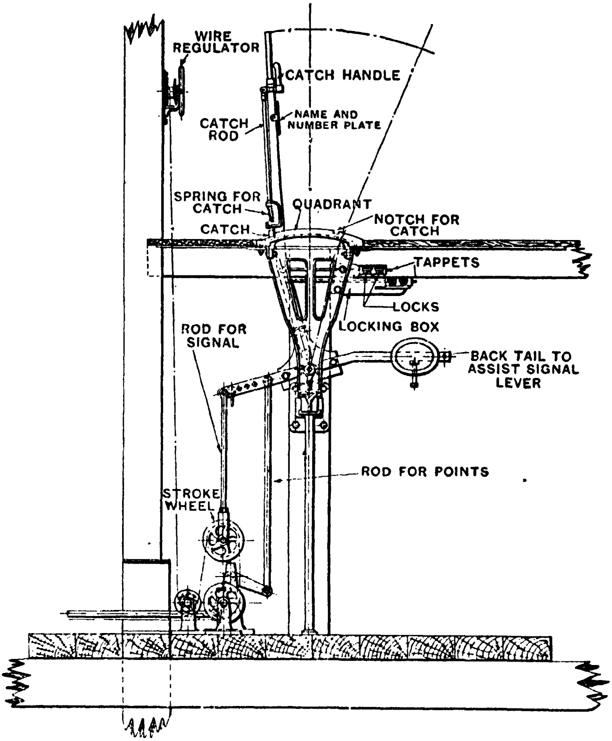

FIG. 4.—Interior of Signal Box.

To avoid any chance of signalmen pulling wrong signal levers, or setting points so that trains following the routes so established would collide, it is necessary for all signal and point levers to

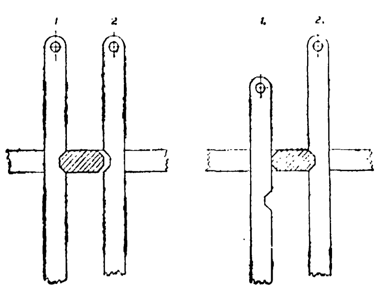

FIG. 5.—Principles of Tappet Locking.

be interlocked with one another. The locking plungers, or tappets, which are attached direct to the levers in the apparatus shown in fig. 4, engage with locking dogs sliding in troughs running the length of the lever frame. The tappets are notched to suit the bevelled ends of the locking dogs, so that when a lever is pulled any dog which is engaged with the particular tappet is forced out of engagement and slides along the longitudinal trough, and its opposite end maybe engages with the tappet of another lever. The principle of tappet locking is illustrated in fig. 5. In designing an interlocking mechanism all the traffic movements in a station or junction must be considered, and a chart prepared showing the conditions for every signal and point lever in the frame. With a junction signal, for example, a study of the layout will show that before this can be pulled to the clear position certain points must be lying in their normal position, and others in the reverse; all signals relating to conflicting routes must be locked at danger by the pulling of this junction signal lever. From the table of locking thus prepared the designer can work out the interlocking mechanism.

Application of Power to Railway Signalling.

(*a*) *Electrical Apparatus in Mechanical Territory.*—In the earliest British installations of power signalling, completed upwards of fifty years ago, power was used solely for the operation of points and semaphore signals. By thus relieving the signalmen of heavy manual work more units could be controlled by one man, and lever operation was quicker. The systems then introduced, and still used to-day, fall into two broad classes: one in which the power is supplied by electric motors and the other using compressed-air cylinders with electrically-controlled valves. The early installations provided no additional safeguards in operation, since no track circuiting was included. Installed at large centres of traffic, such as Bolton, Newcastle, Glasgow Central (Caledonian Railway) and elsewhere, these early plants were 'all-power'; while modern developments in this direction have been rapid, perhaps even more interesting has been the steady infiltration of power signalling practice into what would normally be regarded still as manual signalling territory. To-day, modern signalling practice in Great Britain is becoming largely a blend of mechanical and electrical methods, except where the density of traffic warrants the use of 'all-power' plants—either electro-pneumatic, or all-electric.

To meet the needs of high speed traffic the tendency is for 'distant' signals to be placed farther from the cabin. In the Western Region it is now usual for semaphore 'distants' to be operated by electric motors; elsewhere, in locations where 'distants' have been re-sited, opportunity has been taken to replace the semaphores by day colour light signals. Thus not only has the heavy pull always associated with wire-worked 'distant' signals been eliminated, but in most cases the sighting has been greatly improved from the locomotive driver's point of view. Improvements in the operation of points have developed concurrently. The limit for rod-worked points is 350 yds. from the signal box, and in earlier days it was usual to instal separate cabins for operating the outlying crossovers and siding connections. In localities where traffic conditions do not justify full power working, the remote control of outlying points is now conveniently arranged by using electric point motors, either battery-fed or supplied at 110 volt D.C. by hand generator. Such outlying points can thus be operated from the main signal box in the district, affording that unity of control which is desirable for smooth regulation of traffic working. Remote control systems for point operation proved extremely valuable during the war of 1939–45, when additional facilities were required on many lines carrying war traffic to the Channel ports. Some typical examples of their application were described in *The Engineer* for July 3, 1942.

Remotely controlled points, if not actually out of sight of the signal box, are far beyond the distance at which the man can observe the passage of trains, and track circuiting is essential to hold the points locked while vehicles are passing. There is a tendency to associate track circuiting primarily with all-power installations, and sections of purely automatic signalling—two applications which will be discussed in greater detail later. But its value in manual territory is also very great, for detecting the presence of trains or vehicles on sections of line not easily visible from the cabin concerned, and in providing track circuit locking for points. One of the most extensive early applications of track circuiting in conjunction with mechanicalsignalling was made on the former Midland Railway (now the London Midland Region) after the disaster near Hawes Junction in 1910, caused at a very busy time by a signalman forgetting the whereabouts of two light engines, and lowering the signals for an express to pass over the very track where the two engines were standing. (See *The Engineer*, June 12, 1942.) On the former S.R. the electrification of the main lines from London to the south coast was accompanied by some extensive resignalling works, wherein many of the larger intermediate and terminal stations have been equipped with complete track circuiting, while mechanical operation of the signals and points has been retained. Bognor Regis provides a typical example. The traffic, though considerable, did not warrant the higher cost of complete power working with day colour light signals, but with track-circuiting throughout the station yard and its approaches all the operating safeguards of a modern all-power interlocking are provided. The full-size levers for mechanical operation of the semaphore signals and points are equipped with electric locks, so that points cannot be moved if a train is standing upon, or passing over them, neither can signals be cleared if the track ahead is occupied by another train.

(*b*) *Track Circuiting.*—With examples such as the foregoing in mind, together with less extensive applications in mechanical territory, and its absolute necessity in complete power schemes,

the track circuit may well be called the basis of all modern signalling. In fact, hardly any signalling scheme to-day, even in mechanical territory, is installed without the inclusion of some track circuits. The principle of operation is illustrated in fig. 6. The section of line forming the track circuit is insulated at the rail joints from the adjoining sections, and current is fed to the running rails. If the section is clear, the relay is energised, but if a train or vehicle is standing, or passing, current from the battery takes the path of least resistance, through the wheels and axles, and the relay is shunted. The diagram in fig. 6 shows a track circuit in its simplest form, fed by direct current, though from a study of it some of the major considerations in track circuit design will be appreciated.

Conditions experienced in the performance of track circuits are liable to wide variation. When a train, or vehicle, is standing on a track circuit, current flows through a series of parallel paths from rail to rail; the combined resistance of these paths varies considerably, being theoretically

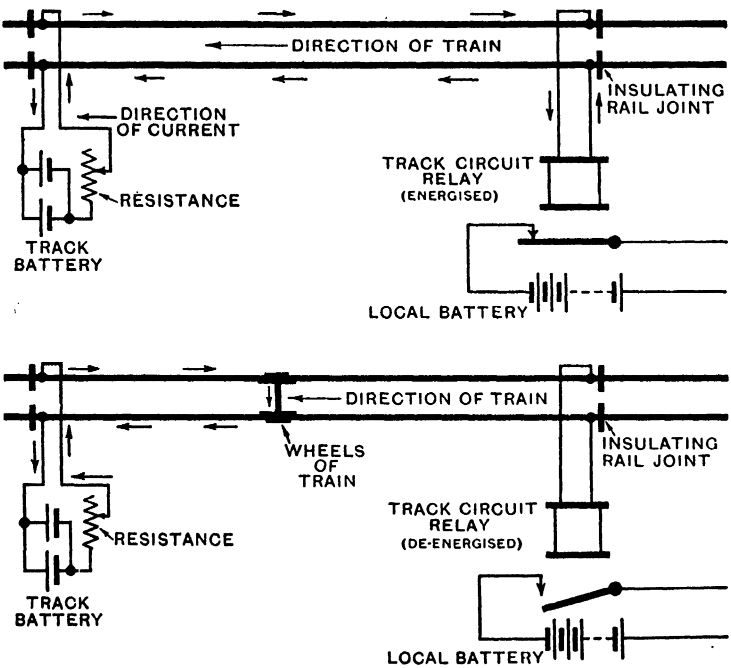

FIG. 6.—Principle of Track Circuit.

highest, of course, for a single pair of wheels and lowest for a long train. Thus it is possible that with a single vehicle—a railcar for example—the shunt resistance would be so high as to prevent the track circuit relay from becoming de-energised. Again, a certain amount of leakage always takes place through the ballast; such leakage varies with the nature of the ballast itself, but in any one locality track circuits may be particularly susceptible to changes in the weather. After heavy rain track, unless very well drained, is apt to hold moisture to a certain extent, and this will, of course, increase the leakage of current from rail to rail. In tunnels where the adverse combination of a wet formation, and deposits of soot and cinders may cause unusually high ballast leakage, it is sometimes very difficult to secure good track circuit performance. The problem of design largely centres upon the value of the current to be fed to the rails so that the relay shall be shunted under any circumstances when the track is occupied, and shall remain energised when the track is clear, even under the worst conditions of leakage through the ballast.

The diagram in fig. 6 illustrates a battery-fed D.C. track circuit. It is, however, not desirable to use D.C. track circuits on electrified roads, even though the traction return is carried in a fourth

rail owing to the possibility of interference from stray currents. In such conditions A.C. track circuits are used. Where the third rail system is used the track circuit insulations would interfere with the traction return current, and to provide a path for this latter impedance bonds are installed at the block joints. The principle of the impedance bond is shown in fig. 7. A coil con-

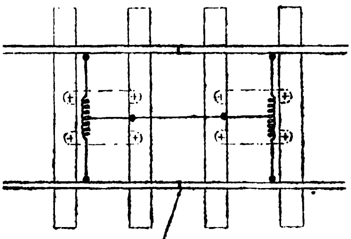

FIG. 7.—Impedance Bond Layout.

sisting of a few turns of heavy copper strip is wound on a laminated iron core, and is connected across the running rails; the A.C. track circuit current tending to flow from rail to rail is prevented by the impedance of the coil, whereas the resistance to the passage of the D.C. traction current is very low. The mid-points of the coils of adjacent bonds are connected as shown so as to provide a path for the traction return current.

ALL-POWER INTERLOCKINGS.

(*a*) *Systems of Operation.*—Developments in electrical engineering practice in recent years have led to a distinct breakaway from traditional interlocking methods in a number of noteworthy British signalling installations put into service shortly before the outbreak of war in 1939. There are now three distinct systems of power interlocking in use in Great Britain:

1. Power frame with mechanical interlocking between levers.
2. Power frame with electric interlocking between levers.
3. Control panel with non-interlocked thumb switches and relay interlocking.

The first type is no longer being used for new works except on the railways of the London Transport Executive. In extensive installations, particularly where a large number of shunting movements required to be signalled, the mechanical interlocking mechanisms grew so complicated, and so expensive to alter when modified traffic arrangements compelled a degree of resignalling, that the system of all-electric interlocking was developed. Instead of a mechanical interlocking mechanism, electro-magnets, additional to those already in use on power frames for track circuit and indication locking, were used for providing the interlocking between levers. An alteration could be made very simply with this type of frame, by changing a few contact bands and carrying out the necessary modification to the wiring. From the signalman's point of view the operation of an all-electric frame is the same as with one of the earlier types of power frame, in that if a signal or a particular pair of points cannot be used owing to prevalent traffic conditions the lever cannot be pulled. A cross-section of a typical signal box with this type of frame is shown in fig. 8.

It is in this respect that the modern control panel constitutes so radical a departure from previous standard practice. The interlocking between signals and points is still provided, as indeed it is essential it should be, but entirely by means of relays; the controlling thumb-switches are free to be moved at any time, and if the particular function which the signalman intends to operate happens to be locked the signal or point machine does not respond to the movement of the thumb switch. Experience with the large and busy relay interlockings in the North Eastern Area of the L.N.E.R. (now the North Eastern Region of British Railways) at Thirsk, Leeds, Hull and Northallerton has shown that no operational disadvantages have arisen from the use of these control panels, and the system may now be considered as well established in British railway practice. One of the most important features associated with relay interlocking is the compactness of the control machine; generally it may be said that a power-frame affording the same facilities will be 2½ to 3 times longer than a control panel. With manual work reduced to no more than the operation of thumb switches the signalman can devote almost his whole attention to the direction of traffic. At Northallerton, for example, one man controls the working over no less than 129 routes.

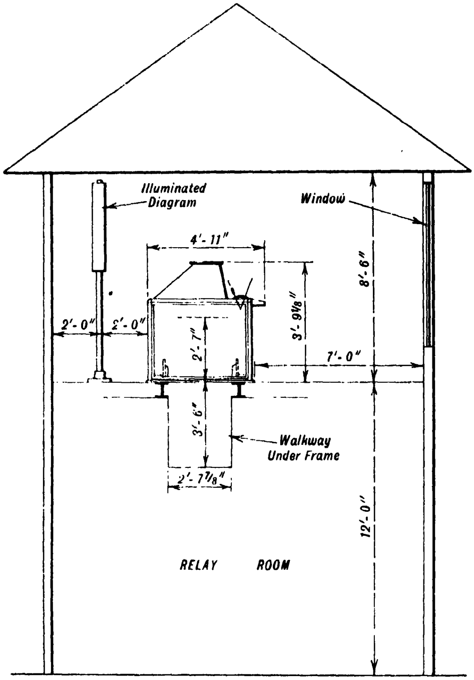

FIG. 8.—Typical Signal Box.

(b) *Control of Colour Light Signals.*—In modern all-power interlockings, whether controlled from power frames or a panel, the use of day colour light signals has become standard practice on all British railways. In a number of installations the so-called 'Searchlight' type of signal has been used, in which there is a single light unit, and the indications displayed—red, yellow, or green—are provided by the interposition of coloured roundels between the lamp and the lens, the roundels being carried on the vane spindle of a three-position relay housed in the signal. Generally, however, the multiple-lens type of signal is favoured, and a description of this is given later. Purely automatic signals are controlled by the relays of track circuits concerned, but in the case of signals operated from a power frame, or other form of control machine, a safety feature is included to ensure that after the passage of the train the signal lever is put to danger, before the signal can be cleared a second time. This fundamental principle of power signalling is illustrated in fig. 9. The essence of the arrangement is the 'stick relay,' which is energised by a circuit passing through a contact on the track relay made when that relay is energised, and a contact made when the signal lever is normal. When the lever is reversed, and the direct feed to the stick relay coil is broken, that relay is held energised, or 'stuck,' as it is termed, by a feed over its own front contact. When the train passes the signal and enters tract circuit 'A' the feed to the stick relay is cut, and owing to the nature of the circuit it cannot be energised again until the signal lever is restored to normal.

(c) *Illuminated Diagrams.*—In all modern schemes of power signalling the illuminated cabin diagram plays a very important part. With the control of large areas concentrated in one signal box, considerable sections are necessarily out of sight of the signalman. But even with the lines in the immediate vicinity of the box it is essential to provide the man with exact information as to the occupancy of all the track circuits. Where a power frame is used the illuminated diagram is a comprehensive track circuit indicator and little more; but in the latest relay interlockings its functions have been increased. In certain cases the thumb-switches have been mouoted on their correct geographical positions on the diagram, and in other instances where route-switching

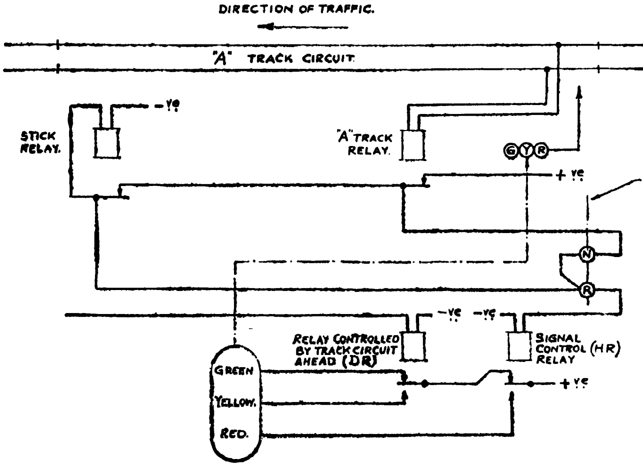

FIG. 9.—Stick Circuit for Power Signal Control.

is used additional lights are provided to show the signalman the routes which have been set up and signalled. The thumb switches are mounted on a separate keyboard below the diagram, and when a particular route has been set up its extent is shown on the diagram in a series of white lights. Thus the signalman is provided with immediate evidence of whether the various point motors and signals have responded to the turning of the thumb switch he has operated.

Apparatus for Power Signalling.

(a) *Point Operating Gear.*—Any mechanism for power operation of points, whether all-electric, or electro-pneumatic, must include all the functions of a mechanical layout as illustrated in fig. 3, p. 598. Track circuiting, of course, obviates the need for a facing point lock bar, and the actions of the bolt lever and the point lever are usually combined in one mechanism. The general tendency nowadays is to mount all apparatus in the 'six-foot,' rather than the 'four-foot' way, and modern types of all-electric point machine include the electric motor, facing point lock, point detector and motor control gear within a single casing, which can be mounted in the middle of the 'six-foot' way. Equally comprehensive mechanisms operated by a compressed air cylinder, are used in electro-pneumatic installations. In large and complicated layouts, owing to the presence of crossings, slip roads, and fixed structures it is not always possible to mount point machines adjacent to the switches to be operated, and then recourse has to be made to combined facing point locks and electric detectors mounted in the 'four-foot,' while the points themselves and the facing point lock plungers are operated by rodding connected to point machines fixed in the nearest convenient place.

Where electric point machines are relatively near to the signal box they are controlled by direct wires from contacts on the signal levers. In more distant locations, to avoid the need for carrying the heavy currents over, maybe, a mile of line wires, contactors are installed adjacent to the point machines, and, as the currents necessary to operate them are small, losses in transmission over these longer distances are avoided. The system of all-electric operation most generally favoured nowadays is 110 volts D.C., supplied from storage batteries in the cabin, keeping the local authority's supply, fed through suitable rectifiers, as a standby. In electro-pneumatic installations modern practice is to use a pressure of about 80 lb. per sq. in. The method of control varies. On the railways of the London Transport Executive, air is maintained in the cylinders after the completion of the stroke, the feed and exhaust being controlled by an electro-magnetically operated needle valve. In the latest installations put into commission before the war of 1939–45 in the North-Eastern Area of the L.N.E.R. a 'cut-off' type of valve is used, in which the air supply is cut off as soon as the points are thrown and locked.

(*b*) *Colour Light Signals.*—The light-unit of a modern colour light signal is shown in fig. 10. With a standard lamp, double-filament (See B.S.I. Spec. 469), such a lens combination gives a concentrated beam of light, and the indications can be clearly seen up to a mile away in brilliant sunshine. The 'spread' of the beam is very small, not more than 2½°, and this feature introduces certain problems in design and installation. When outside the beam the indication displayed by the signal is practically invisible in daylight, and to meet the frequent case of multiple-unit electric trains drawing close up to such signals, side lights incorporating lenses 1¾ ins. diameter are provided at a convenient angle for observation from the motorman's cabin.

In earlier installations of colour light signals, the subsidiary units, for controlling shunting, and draw-ahead movements, were also multi-lens day colour light signals. though having a short range and lenses of considerably smaller diameter. More recently, however, subsidiary signals displaying indications totally different from those of the main running signals have been installed.

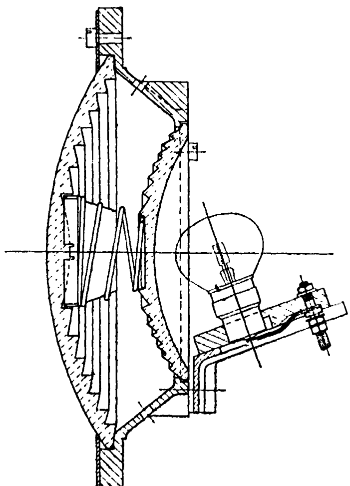

FIG. 10.—Lens Arrangement of a Colour Light Signal.

In the Southern Region solenoid-operated disc signals are now used ; to provide the same indication by night and day the discs are flood-lighted, thus contrasting to the discs in mechanical territory which have spectacle glasses in the discs and display reduced-size coloured lights at night. On the former L.N.E.R. and L.M. & S.R., what are termed 'position light' signals were adopted for subsidiary purposes. In the case of ground shunt signals two white lights displayed horizontally indicate 'stop,' and two white lights displayed diagonally indicate 'proceed.' 'Draw-ahead' signals are normally extinguished ; when the main signal is 'red,' and a train is required to draw forward, two white lights are displayed diagonally. With all forms of colour-light, or position light signal it is usually necessary to reduce the voltage at night ; otherwise the indications would be too brilliant and would cause dazzle.

(c) *Route Indicators.*—While it is generally desirable with any form of signalling to reduce as much as possible the number of semaphore arms, or coloured lights displayed, the long distance from which colour-light signals can be sighted makes this desideratum particularly necessary with modern power signalling. In the approach to large stations speed is relatively low and indicators showing the platform to which a train is routed have been successfully employed for many years. There are various forms in regular use ranging from the electrically-driven roller-blind type, as installed at King's Cross Station, to the theatre-sign indicators used in recent installations on the former S.R. The principle of the latter type is illustrated in fig. 11, and with this the indication is the same by day and night. Although such indicators show up well, the letter or figure displayed could not be read by the driver approaching a high-speed junction—at any rate not in time to take the necessary action—and a different form of indicator is essential. To meet such requirements the illuminated directional indicator has been developed, the principle

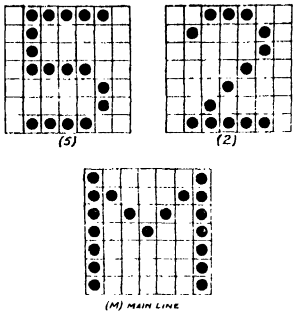

FIG. 11.—Theatre Sign Indicator.

of which is illustrated in fig. 12. When a train is signalled along the main line, and no reduction in speed is required the directional sign is not lighted at all; for diverging movements the line of white lights corresponding to the route to be followed is illuminated, and appearing above the coloured lights of the signal itself gives a striking indication to the driver of an approaching train.

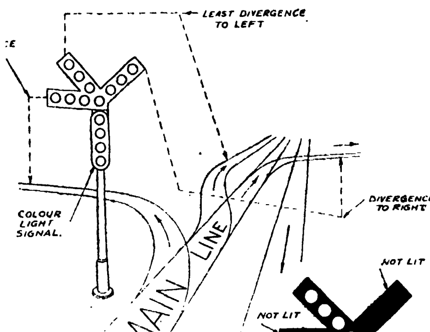

FIG. 12.—Principle of Illuminated Directional Sign Indication.

(*d*) *Structures for Colour Light Signals.*—The concentrated nature of the light beam from a day colour light signal introduces certain unusual problems in the design of structures carrying groups of signals, or signals associated with route indicators or the junction directional signs just described. The signals require to be mounted as close as possible to the running road to which they refer, and in busy areas this often necessitates the use of cantilevers with a considerable overhang. Such structures must be designed for the minimum deflection at the extremity, for any appreciable swing, under wind pressure, might deflect the beam of light out of the drivers' line of vision. It is thus usual to make the towers extremely stiff, a point that is often rendered more difficult by restricted space between running roads. Apart from wind pressure, and the dead loads, such structures are liable to be subjected to a type of loading which it is not possible to calculate with any accuracy—namely, the suddenly-applied upward loads on the underside of the landing due to the blast from the locomotive exhausts. Instances have been recorded where these upward loads have been of sufficient magnitude to deflect the beam of colour light signals upward out of the drivers' line of vision. A further point in the design of structures for colour light signals is that they should be capable of easy and rapid handling in erection; usually very little time is available between trains, even on Sundays, when such erection work is usually done.

(*e*) *Relays.*—In modern signalling relays are used for so great a variety of purposes, that the merest outline of their design and uses is all that it is possible to give in the space available. Where D.C. track circuits are used the track relays are generally similar in design to those used for line purposes, signal control and such like, differing only in the voltage on the coils. Performance characteristics for track and line relays are laid down in B.S.I. Specs. 452 and 475 respectively. For indicating the lie of points, and thus affording the necessary 'proving' for inclusion in signal control circuits polarised D.C. relays are used. When no current is applied to the coils this type of relay takes up a central position, while the normal and reverse positions are assumed when the coils are energised according to the direction of flow of the direct current. A further type of D.C. relay, now in increasing use, is the small single-coil instrument roughly of the same proportions as those used in automatic telephone switching. These have been used in a number of relay interlocking and remote control schemes.

In A.C. signalling schemes the vane type of relay is in general use. An aluminium vane takes the place of the conventional armature in a D.C. relay, moving vertically between the pole faces of a horse-shoe shaped core; the form of construction used gives rise to eddy currents in both the pole faces and the vane when alternating current is applied to the coils, and the resultant reaction between the vane and the pole causes the vane to move upwards and rotate the horizontal spindle on which it is mounted. This movement, transmitted through a suitable link mechanism, is utilised for the opening and closing of the relay contacts. For line relays a single core is used, and the entire control current passes through the coils mounted on this core; this type is known as a single element relay. For A.C. track circuits two-element relays are used in which the greater part of the power necessary to produce the required torque on the spindle is provided by a local supply, thus leaving only a very small proportion to be furnished by the current flowing through the track circuit. Efficient performance of the relay is thereby ensured, on the lowest possible track circuit current. As in D.C. installations, three position relays are used also in A.C. territory for point indication, and these are of the two-element type.

The importance of providing for easy maintenance of signalling relays is reflected in the present tendency to use detachable terminal boards. In large interlockings each relay will have a number of wire connections, and should it be necessary to remove a relay for attention, or routine examination, the uncoupling of so many wires takes a considerable time; and after replacement has been done the re-connected wires must be tested out. On the railways of the London Transport Executive it has for some years now been standard practice to use relays with detachable terminal boards. With this arrangement no wiring need be disconnected at all in order to replace a relay; manipulation of simple screw fastenings enables the terminal board to be lifted clear, and the relay mechanism may be removed and another substituted in a very short time.

Remote Control.

The remote control of signalling apparatus offers almost limitless possibilities for the co-ordination of traffic working in a wide area, with, at the same time, a considerable saving in man-power. The operation of points and semaphore signals by high voltage D.C. supplied from hand generators has already been discussed, though this method is limited largely to the working of isolated functions which would otherwise be beyond the range of control of the nearest manual signal box. There are other cases where it may be desirable from a traffic point of view for an entire interlocking to be remotely controlled. For this purpose an interesting system was developed by the London Passenger Transport Board, now London Transport Executive.

A signal box is fully equipped with a power-frame similar to the Board's standard type, complete with all the usual mechanical interlocking between levers, and the electric magnets for track and indication locking. But instead of being operated by a man, the entire machine is remote-controlled. Each of the levers in the locking frame is moved by two small compressed air cylinders, governed by electro-pneumatic valves. The circuits for controlling the operation of these small cylinders have no effect upon the safe working of the signalling as every safeguard is provided by standard apparatus between the remotely-controlled locking frame and the signals and point mechanisms concerned. Thus the remote control circuits can employ telephone type relays wiring and cable, rendering this part of the system relatively cheap. One of the principal advantages claimed for this arrangement is the reduction in cost over that of a single large interlocking frame in an extensive layout, since the small remotely-controlled frames can be situated near to the signals concerned, and the signalling cables kept short. For a fully detailed description of this system see *Proceedings of the Institution of Railway Signal Engineers*, 1942.

On the main line railways, the use of power signalling apparatus, and the means not merely for controlling it but of indicating its performance, has enabled many remote control schemes to be successfully operated. The 14-mile stretch of the London-Edinburgh main line between Northallerton and Darlington has only one intermediate signal box; some of the outlying points and crossover roads are two miles from the controlling signal box, and although many of the signals work automatically the whole line is under the surveillance of one or other of the three signal boxes concerned—Northallerton, Darlington and the intermediate junction at Eryholme. The location of trains, including those on the automatic sections, is indicated on the illuminated cabin diagrams, and in the event of a stop being required at an automatic signal displaying the danger indication the trainmen are required to telephone the signal box ahead for instructions. There is always

the chance that such a stop may not be due to occupancy of the road ahead, but due to some failure of the signalling apparatus. With the traffic position displayed on his illuminated diagram a signalman on being telephoned can judge the reason for the train being stopped and can advise the trainmen accordingly.

There is now theoretically no limit to the distance from which points and signals can be operated; the practicable limit is set by the cost of cable, which beyond a certain point will outweigh the savings effected by remote control. In recent years, however, the entire complexion of the problem has been changed by the development of the coded system, first introduced in the U.S.A. for regulation of traffic working on long stretches of single line. It is now widely known as Centralised Traffic Control, or C.T.C., and although there has so far been only one example in this country, the possibilities are great, and it is already being extensively installed on the New Zealand Government Railways. Instead of direct wire transmission from the control machine, or power-frame, to each individual signal, or pair of points, the entire control is carried out on two line wires. Not only one station, but a complete section, or subdivision of the line may be controlled from a central office. The limitation with this system lies in the use of only two line wires. Only one code can be transmitted at a time; for each code sent out from the control machine there is a corresponding return code, proving that the particular signal or points have responded. The time taken for the complete transmission of a code, outward or return, is approximately 3½ seconds. To the operational and proving codes, must be added the numerous incoming codes showing the changing occupancy of the track circuits. An analysis of traffic movements, together with the number of signal and point operations, will therefore show the extent of the area which can be brought under the control of one machine, as represented by the capacity of the two line wires to handle all the codes likely to be transmitted. The electrical principles on which C.T.C. is based were described in *The Engineer* for September 10, 1943. By utilising the principles of carrier telephony it is now possible to superimpose other codes on the two lines of a C.T.C. system. If the line extending through a controlled area be divided into two sections, the section nearest the control machine will be operated by ordinary C.T.C. codes; on this same section of the two line wires are superimposed the higher frequency carrier codes for the more distant section. At the division point the carrier codes are changed into ordinary D.C. codes for the control of points and signals on the section furthest from the control machine.

Automatic Train Control.

The numerous safeguards so far mentioned, lever interlocking, 'lock and block,' track circuiting and so on, are all designed to safeguard against errors in working on the part of signalmen; it is to provide against possible misinterpretation of the signals, misjudgment of distance, and such like, on the part of locomotive drivers that a series of safety features, which may be grouped together under the general heading of Automatic Train Control, have been introduced. In studying the subject, the speed and brake power of the trains must be considered no less carefully than the wide variation of traffic conditions existing in different parts of the country. On the intensely used railways of the London Transport Executive, and certain other electrified suburban lines, the speeds are relatively so high and the interval between successive trains so short, that the chance of an overrun at a signal displaying the danger indication is unthinkable. There must be no question of 'warning' a motorman in such circumstances; control must be taken completely and instantly out of his hands, and the train stopped in the shortest possible distance. From the practical point of view the problem is made simpler by the maximum speed and brake power of the trains being alike. A train stop mechanism is installed, co-acting automatically with each stop signal, in which a stop arm is raised when the signal is at danger; in the case of an overrun this stop arm is struck by the hanging lever of a trip cock on the train. When a train is thus 'tripped' an emergency application of the brakes is made, which the motorman is powerless either to cancel or forestall. On the railways of the L.T.E. the train stops are electro-pneumatic, while on the lines of the former L.M.S.R. in the London suburban area they are all-electric.

This necessarily drastic system would not be practicable in main line railway working. In the maintenance of high speed express passenger services the 'distant' is the important signal. Unless a driver has an adequate sight of this warning signal he cannot be expected to run with confidence, and the effects on punctuality caused by foggy weather are only too familiar. The G.W.R. system of automatic train control was originally designed to lessen the difficulties occasioned by fog, but it has proved a most valuable aid to efficient train operation in any circumstances, and is now installed over the Western Region main line network. It provides an audible indication, in the locomotive cab, of the aspect displayed by each distant signal along the line. If the wayside signal is clear, a short loud ring is given on a bell in the cab, and no action is required on the driver's part. If the distant signal is displaying the 'caution' indication, the cab signalling apparatus causes a siren to start up, the blast of which continues until the driver operates an acknowledging switch. A system of automatic train control, giving similar indications, was being developed on the L.M.S.R. and L.N.E.R., though the details of operation, as will be shown later, are quite different.

In these British systems of A.T.C. the operating of the acknowledging device forestalls the automatic application of the brake, and enables the driver to retain control of the train. While it might at first be thought that the provision of such a device goes some way towards nullifying the whole advantage of the automatic control, it must be recalled that the number of accidents in Great Britain due to drivers overrunning or misreading signals are astonishingly few. The purpose of A.T.C. in main line working is not to take control out of the driver's hands, but primarily

to provide him with confirmation of the aspect displayed by the distant signal, in the form of an audible indication in the cab. To introduce a purely automatic stop, on the same principle as that used on the L.T.E., would be to cause widespread delay, particularly in the operation of freight trains. Drivers of heavy trains on sighting a distant signal in the 'caution' position almost invariably take steps to reduce speed to dead slow, and then they draw slowly forward, by which time the section ahead has probably cleared. By this practice a very large number of dead stops are avoided.

In the Great Western system, connection between the apparatus on the locomotive and the wayside signals is made through a contact ramp fixed in the 'four-foot' way. The act of passing over a ramp raises a contact shoe on the locomotive, and this mechanical action takes place irrespective of the indication displayed by the distant signal. The shoe is fitted with circuit breaker contacts, which are normally made; the raising of the shoe when passing over a ramp opens the circuit to a valve magnet. When the distant signal is at 'caution' no current is picked up when the locomotive passes over the ramp, and the de-energising of the valve magnet (due to the opening of the contact shoe circuit breaker) opens the valve and causes the siren to sound. The driver can restore the circuit, and thus silence the siren, by operating his acknowledging lever. If he did not acknowledge promptly, not only would the siren continue to sound, but the reduction in vacuum, due to air entering the train pipe through the valve, would apply the brakes. If the distant signal is in the clear position current is applied to the ramp, through a signal arm circuit breaker, and this current is picked up by the locomotive contact shoe when passing over; it provides an alternative feed to the valve magnet to prevent the sounding of the siren, and supplies also a feed to ring the bell. In a test stop, when a locomotive and train together weighing 430½ tons passed a distant signal at danger, the siren was not acknowledged and steam was kept full on. This test took place on a length of straight and level track, and from an initial speed of 69 m.p.h. the train was brought to rest in 900 yds. from the ramp.

This G.W.R. system was designed to operate in semaphore signalled territory. It can, of course, be applied to colour light signalling, though on stretches where four indication signals were contemplated the necessity arose for some distinction to be made between the preliminary warning, as provided by the 'double yellow' indication of the wayside signals, and the second warning given by the single yellow. With some ingenuity the standard system was very simply adapted to give a double blast on the audible cab signal to correspond with the 'double yellow,' leaving the sounding of the siren to accompany the approach to a single yellow, as at present when approaching a semaphore distant signal in the caution position. The result was obtained by polarising the current applied to the ramp, one polarity being used in conjunction with the 'green' indication, and opposite polarity for the double yellow, in which latter case an electro-pneumatically controlled horn was sounded immediately prior to the sounding of the ordinary siren. A full description of this arrangement, together with particulars of a test run at 97 m.p.h. was published in *The Engineer* for October 17, 1947.

In the system installed on the former L.M.S.R. Southend line and at one time projected on the Edinburgh and Glasgow section of the L.N.E.R., the contact ramp is replaced by an inductive pick-up. On the lines so far equipped the audible signals received in the cab are a short blast of the siren for 'clear,' and a continuous blast for 'caution'; this latter is silenced by the driver operating the acknowledging plunger. Developments are in progress, however, with this inductive system which in later installations will bring the audible cab signals almost exactly into line with those provided by the G.W.R. The subject of the automatic train control was discussed at length in *The Engineer* (July 12, 19, 26, August 2 and 9, 1940), when existing British systems were compared with those in use overseas.

An experimental installation of continuously-controlled cab signals has been made between New Barnet and Potters Bar on the main line from King's Cross to the North. In many ways this installation follows the practice standardised on the Pennsylvania Railroad, but certain adaptations have been made to suit the arrangement to British practice (see *The Engineer*, November 14, 1947). The section of line is track circuited throughout, with track circuits of the coded type, and the coded currents flowing in the running rails are conveyed to the receiving apparatus on the locomotive through an inductor mounted on the policeman irons. The principle of coded track circuits was discussed at some length in *The Engineer* for September 24, 1943, but a brief summary follows for ready reference.

Whereas ordinary track circuits of the non-coded type depend for their operation on a supply of power being applied continuously at one end of a section of insulated rail, in the coded track circuit the supply of power to the rails is interrupted by code transmitters located at the feed end of each track circuit. At the other end of the track circuit the normal type of relay is replaced by what is termed a code following relay, which is alternatively energised and de-energised in synchronisation with the current impulses applied at the feed end of the track circuit. With this arrangement the current feed with the running rails is interrupted at different periods according to the occupancy, or otherwise of the road ahead, and codes are picked up by the inductor apparatus and used for the control of the cab signal.

Control of Marshalling Yards.

Marshalling yard operation has been studied extensively in recent years, with a three-fold view: to increase safety of working, both from the viewpoint of damage to merchandise and injury to personnel; the more efficient use of motive power; the quicker clearance of traffic. The actual layout of marshalling yards is not primarily a signalling matter, though in such yards the work of

the signal engineer is more intimately bound up with the actual running of vehicles than perhaps anywhere else, save on such intensely used lines as the London tube railways. The use of the hump type of yard introduces wagon speeds up to about 20 m.p.h., as they approach the classification roads; but it is not so much the speed as the short distance between successive wagons, or groups of wagons coupled together, that makes necessary the quickest possible operation of points. The interval is so short that it would be unreasonable to expect a man watching from the control tower always to judge the correct moment for moving the points, and the control is therefore arranged automatically, by the passage of the wagons themselves over critically-sited track circuits.

When a train enters the reception sidings of a marshalling yard, prior to classification, a list is compiled of the sidings into which each wagon must be switched after shunting over the hump. Where two or more successive wagons are routed to the same siding they are coupled together, and known generally as a 'cut.' The list of 'cuts' is sent to the man in charge of point operation, and he must arrange for the route to be set for each. By utilising the principles of relay interlocking the routes can be pre-set, or 'stored' as it is termed, so that as soon as one wagon, or cut, has passed over the first pair of diverging points route-setting for the next is begun immediately; the 'storage' circuits are so arranged that the various stages in the setting up of a route take place only after the preceding 'cut' has cleared the fouling points. As yet no standard practice for route setting has been evolved. As with most new developments the earliest installations embody successive new ideas. A description of British systems of working mechanised yards, and the part these played in the handling of wartime traffic appeared in *The Engineer* for July 10, 1942.

In adapting power signalling apparatus for automatic point control in marshalling yards certain fundamental changes were made in design in order to secure the fastest possible operation. In so doing, two safety features which it is imperative to include on passenger lines were dispensed with. The first of these concerns the track circuits. In ordinary signalling the track circuits are normally energised, and the relay is shunted by the entry of a train, or vehicle on to the particular section; in hump yards the track circuits are normally de-energised. D.C. relays pick up more quickly than they release, and by using this characteristic the point control circuits depending upon the occupation of a particular track circuit can be initiated more rapidly. The saving does not amount to more than a split-second, but in the limited time available for throwing the points any saving is worth having. The second important change is that no facing point locks are used; in cases of electro-pneumatic working the cylinders are coupled direct to the first stretcher bar, and the control valves are diaphragm operated, again to giveth utmost speed in working.

B.S.I. Specifications relating to Railway Signalling.

For ready reference a list is given below of the British Standards Institution specifications at present issued relating to mechanical and power signalling apparatus and wiring diagrams.

Apparatus.	*B.S.I. Spec. No.*
Cartridge fuses	714
Colours for signal glasses	623
Electric lamps	469
Lenses (plano-convex)	624
Mechanical signalling apparatus	689
Electric point operating machines	581
Line Relays	
A.C. Single element (2 position)	557
A.C. 2-element, 3 position	561
D.C. tractive armature neutral	475
D.C. tractive armature neutral-polarised	519
Relays, thermal type, time-element	635
Track Relays	
A.C. 2-element 2-position	520
D.C. tractive armature	452
Terminals for power signalling	442
General.	
Glossary of terms	719

SECTION XXXIII

GAS AND GASWORKS

(Contributed by Harold Moys, B.Sc. (Eng.), A.M.I.C.E., M.Inst.Gas E.)

Parliamentary.

The public supply of gas in this country is governed by Acts for particular undertakings and by Acts applying to the whole industry. The latter class include the Gasworks Clauses Acts of 1847 and 1871, the Sale of Gas Act of 1859, the Gas and Water Works Facilities Acts of 1870 and 1873, the Gas Regulation Act of 1920, the Gas Undertakings Acts of 1929, 1932 and 1934. London companies are, in addition, under the regulations of the Metropolitan Gas Act (1860). Under the Public Health Act of 1875 the local authority may become its own gas supplier or may purchase an existing undertaking by agreement. In addition to the Acts named above the supply of gas in Scotland is governed by the Gas Acts of 1864 and the Burghs Gas Supply Acts of 1876 and 1893. Thus gas works are controlled by—

(*a*) Statutory companies.
(*b*) Non-statutory companies.
(*c*) Local authorities.

The supply of gas is, for the most part, in the hands of the local authorities in Scotland and the northern counties of England, particularly Yorkshire and Lancashire, but in the Home and Southern counties private ownership is the rule.

The Gas Regulation Act of 1920 is divided into four sections:—

(*a*) Price and quality of gas.
(*b*) Testing of gas.
(*c*) Forfeiture and Penalties.
(*d*) Power to make Special Orders.

Section (*a*).—The Board of Trade is authorised to make orders allowing undertakings applying to it to charge for gas on the thermal basis, to adjust the standard or maximum price (on the heat unit basis) to meet the additional expenses of manufacture and distribution arising from post-war conditions and to revise these charges should it be shown by the local authority or the undertaking that the profits are excessive or unjustly small. The undertaking is given freedom to choose the calorific value of the gas it will distribute, provided that it advertises the value and adjusts at its own cost all burners and appliances to use the gas with safety and efficiency. The gas must be free from sulphuretted hydrogen and shall be supplied at not less than the permissible pressure, *i.e.* 2 ins. water pressure in mains or services of 2 ins. diameter or upwards.

The Board of Trade were authorised to prescribe the limitations of inert constituents and carbon monoxide content but a Departmental committee recommended no such restrictions (1922).

Section (*b*).—This section deals with the Testing of Gas and the appointment of the Gas Referees, Chief Gas Examiner and the local gas examiners; the duties of the Referees, the appeals to the Chief Gas Examiner and the creation of the Gas Fund.

Section (*c*).—The penalties and forfeitures for non-compliance with any lawful prescriptions of the Gas Referees and failure to maintain the gas within the normal range of calorific power, purity and pressure.

Section (*d*).—Under this section the Board of Trade is enabled to do by Special Order practically everything which had previously been done by Act of Parliament or provisional order made under the Gas and Water Works Facilities Act, 1870.

The Gas Undertakings Act of 1929.

This Act was the result of a compromise between the parliamentary authorities and the gas industry. The latter had complained that it was working under obsolete legislation which tended to cripple its freedom of action and that the Government by creating the Electricity Commissioners and guaranteeing interest on a large amount of capital and by generally encouraging electrical development was supporting a newer industry to the detriment of the older one. The Gas Undertaking Act of 1929 was the outcome, and although satisfactory so far as it went, it was only regarded as a first step towards greater freedom. The principal powers of this Act are as follows:—

1. Without any further authorisation a company can raise by way of a loan an amount up to 50 per cent. of the ordinary and preference capital including premiums.

2. Subject to the consent of the local authority the Board of Trade can authorise a company to raise by way of loans a sum equal to 100 per cent. of the ordinary and preference capital. Under certain conditions the Board of Trade may grant this power even if the local authority objects.

3. In the case of the old reserve fund or the more modern special purposes fund the permissible total can be increased to include the prescribed proportion of loan capital.

4. Restrictions on the manufacture of residuals were removed.

5. The Board of Trade can authorise the supply of gas to premises outside the limits of supply of any specific undertaking.

The Gas Undertakings Act, 1932.

This Act permits any undertaking which has supplied more than 250 million cub. ft. of gas in a year to invest (*a*) if a local authority up to one-tenth of the capital expended in certain defined companies or local authorites, (*b*) if a company, up to one-twentieth of its authorised share and loan capital or with the approval of the Board of Trade up to one-tenth.

The Gas Undertakings Act, 1934.

This, the most recent general legislation for gas undertakings, is extremely important as it alters the text of the main Act and introduces several new principles into gas law. It is subdivided under five headings:—

(*a*) Capital and Renewal Funds.
(*b*) Charges for Gas.
(*c*) Non-Statutory Undertakers and Undertakers other than Thermal Unit Undertakers.
(*d*) Amendments of Principal Act.
(*e*) Miscellaneous and General.

(*a*) *Capital and Renewal Funds.*—The Board of Trade is given power to authorise the issue of share capital and debentures by public subscriptions provided it is satisfied that the terms are the best obtainable. The payment of underwriting commission is sanctioned. Permission is given to create redeemable preference stock and debentures within the authorised capital. The contribution to the Renewal Fund shall now be limited to ½ per cent. of the capital of th : undertaking and the amount shall not exceed 5 per cent.

(*b*) *Charges for Gas.*—Any thermal unit undertaking can give notice in writing to the local authority of the price or prices, if differential prices for different areas have been previously enacted, at which they are prepared to supply gas to persons who do not enter into a special contract. A copy of this notice must be displayed in all showrooms and offices. This price is the published price and is the price to be used in the calculation of dividend which already appertains to the undertaking. The undertakers can then enter into Special Contracts with consumers upon any agreed terms ' provided that the terms of every contract under this section in the like circumstances and for the same purposes shall be alike.'

(*c*) *Non-Statutory Undertakers and Undertakers other than Thermal Unit Undertakers.*—Any non-statutory undertaking supplying more than 30 millions cub. ft. of gas in a year must make application to the Board of Trade who can make an order conferring upon the undertaking the power and restrictions applying to the statutory undertaking. Non-statutory undertakings supplying between 20–30 millions cub. ft. of gas per annum who fail to maintain a satisfactory supply of gas shall be served with a notice by the Board of Trade requiring them to seek statutory powers. The gas supplied by non-statutory or non-thermal unit undertakers must be free from sulphuretted hydrogen and be supplied at adequate pressure (2 ins. W.G.). This provision does not apply to undertakers supplying less than 20 million cub. ft. per annum.

(*d*) *Amendments of Principal Act.*—The office of chief gas examiner was abolished on January 1, 1935, and appeal is now to be made to the Board of Trade. The office of Gas Referees was abolished on January 1, 1939, and their function is performed by the Board of Trade

who have power to appoint up to three persons to advise them. The gas examiners will be appointed by the local authorities or quarter sessions upon the application of five or more consumers. When the average calorific value of the gas supplied during one quarter is less than the declared value the excess revenue if less than one-fifth of a penny per therm, shall be paid into the Gas Fund (in addition to the usual contribution) or if more than one-fifth of a penny per therm shall be allowed to the consumers as a credit at the end of the next quarter.

A minimum of six tests is specified for the calculation of the average calorific value.

(e) *Miscellaneous and General.*—Only a few of the more important revisions made under this section are given below.

Closer co-operation possible between undertakers with regard to bulk supplies and joint use of research establishments.

All consumers must give 24 hours' notice before quitting premises or accept responsibility for the gas consumed up to the next ordinary meter reading.

The undertaking can refuse a supply of gas to a consumer who has previously quitted premises without payment until such debts are discharged.

Additional powers of entry for the inspection of factories.

A consumer who is connected up to the mains merely as a standby is not entitled to receive a supply unless he agrees to make certain minimum payments.

Consumers must fit and maintain back pressure valves and antifluctuators, if deemed necessary.

The Kettering Clause is inserted in the general Act 'It is not lawful for any local authority to insert in any instrument for the sale or letting of premises a provision restricting the right of any occupier to take a supply of gas.'

A non-statutory company operates as a result of established practice or under the goodwill of the local authority. Its position is in many respects similar to that of a statutory company, but before opening roads for the laying of mains permission must be obtained from the district or county authority.

Emergency War Regulations affecting Gas Undertakings.

The laws affecting gas undertakings during the War Emergency were many.

Orders made specifically for the Gas Industry, the Gas Supply (War Damage) Order, 1940, the Gas Supply War Damage (No. 2) Order, 1940, protected the undertaking from the usual penalties for the failure of normal supply or maintenance of declared calorific value. Additional Orders under the Defence (General) Regulations, 1939, have helped the undertaking to alter its declared calorific value in a shorter period than hitherto and have given them additional powers to meet the present conditions.

The industry is affected by orders dealing with the control of timber, steel, non-ferrous metals, fertilizers, and war risks insurance, and the scheduling of protected industries.

Since 1942 the powers formerly vested in the Board of Trade have been transferred to the Minister of Fuel and Power.

Statistics of Gas Undertakings in Great Britain.

The following figures are taken from White Papers issued by the Ministry of Fuel and Power.

Number of Undertakings, Materials Used, Gas Made and Total Gas Available.

	1938.	1940.	1942.	1944.	1946.	1947.
Number of undertakings:						
Statutory: Local Authorities	298	284	275	274	274	275
Companies .	405	409	406	406	406	402
Other Companies . .	402	380	371	367	366	361
Total . . .	1,105	1,073	1,052	1,047	1,046	1,038
Materials used for making gas:						
Coal (thousand tons) .	19,128	17,983	20,634	20,777	22,646	22,716
Gas oil (thousand gallons) .	32,707	40,180	52,858	96,116	132,220	172,958
Total gas made (million cu. ft.)	319,549	306,557	343,063	363,889	418,855	432,413
Gas bought from coke ovens (million cu. ft.) . .	29,621	36,765	46,880	49,081	53,088	53,984
Total gas available:						
Million cu. ft. . . .	349,170	343,322	389,943	412,970	471,943	486,397
Million therms . .	1,659	1,579	1,813	1,924	2,240	2,310

Gas Consumers—Consumption per Consumer.

The following statistics are taken from the Ministry of Fuel and Power Statistical Digest, 1946 and 1947.

STATISTICS FOR YEAR, 1947.

	Number of Consumers.	Million Therms Sold.	Therms per Consumer.
Mainly domestic: Prepayment	7,634,980	918·9	120·3
Credit	3,287,171	472·2	143·7
Total	10,922,151	1,391·1	127·4
Industrial	105,094	416·2	3,960·4
Commercial (shops, offices, etc.)	511,041	202·4	396·1
Local Authority establishments	54,293	43·9	807·6
Government Departments	14,389	9·4	656·2
Total	579,723	255·7	441·1
Service Departments	5,690	6·3	1,111·9
Public Lighting	—	25·8	—
Total	11,612,658	2,095·1	180·4

The fuel used for gas production in the Gas Industry during 1947 was:—

Coal Carbonisation.

	Tons.
In horizontal retorts	9,381,508
„ continuous vertical retorts	10,892,957
„ intermittent vertical chambers	1,547,623
„ inclined retorts, static vertical retorts and coke ovens	589,634
	22,411,722

It will be seen that the continuous vertical retort is most widely used and is gradually replacing inclined and horizontal retorts.

Carbonising Plant.

There are four main types of carbonising plant in general use in this country, namely:

Horizontal retorts;
Continuous vertical retorts;
Intermittent chamber ovens; and
Coke ovens.

In all settings except the continuous vertical retort, the charging is intermittent, the coal being carbonised for a fixed time.

The following factors influence the type of plant selected:

Type and grade of coal to be used.
Calorific value of gas to be made.
Type of coke required.
The market for tar.
Size of the installation.
Ground space available.
Local amenities.
Degree of flexibility in operation required.

With horizontal retorts, intermittent chambers and coke ovens the widest range of coals is available for carbonisation, but the choice with continuous settings is more limited due to the difficulty in dealing with strongly swelling coals.

It is generally found difficult to produce a high grade gas, *i.e.* above 520 B.Th.U's. per cub. ft., in continuous vertical retorts and to produce an economic low grade gas in horizontal retorts or coke ovens. Intermittent vertical chambers are the most flexible in this respect.

The coke produced from continuous vertical plants is very free burning but somewhat friable, whilst that from intermittent vertical chambers and coke ovens is dense and somewhat difficult to ignite; this latter is excellent for steam raising purposes.

The tar produced from coke ovens and horizontal retorts is superior to that from continuous vertical retorts and can easily be treated to comply with the B.S.S. for road tar.

Coke ovens are only employed in large installations. With the other systems the charging and discharging machinery necessary with horizontal retort and intermittent vertical chamber installations renders their capital cost high in small units. In such cases the continuous vertical retort would prove attractive.

The table below, taken from F. B. Richards' paper, shows the output in therms per sq. ft. for plants actually installed.

Type of Installation.	Total output Therms/day.	Total ground space occupied Sq. ft.	Therms/day per sq. ft. of ground space.
Horizontal retorts	34,560	23,400	1·48
Continuous vertical retorts	50,388	14,212	3·55
	42,028	13,230	3·18
	19,890	7,326	2·72
	1,210	950	1·27
Intermittent vertical chambers	45,060	18,914	2·37
	20,780	9,388	2·21
	1,920	1,830	1·05
Coke ovens	84,500	62,200	1·35

On the grounds of local amenities the claims of the continuous vertical retort are greater than those of the other types although the intermittent vertical chambers can be improved by the installation of dry cooling plants for coke quenching.

Flexibility of output can be obtained with all plants, but widely ranging calorific values are most easily obtained with intermittent vertical chambers.

Proportions of Horizontal Retort Benches.

The following normal dimensions are given as exemplifying the usual proportions of various types of retort houses and benches:—

(*a*) Single retort bench, 10-ft. retorts:—

	ft.	ins.
Width of bench	12	6
At back of bench	1	6
In front of bench	18	0
Total width inside houses	32	0

The height of the retort house to the eaves would be 20 ft., and the height of the retort bench from ground level 11 ft.

(*b*) Through retort bench, hand charging and discharging:—

	ft.	ins.
Width of bench	20	0
Each side of bench, 20 ft.	40	0
Total width of house	60	0

The height of the retort house to eaves, if house of the stage type, would be about 35 ft.; if of the subway type 8 to 10 ft. less. The height of the retort bench from base of producers to top of brickwork about 20 ft., if retorts set in three tiers.

(*c*) Through bench, mechanical charging and discharging:—

	ft.	ins.
Width of bench	20	0
Charging side of bench	23	0
Discharging side	17	0
Total width of house	60	0

The height of the bench from base of producers to top of brickwork would be about 25 ft. if retorts are set in five tiers. The height of the house (stage type) to eaves would be about 40 ft. if continuous coal hoppers overhead were included. As an approximate rule for ascertaining the height of the bench from charging floor to top of brickwork, allow 29 ins. for each tier of retorts. The width of the main setting arch will be, for two rows of retorts, from 7 ft. 9 ins. to 8 ft. 9 ins.; for three rows of retorts, 8 ft. 6 ins. to 9 ft.

Vertical Retorts.

Modern vertical retorts are of three types. (*a*) Continuous; (*b*) Intermittent; (*c*) Static.

Continuous Vertical Retorts.

Woodall-Duckham System.—The retorts are now built in five standard sizes which vary only in the dimensions of the major axis, the minor axis being the same in each case. The coal carbonised and the average gas output per day of the different sizes of retorts are as follows:—

Mean Major Axis.	Coal Carbonised.	Gas Output.
	Tons.	Cu. ft. per day.
44 inches . . .	3 to 5½	51,000 to 59,000
53 " . . .	3½ " 6½	59,000 " 94,000
62 " . . .	4½ " 7½	72,000 " 109,000
82 " . . .	5½ " 9½	90,000 " 142,000
103 " . . .	6½ " 12	115,000 " 180,000

Glover-West System.—In this system the retorts are elliptical in shape, having a taper towards the bottom. At the base of the retort is fitted a large steaming chamber and this has allowed the amount of steam admitted to the retort to be increased with the consequent increased yield of gas per ton of coal carbonised. The retorts are set in units of 2, 4 or 8 and they are made in three sizes, the particulars in connection with which are given in the following table:—

	Type 1.	Type 2.	Type 3.
Major and minor axis of ellipse at top	33 ins. × 10 ins.	40 ins. × 10 ins.	50 ins. × 10 ins.
Major and minor axis of ellipse 21 ft. from top	39 ins. × 18½ ins.	46 ins. × 18½ ins.	56 ins. × 18½ ins.
Total length of retort . . .	25 ft.	25 ft.	25 ft.
Capacity per day in cubic feet of gas	60,000	75,000	90,000

Drake's System.—The 'Drakes' Vertical Retort is made in varying sizes to cope with individual requirements, the minimum size being a nominal 3-ton retort, having a major axis of 36 ins. and a minor axis of 18 ins.

All the retorts are rectangular in shape and have a uniform taper from top to bottom on both major and minor axes.

The retorts can be grouped in single or double units or in units of four, each separate unit having individual producer gas and air supplies and waste gas outlets.

Intermittent Vertical Chambers.

Continuous vertical retorts are generally considered unsuitable for the carbonisation of highly expanding coals. Where such coals have to be used intermittent vertical chambers would be considered. Compared with horizontal retorts they have these advantages. (1) No costly machinery for retort charging and discharging. (2) Bulk carbonisation. (3) Increased flexibility due to the suitability of the charge for steaming.

The capacity of the chambers varies, but a normal figure is 3½ tons, the chamber having a minor axis of 8 ins. at top and 12 ins. at bottom, major axis of 9 ft. 8 ins. at top, 10 ft. 0 in. at bottom and a height of 21 ft.

Settings have been designed with built-in producers and recuperators or with outside producers.

It is usual to provide gas off-takes at the top and bottom of the chamber, both off-takes being closed during charging and discharging. The top off-take is fitted with a saucer valve so that, when open, the pull of the collecting main is transmitted to the retort. The bottom off-take is sealed to a depth of about 2 ins. so that it is used only to reduce the pressure at the bottom of the chamber during peak pressure conditions. Due to the high temperature of the whole of the charge, steaming during the last two hours is extremely efficient. The tests on the intermittent vertical chambers at Croydon carried out by the Joint Research Committee of the Institution of Gas Engineers and Leeds University, 1931–32, show that the thermal output was 78·6 therms per ton and a dry coke yield of 11·3 cwts. The calorific value of the gas was 549 B.Th.U./cub. ft.

Static Vertical Retorts.

The best-known plant of this type is the 'Westvertical.' In this retort the charge remains static during the carbonising period. The system is, however, completely enclosed and steaming is continuous. The carbonising chambers so far constructed have been 8 ft. 4 ins. wide on the major axis and about 20 ft. deep in the carbonising zone The chamber is extended downwards through the intermediate zone to the cooling zone, the charge being dropped after carbonisation

into the zones for steaming and cooling. The residual heat of the coke is restored to the system, the coke is discharged cool and dry and the intermediate zone is sufficiently hot for the producton of water gas. It is suggested that hydrogenation of the tar vapours is effected and that the overall thermal efficiency is improved.

The static vertical retort has also been developed by the Woodall-Duckham companies and a full scale model plant was installed at the Croydon Gas Works. Like the 'Westvertical' plant the static vertical retort consists of an intermittently operated two-stage vertical carbonising retort divided into two superposed portions, the upper one heated by external flues forms the carbonising zone, and the lower forms a zone in which the coke to a certain extent is cooled. From the published figures available for this test plant it would appear that the thermal yield is considerably improved over those for both intermittent vertical chambers and continuous vertical retorts.

Whilst the number of commercial installations of the 'Westvertical' and Woodhall-Duckham static vertical retort is not large it would seem that this method of carbonisation has many attractive features.

Admission of Steam.

The process of admitting steam to the base of the retorts on continuous and intermittent vertical retort installations has now become standard practice. This process has also been applied with varying success to horizontal retorts. Blue water gas is generated *in situ* and besides increasing the yield of gas and the therms per ton of coal carbonised, some noticeable augmentation of the liquor and tar yields has resulted. The effect of steaming is well illustrated by the following results obtained at the Fuel Research Station at East Greenwich with Mitchell Main gas coal:—

	Cu. ft. of Gas per Ton of Coal.	Calorific Value B.Th.U. (gross).	Therms per Ton of Coal.
Without steaming	13,100	544	71·26
Steaming 20·53 per cent.	22,580	460	103·86
" 30·03 "	35,610	432	110·63

Dilution of Coal Gas with Producer Gas.

Coal gas produced in continuous vertical retorts and intermittent vertical chambers can be diluted to about 400 B.Th.U. per cub. ft. by water gas produced *in situ*. For small works without water gas plants dilution of the high grade gas from horizontal retorts is best effected by the admixture of producer gas. This can be obtained from the ordinary built-in producers or from an independent producer. Various devices have been designed for controlling automatically the rate of admission of the diluent so as to give a steady calorific value. The advantages derived from the use of producer gas dilution are:—

(1) Improved working in retort house due to the absence of overpulling.
(2) Decreased wear and tear in retort houses.
(3) Increased thermal yield.
(4) Decreased cost per therm of mixed gas.
(5) More stable gas for use on the district.

Owing to the acute shortage of plant resulting from the war period, many experiments have been tried to increase the capacity of existing plants. As the result of one such experiment it has been found that running continuous vertical retorts on high coal throughputs with reduced steaming and diluting the high grade coal gas by producer gas gives a greater output than when producing the correct type of gas by steaming in continuous vertical retorts.

Heating of Retorts.

All modern settings on gasworks are heated by producer gas made either in a small built-in producer, a battery of step grate or similar hand-clinkered producers, or in mechanically operated producers.

At coke oven plants not situated at gasworks the rich coal gas or blast furnace gases are used for heating purposes.

The fuel consumptions that may be expected with various types of setting are:—

	Lbs. of coke per 100 lbs. of coal carbonised.
Horizontal retort setting with recuperators	14–17
Continuous vertical retort without recuperators	13–15
Intermittent " " " "	16
" " " with "	14
Coke ovens with regenerators	12

The provision of recuperators or regenerators depends very much on local conditions. If they are fitted, the interest on the extra capital cost involved in recuperators and additional steam raising plant has to be offset against the saving in fuel, less the cost of raising the steam. When fuel costs were low it was generally economic not to fit recuperators to continuous and intermittent vertical installations. During, and since, the war conditions have changed considerably, and it is now unusual not to fit recuperators on intermittent vertical retort installations. It is still usual not to adopt recuperators on continuous vertical retorts, as already much preheating of the secondary air is done by circulation around bottom castings and main seating joists.

In general, horizontal retorts are heated by built-in producers fitted with step grates, one producer serving one setting. On large installations of continuous and intermittent vertical retorts it is the practice to construct outside producers in batteries. The variations in quality and quantity of producer gas are thereby minimised.

Until recently mechanical producers had not been extensively used on gasworks for supplying producer gas to settings. The horizontal retort house at the Partington Works of the Manchester Corporation has used cold producer gas for many years. Some difficulties with gum and tar deposits do occur with cold gas, and recent experiments with hot gas (400° C.) have been made on continuous vertical retort installations. The advantages claimed for the adaption of mechanical producers to gasworks' use are :—

(1) Provision of ample supplies of producer gas under all conditions and at exact pressure required.

(2) Steady quality and heating valve of gas as compared with the fluctuations on small built-in producers frequently inadequate in depth and area.

(3) Provision of dust-free gas leading to long life of refractories and less leakage.

(4) Elimination of poor working conditions on feeding and clinkering producers of horizontal installations.

(5) Ability to produce ample supplies of gas from coke of varying qualities.

(6) Ability to use the smaller grade of coke at present difficult to market.

Producer Grate and Chimney Areas.

Step grate producers are now most commonly employed for heating retorts. The rate of gasification with a modern design varies between 10–20 lbs. of coke per sq. ft. per hour. The higher figure is obtained under forced draught conditions with steam admission.

With mechanical producers high rate of gasification can be obtained. Using graded cokes the following rates were obtained during a recent test :—

Using breeze containing 30 per cent. below $\frac{1}{8}$ in., 40 per cent. $\frac{1}{8}$ in. to $\frac{1}{4}$ in., 30 per cent. over $\frac{1}{4}$ in., the average rate of gasification was 15 lbs. of breeze per sq. ft. per hour.

Using coke nuts containing 10 per cent. below $\frac{1}{2}$ in., 60 per cent. $\frac{1}{2}$ in. to 1 in. and 30 per cent. over 1 in., the average rate of gasification was 23 lbs. of coke per sq. ft. per hour.

These figures are capable of considerable improvement where the producers employ mechanical means to ensure that the top of the bed is level and that rat-holing is minimised. This last trouble is most acute where the material consists of a wide mixture of grades.

For horizontal retort installations brick-built chimneys are most common. The height varies between 50 to 70 ft. The chief considerations to bear in mind are heights of adjoining buildings, avoidance of down draught and shifting winds. The rectangular chimney with an external batter is commonly employed. The batter varies between the limits 1 in 36 to 1 in 40. Retort house chimneys are usually braced for their entire height ; the general method being to run angle irons up each corner, the angles being held in position by tie bands at intervals of 6 ft. An inspection door should be left at the base for cleaning purposes. As regards materials of construction, stock bricks may be employed for external courses, but a lining of fire bricks in the interior is essential. Very frequently the whole chimney is constructed in fire brick, in which case no separate lining is necessary. The height of the chimney is calculated from the formula :—

$$D = H\left(\frac{7 \cdot 6}{t_1 + 460} - \frac{7 \cdot 9}{t_2 + 460}\right).$$

D = Draught in inches water gauge.
H = Height of chimney in feet.
t_1 = Air temperature °F.
t_2 = Mean gas temperature °F.
7·6 = Weight of 100 cu. ft. of air at 60° F. in lbs.
7·9 = „ „ „ „ „ waste gas at 60° F. in lbs.

Mean gas temperature = temperature of the gases entering the chimney less 2° F. for each 3 ft. of chimney.

The draught required by most horizontal settings is about 0·8 ins. water gauge.

The velocity of gases up the chimney should not exceed 15 ft. per second at working temperature, and the area of the chimney should be calculated using this factor.

The gas velocity that can be set up by a chimney varies as the square root of the height.

Composition of Producer Gas.

The following is the average composition under good conditions :—

	Per cent. by volume.
Carbon monoxide	25
Carbon dioxide	5
Hydrogen	6
Methane	1
Nitrogen	63

The analysis of the waste gases emitted from the retort setting should approximate to the following :—

	Per cent. by volume.
Carbon dioxide	19
Oxygen	0·4
Nitrogen	80·6

(The presence of carbon monoxide in the waste gases is indicative of a deficiency of secondary air, and is wasteful in firing. The oxygen, if above 0·5 per cent., denotes an excess of secondary air.)

Gasworks Temperatures.

	°F.
Retorts	1,800–2,100
Ascension pipes	200–300
Foul main (inlet)	140
Condenser inlet)	125
,, (outlet)	78–85
Washers and Scrubbers (outlet)	60
Purifiers (inlet)	60
,, (outlet)	65
Holders	60

The combustion chamber temperatures are varied according to the class of material used in the construction of the setting.

Thus with an all silica setting it would be possible to maintain temperatures between 1,420° and 1,480° C.

With siliceous retorts and silica combustion chambers, temperatures up to 1,400° C. are worked.

Before the introduction of the regenerative system, one of the chief causes of the loss of heat arose from the escape of the waste gases at unnecessarily high temperatures. In such cases the normal temperature at which the gases are allowed to leave the settings is in the neighbourhood of 1,700° to 1,800° F., but by the transference of the sensible heat from these gases to the inflowing secondary air the temperature of the waste gases has, in the modern regenerator, been reduced to 600°–800° F. before their escape is permitted. In the ordinary way, the secondary air approaches a temperature of 1,800° F. before combustion.

The introduction of cold producer gas made in mechanical producers external to the retort house necessitates a design of recuperator such that the secondary air and producer gas can both be preheated to conserve heat, but more especially to permit the necessary combustion chamber temperature of 1,400° C. to be attained.

Waste Heat Boilers.

Even with the installation of regenerators for preheating the secondary air it is found that the waste gases still leave the settings at a high temperature (600°–700° C.), and it is economic to install waste heat boilers for the transfer of this heat into steam.

The horizontal fire tube boiler is commonly used for this purpose, and the gases are drawn through the tubes at high velocity by a mechanically-propelled fan. The fan aids the control of combustion chamber temperatures by giving a steady 'pull' on the waste gas main.

Pressure up to 300 lbs. per sq. in. is now being employed. Depending on the temperature of the waste gases the evaporation on the boilers varies between 2 to 6 lbs. of steam per 1 lb. of fuel fed to the producers.

Horizontal Retort Benches.

The modern horizontal retort house consists of a number of beds each containing 8 to 10 retorts. It is now common to arrange that no more than 10 beds shall be built in one unit braced together so that this unit can in modern works be heated up, worked and cooled down as a unit. The wracking of settings, owing to uneven expansion and contraction, is thereby avoided.

The retorts are generally D shaped, though the elliptical retort gives a better distribution of heat to the coal and reduces the free space in the retort (*i.e.* over the coal and under the crown of the retort). Lately, experiments with narrow rectangular retorts have been tried. The rapidity of the heat transfer leads to greater output for each sq. ft. of ground area.

Most horizontal retorts are now built with silica segments shaped to form the D or ellipse. Such segments would be about 18 ins. long. Siliceous and fireclay retorts are extruded and can be obtained in lengths up to 11 ft. 0 in. The temperatures to which such materials can be heated are lower than the almost pure silica.

Retort Bench Fittings.

The following may be taken as giving the approximate size of ascension pipes necessary with horizontal retorts:—

Works making under 10 million cu. ft. per annum	**5-in. pipes.**
" " between 10 and 200 million cu. ft. per annum	**6-in. "**
" " above 200 million cu. ft. per annum	**7-in. "**

The above refer to retorts having an ascension pipe at both ends. If a single pipe is used it should not be less than 8 ins. in diameter.

Joints for Ascension Pipes.

These must on no account be made with lead. Many engineers will employ none but a rust joint, although the labour entailed in cutting out is considerable and the number of replacements is high. To prepare the material for these joints cast-iron borings should be damped down with gas liquor; the mixture is then rammed well down into the joint space. When the bench is at work the heat soon hardens off the joint. A serviceable joint may be made from the following:—

Ewell brick-dust	**1 part.**
Slaked lime	**2 parts.**

This is rammed into the joint dry, no moistening being necessary.

An excellent joint which combines the hardness and durability of the rust joint with easy cutting out is: The socket is packed with two turns of suitable size asbestos rope, filled with moist fireclay to within half an inch of the top of the socket and finished off with borings to form a rust joint.

For the joints between the cast-iron mouthpiece and the fireclay retort the following may be used: 1 part of cast-iron borings to 2½ parts of fireclay. This mixture is then damped down with a solution of sal ammoniac. The amount of sal ammoniac required is about 1 lb. to every cwt. of fireclay and borings. Ammoniacal liquor may be used in lieu of the sal ammoniac, but the latter is to be preferred as a more complete rusting action is thereby set up.

Hydraulic Mains.

These are now of two types:—

(*a*) Distinct mains, one to every retort bench on either or both sides.

(*b*) Continuous mains, one main extended over a number of settings.

The latter type have their advantages as regards initial cost, but distinct mains are otherwise to be preferred owing to the greater ease with which they are adjusted. In addition, by their use a single setting may be readily shut down and isolated.

The gas off-take from the hydraulics should be arranged from the cover of the box rather than from the side, as is so frequently found.

Owing to the difficulties involved in maintaining the same seal in the various sections of the hydraulic main, which causes either loss of gas due to heavy seals or in-leakage of air due to light seals, other systems of gas collection have been adopted.

With the 'Anti dip' system each dip pipe is fitted with a sleeve which can be raised or lowered from the outside. The retort is discharged with the sleeve down, *i.e.* retort sealed from the hydraulic main. As soon as the charge is laid the sleeves are raised and the retort will then be in direct communication with the gas space in the hydraulic main. Every retort is under the same conditions.

Another development is the use of the scrubber standpipe. The retort mouthpieces are directly connected to a standpipe which is increased in area in proportion to the volume of gas

passing to ensure maximum scrubbing effect and the maintenance of equal pressure on all retorts. At the top of the standpipe is a scrubbing chamber with baffle plates. The foot of the standpipe is connected to a steel box with provision for collecting foreign matter which might be pushed in from the mouthpieces. The tar and liquor flow to separating tanks in the cellar and the liquor is recirculated. It is claimed for this system that it is possible to control accurately the pressure conditions in the retort to within $\frac{1}{50}$ of an inch water gauge; that there is always a free passage for the gas from the retorts and that the irksome labour of cleaning ascension pipes is eliminated.

Retort House Foul Main.

The size of the foul main must depend upon the combined areas of all pipes leading into it. Generally speaking, the following sizes are those prevailing and which may be safely applied :—

Capacity of Bench per 24 Hours.	Size of Foul Main. If one.	If two.
30,000–100,000 cu. ft.	6 ins.–9 ins.	—
200,000–500,000 cu. ft.	12 ins.–15 ins.	—
1 million–1½ million cu. ft.	18 ins.	14 ins.
2 million–3 million cu. ft.	24 ins.	18 ins.

Another rule is that which states that the foul main (if it delivers all the gas) should be 125 per cent. of the area of the main works connections.

The modern practice is to construct the foul main of steel plates either welded or riveted together instead of cast-iron pipes. When steel is used, however, some form of expansion joint should be introduced, for the main is liable to undergo some considerable expansion when the settings are fired from cold. With the cast-iron mains, the lead joints at the spigots will be sufficient to cope with any change of length and flange joints should therefore be avoided, unless some form of expansion joint is inserted.

Tar and Liquor Removal.

The method employed for removing the tar and liquor condensed out of the gas in the hydraulic main is of extreme importance, for if an efficient principle is not employed endless trouble results, in the shape of pitched-up hydraulics, stopped ascension pipes and tar mains, and considerable loss of ammonia. The tar-tower system has been regarded as one of the best methods and is a considerable improvement on the older systems. The objection to the tar tower is that it is not automatic in action requiring periodical 'running off,' during which process there is every possibility of temporarily unsealing the dip pipes.

Retort House Governors.

The retort house governor is an essential auxiliary of the modern retort house. It differs from the station governor in that, whilst the latter is employed with the object of reducing pressure the retort house governor is interposed for the purpose of reducing the intensity of vacuum created by the exhauster. Thus the governor ensures a constant vacuum in the hydraulic main whatever the volume of gas coming away from the coal charges may be. With the bell type of governor the variations of vacuum are transmitted from the bell direct to the valve. Owing to the large size of bell and valve needed for large installations some sluggishness may be experienced.

In such cases it is common to use relay governors, *e.g.* Askania, Arca, Bryan Donkin, etc., in which the pressure changes operate a sensitive mechanism which uses a power-operated circuit using oil, water or gas to move a butterfly valve in the foul main.

The best place for the governor is on the top of the retort bench, as close up to the end of each section of the foul main as possible, for it is not so sensitive when interposed at the inlet or outlet of the condenser as is occasionally found. By-passes should be fitted to the governor, for it will require cleaning out every four months.

CONDENSERS.

The process of condensation is best divided into two sections: (1) Gas cooled to about 80–90° F. in either an atmospheric or water cooled condenser; (2) Gas cooled to about 60° F. in a water cooled condenser. The plant should be arranged so that the exhausters are placed between the two sections of condensers, as this layout ensures that the temperature of the gas at the inlet to the ammonia scrubbing plant is low and should enable the ammonia slip into the purifiers to be kept below 5 grains per 100 cub. ft. without the addition of water.

The table below shows the amount of moisture liberated and the heat to be removed per 1,000,000 cub. ft. (60° F. and 30 in. Bar) when saturated gas is cooled down to 60° F.

Gas Temp.	Vol. of Moist Gas.	Water deposited in cooling to 60° F.	Heat liberated in cooling to 60° F.
70	1,027,000	34·7 galls.	$0{\cdot}6 \times 10^6$ B.Th.U.
80	1,057,000	82·7 ,,	$1{\cdot}3 \times 10^6$,,
90	1,091,000	147 ,,	$2{\cdot}2 \times 10^6$,,
100	1,131,000	237 ,,	$3{\cdot}4 \times 10^6$,,
110	1,179,000	357 ,,	$4{\cdot}9 \times 10^6$,,
120	1,238,000	521 ,,	$6{\cdot}7 \times 10^6$,,
130	1,312,000	742 ,,	$9{\cdot}3 \times 10^6$,,
140	1,409,000	1,050 ,,	$12{\cdot}5 \times 10^6$,,
150	1,534,000	1,479 ,,	$17{\cdot}3 \times 10^6$,,
160	1,724,000	2,120 ,,	$24{\cdot}2 \times 10^6$,,
170	2,002,000	3,099 ,,	$34{\cdot}5 \times 10^6$,,
180	2,460,000	4,745 ,,	$50{\cdot}9 \times 10^6$,,

As can be seen the amount of heat to be removed from the gas rises rapidly with the temperature, and particular attention should be paid to the consideration of condensers if intermittent or continuous vertical plants are installed and steaming of the charge is practised.

The following areas to be allowed for condensing plant represent average practice :—

Atmospheric Condensers.

For air cooled annular condensers allow 5–10 sq. ft. per 1,000 cub. ft. per day.

Water Cooled Condensers.

The modern water cooled condensers are all of the water tube type. Horizontal water tube condensers are normally provided with surfaces of 1·5–2·5 sq. ft. per 1,000 cub. ft. per day. For a modern type of vertical water tube condenser the tube surface provided varies from 2·0–3·0 sq. ft. per 1,000 cub. ft. per day.

The design of water cooled condensers depends on the temperature and moisture content of the gas and the temperature and cost of the available water supply. The larger the cooling area the smaller the water supply needed. It is therefore necessary for each installation to be designed to meet local conditions.

EXHAUSTERS.

The type of exhauster used on gasworks depends largely on the size of that works.

For the smallest size the 2-, 3- or 4-bladed rotary exhauster is commonly used. It is driven by a slow-speed steam engine and gives remarkably trouble-free running provided it is given reasonable attention.

The following formula is a useful guide to the output of 4-bladed exhausters of medium size :—

$$Q = 65D^2LN\,;$$

where

Q = cub. ft. passed by the exhauster per hour.
D = inside diameter of outer drum in ft.
L = length of drum in ft.
N = number of revolutions per minute.

This gives the gross capacity. To arrive at the nett capacity, about 20 per cent. must be deducted (for slip) from the figure obtained.

The speed at which the exhauster operates should be gauged not by a consideration of the revolutions performed per minute but by the peripheral speed of the tips of the blades. This should be approximately constant for all sizes of exhausters and should lie within the limits of 650–850 ft. per minute.

The lubrication of bladed exhausters requires the most careful attention. The best type of lubricant is a mixture of refined creosote and a mineral oil in the proportions of one part of creosote to three parts of mineral oil. A vegetable oil should not be used as this tends to thicken the tar inside the drum.

On the medium size works there is a tendency to abandon the bladed rotary exhauster and to adopt the Roots blower or Connersville exhauster.

This consists of two cast iron impellers formed similar to figure eights rotating in opposite directions alternately trapping pockets of gas and discharging a definite volume at each revolution. The absence of frictional bearing surfaces within the exhauster obviates any necessity for internal lubrication and reduces the power consumption.

Since small high speed steam engines can be used with these exhausters, considerable economies, compared with the bladed type, can be expected in

(a) Ground space occupied.
(b) Steam consumption.

On the largest works and on coke oven plants the high speed turbo exhauster working on the fan principle and providing large clearances is commonly employed.

An advantage of this type is that it has some considerable volumetric capacity per unit of floor space occupied. The construction consists of an outer case provided internally with two or more impellers which rotate on a common axis but in distinct cells. The gas is passed from cell to cell in series until it is discharged from the machine at the requisite pressure, this being dependent upon the size and speed of the impellers. This machine has considerable power in removing tar fog and it can be used for the removal of tar from hot gas.

On the larger works it is usual to maintain a vacuum of about 4 ins. W.G. at the exhauster inlet. At the outlet the pressure to be overcome varies in accordance with the resistance offered by the apparatus following and the quantity of gas passing at that time. As a general rule the total back pressure may vary between 8 to 10 ins. W.G. on a small country works to as much as 50 ins. W.G. on the largest plants, but under average conditions the following pressures will approximate to those found at the different portions of the apparatus :—

Retorts	Level gauge.
Hydraulic main	½in.–1 in. vacuum
Exhauster inlet	4 ins. ,,
,, outlet	30 ins. pressure.
Tar extractor outlet	25 ins. ,,
Washers outlet	24 ins. ,,
Scrubbers outlet	22 ins. ,,
Purifiers outlet	9 ins ,,
Station meter outlet	8·5 ins. ,,
Holder inlet and outlet	8·5 ins. ,,

It will be seen from the above that the forcing of the gas through the dry purification material and the raising of the holder bell forms by far the greatest portion of the work against back-pressure which the exhauster is called upon to perform.

TAR EXTRACTION.

This is done (a) by the use of Livesey type washers in which the gas is forced in fine streams through a layer of a few inches of ammoniacal liquor operating on the wire drawing and bubbling principle; (b) by the use of such an apparatus as the Pelouze and Audouin extractor in which the gas is split into fine streams and impinges at high speed on steel plates. The tar particles, due to inertia, make contact with the plate and the tar flows away as a liquid. (c) By electrical precipitators in which the gas passing through a strong electric field is subjected to a silent or corona discharge. The static rectifier system using a direct current of 40,000–50,000 volts as a rectified sine wave gives excellent results even on hot coal gas or crude water gas. The efficiencies of tar removal with (c) are normally over 99·5 per cent.

WASHERS AND SCRUBBERS.

The capacity of the wet purification plant depends very largely upon the type of apparatus employed, whether mechanical or merely static. The static washer, which was being gradually superseded by the mechanical washer scrubbers, has again become prominent due to the improvement in packing material and the compactness of the circulating pumps. The Livesey type of washer is excellent as a tar extractor and a means of working up the liquor strength when placed immediately prior to some other form of final scrubber, but it is not sufficient on its own to reduce the ammonia content of the gas to the limit of 5 grains per 100 cub. ft. of gas which is common practice.

The Horizontal Mechanical Washer.—In this the gas passes through a number of compartments in each of which it has to pass over packing material fixed to a slowly rotating shaft which dips it in the washing medium.

The Vertical Mechanical Washer.—The gas rises through a cylindrical chamber and has to pass a series of contacts set up by liquid sprayed from members mounted on a rapidly rotating vertical axis.

Tower Scrubber.—The gas ascends a comparatively long tower and is met by a descending stream of liquid which is spread over solid packing elements to give even distribution and maximum contact between liquid and gas.

Static Washers.—These consist of a series of small chambers containing packing material through which the gas passes in series whilst the liquor is pumped over the packing material by means of circulating pumps. With all types of washers and scrubbers counter flow of gas and liquid should be employed and the temperatures of both should be kept as low as possible. The table below, taken from a paper read before the Institution of Gas Engineers in June 1929, shows the effect of temperature upon the possible concentration of ammonia in liquor.

Temperature ° F.	50	60	70	80	90
	Grains of NH_3 per 100 cu. ft. of gas.				
Ammonia in gas in equilibrium with:—					
1 oz. liquor . .	2	3	5	9	17
2 ,, ,, . .	3	6	10	20	35
3 ,, ,, . .	6	10	16	30	55
4 ,, ,, . .	7	13	20	39	69

It is possible to eliminate water from the scrubbing plant by obtaining a supply of liquor weak in free ammonia either from the retort house circulating system or the first section of condensers and by using this instead of water in conjunction with gas which has been cooled to a low temperature. (The normal amount of water added varies between 10–13 galls. per ton of coal carbonised.)

DRY PURIFICATION PLANT.

The capacity of the dry purifiers depends upon the extent to which purification is carried. Nowadays it is customary to remove sulphuretted hydrogen alone, but if lime purification (for the removal of carbon bisulphide) is resorted to, it is advisable to employ rather larger vessels. It is always as well, however, that the vessels should be too large rather than too small, for the first cost increases but slowly as compared with the capacity and purification charges undergo considerable reduction as the unit capacity becomes greater. For oxide boxes the following rule may be taken :—

For a set of four purifiers allow FOR EACH BOX an area of 0·5 sq. ft. per 1,000 cub. ft. of gas to be dealt with per maximum day. If lime is to be used increase this allowance to 0·6 or 0·65–0·7 if no catch boxes are available (Meade). Hunts' rule for the total amount of purification space required, *i.e.*, the combined area of all boxes, says that 20–30 sq. ft. per ton of coal carbonised per maximum day should be allowed.

It may be taken that the purifying capacity of one ton of oxide of iron is two million cub. ft. of gas before it is finally spent.

In order that the oxide of iron in the dry purifiers may be retained in an alkaline condition it is not advisable to remove the whole of the ammonia from the gas. The usual practice is to allow between 1–5 grains of ammonia per 100 cub. ft. of gas to remain.

Purifiers are invariably square or rectangular in shape. Cast iron plates bolted together are generally employed, but many installations built in reinforced concrete have been made. Some welded steel purifiers have also been constructed. As regards the necessary thickness of cast iron plates the following figures may be taken as indicative of the general practice :—

Purifiers up to 10 ft. square	. . . .	$\frac{5}{8}$ in. plates.
,, ,, 20 ,, ,,	. . . . .	$\frac{11}{16}$ in. ,,
,, above 20 ,, ,,	. . . . .	$\frac{3}{4}$ in. ,,

The flanges are usually cast $\frac{1}{16}$ in. to $\frac{1}{8}$ in. thicker than the body. The smallest vessels are usually 3 ft. deep while the largest sizes vary from 6–8 ft. in depth. The following rule is suggested for ascertaining the required depth :—

$$\text{Depth in ft.} = \sqrt[4]{\text{Total superficial area}} \times 1\cdot 1$$

The depth as given may be taken to the nearest foot. For smaller purifiers, *i.e.* up to 300 sq. ft. in area multiply by 1·3 instead of 1·1.

It is advisable to stiffen the sides of purifier boxes by the casting of vertical rib stiffeners at about 2 ft. 6 ins. centres on the plates.

TOWER PURIFIERS.

The latest developments have been in the direction of reducing the ground space occupied by an installation. One method is to use very deep boxes with oxide in eight tiers each 16 ins. deep, arranged so that the flow of gas can be frequently reversed. Another attempt at reducing the superficial area of the plant has been tried at the Wandsworth and District Gas Company's main works in the 'Tower' purifiers. These consist of six towers each of which has an outer

shell 22 ft. in diameter and 52 ft. in height, closed at the top and bottom. The top cover is removable. Each tower contains 12 superimposed containers filled with oxide; each of these is polygonal and holds two tiers of oxide supported on wooden grids. Each container consists of a central tube and two oxide containing trays. The gas is introduced between the layers of oxide from a centre feed and passes through a single layer of oxide to the annular space between the trays and the body of the tower and thence to the outlet. It is claimed that this method required only one-third of the area covered by the old ground level boxes and less than two-thirds the area covered by deep overhead boxes.

The capital cost is comparatively low and the handling charges should be less than normal due to the increased use of machinery. For this reason also the time during which a tower is out of action is small.

Purifier Valves.

The modern practice is to construct new purifiers without catch boxes. It is customary to work 'backward rotation,' *i.e.* to alter the sequence of boxes thus :—

1234 4123 3412 2341 1234

the time between changes depending on the condition of the oxide in the boxes, the amount of gas passed and its sulphuretted hydrogen content. This time varies from hours to about five days. It is essential that the changes shall be made rapidly and easily and that the valves shall remain gastight since the Gas Referees test paper is darkened if the H_2S content of the gas is more than 1 part in 500,000 parts.

For small installations the centre valve working on the principle of the plug cock is employed.

For larger units the connections can be brought to one central box divided into inlet and outlet sections. The gas is controlled by disc valves. The discs may provide iron to iron connections or may be packed with white metal or greasy hemp packing. The best known of this centralised type is the Weck valve. The Milbourne valve employs disc valves but has not the central box.

The hydraulic valve employing either U-shaped connections or a box with a midfeather has been used for many years and has been employed on many modern large installations.

On all types of purifiers it is possible to instal the ordinary double-faced or single-faced gas valves instead of using the types given above. Care should be given to maintenance of all valves as faulty seatings will quickly allow foul gas to go forward to the holders.

Purifier Connections.

The diameter of the connecting mains is most readily and accurately computed from the following formula :—

$$\text{Diameter of pipe in ins.} = \sqrt{\text{area of each box in sq. ft.}}$$

For small purifiers (up to 60 sq. ft. area) the result can be taken as it stands, but for medium size boxes deduct 16 per cent. and for large vessels 25 per cent.

Modern purifiers are of the dry lute type which does not blow under temporary additional pressure and is not subject to freezing in the winter.

The cover is constructed of steel or wrought iron plate about ¼ in. thick, supported by some form of trussing. The joint between the cover and the box is made by inserting a strip of rubber or tallowed hemp between the parallel flanges, the two flanges being afterwards pulled together by means of special fasteners or ordinary bolts.

With modern purifiers it is customary not to have the boxes at ground level so that discharging can be quickly done by unloading the oxide through convenient openings in the bottom of the box on to the ground. The rate of recharging can be made equally rapid if a storage floor is provided over the box or rapid mechanical elevators and conveyors are available.

The effect of the elevation of the boxes has been the chilling and subsequent lack of activity of the oxide in the box.

The purifier preheater has been designed to minimise this trouble. In general it consists o a nest of steam-heated tubes around which the gases circulate before purification.

Insulation of the lids by blankets filled with glass wool or fibre glass has proved of advantage in maintaining the boxes in an active state.

Station Meters.

Station meters are for measuring the production of gas or the sale of gas in bulk. They may be divided into three classes.

(1) Positive displacement meters.
(2) Semi-positive meters.
(3) Inferential meters.

Positive Displacement Meters.

The drum type is widely used as a station meter. It is extremely accurate over its whole range. In this meter the water level is fixed just about the centre and gas enters through the hollow axis in the four compartments of the drum, filling each in turn. The pressure of the gas causes the

drum to rotate and operate the integrating device. The Holmes 'B.M.' meter is also of the wet type, using oil or water as a sealing fluid. The method of metering is the filling and emptying of three or more chambers which form part of a roughly spherical drum. This drum is supported on a central pivot and runs on an outer circular rail. The drum itself does not revolve but its axis performs a circle and thereby gives the drive to the counter mechanism. This meter is being increasingly used for metering the gas consumption of large industrial users.

Semi-Positive Meters.

The best known of this class—the 'Holmes-Connersville'—is similar in construction to the exhauster of the same name. Two impellers, figure 8 in section, are geared together and supported on bearings within a cast iron casing. The gas entering the top exerts a pressure on the impellers causing them to rotate. In each revolution the gas trapped between the impeller and the casing is allowed to pass. Since the impellers do not touch the casing there is some slip. The meters have an accuracy within 1 per cent. The space covered by the meter is small and the pressure loss across the meter about ½" W.G.

Inferential Meters.

These are the rotary fan type, the thermal meter or differential pressure meter.

STORAGE CAPACITY.

The holder capacity necessary is somewhat dependent upon whether or not the works is provided with a water gas plant. If such a plant is available the storage allowed for need not exceed 18 hours maximum make, but if there is no water gas to fall back upon provision should be made for 21 to 24 hours maximum production. In years gone by it was customary to provide considerably greater storage chiefly on account of the heavy fluctuations in output. The levelling up of the hourly load-curve has, however, had a marked effect in the direction of diminishing the quantity of gas kept in hand.

PROPORTIONS OF GASHOLDERS.

Single lift height = 0·3 to 0·4 of diameter.

Multiple lift height = 0·6 to 1·0 of diameter.

In computing the capacity of a holder the volume enclosed by the crown is neglected, as the gas contained therein is not available for distribution. Accordingly

$$\text{Capacity in cub. ft.} = 0{\cdot}7854 \times \text{diameter in ft.}^2 \times \text{height in ft.}$$

With multiple lift holders the capacity of each lift should be estimated separately by applying the above formula to each section.

DEPTH OF LIFTS.

Each lift will be approximately of equal depth.

RISE OF CROWN.

The greater the rise the stronger will be the crown. The dome should conform to a segment of a sphere. Normally, the rise will range between $\frac{1}{15}$th to $\frac{1}{20}$th of the diameter, but when trussing is employed it may be less than when the plain crown only is used.

The cubic capacity of the crown space may be found from the following :—

$$\text{Volume in cub. ft.} = {\cdot}5236R\left(R^2+\frac{3D^2}{4}\right),$$

where,

R = rise of crown in ft.;

D = diameter of top lift in ft.

The depth of each lift should never be less than one-seventh of its diameter, otherwise locking or tilting may occur. In general, the proportion varies between one-fourth to one-fifth of the diameter.

The crown sheeting of gasholders varies from 14 gauge to 10 gauge (about $\frac{5}{64}$ in. to ⅛ in.); but much depends upon the size of the holder.

The side sheeting varies from 12 gauge to 10 gauge, but curb or cup and grip rows are thicker, ¼ in. to ⅜ in. Top lift sheets are usually thicker than those of succeeding lifts, often about 8 gauge.

The thinner sheets of the bell are generally riveted up cold with ¼ in. rivets at a pitch of 1 in. to 1¼ in. All rivets above ⅜ in. must be driven hot.

GASHOLDER TANKS.

Steel tanks have many advantages over the masonry variety, and cast-iron as a material for this purpose may now be looked upon as obsolete.

The thickness of plate required may be calculated as follows :—

$$T = \frac{PD}{2fe},$$

where

T = thickness of the plate in ins.

D = diameter of the tank in ins. ;

f = allowable working stress (usually $5\frac{1}{2}$ tons per sq. in.) ;

e = the efficiency of the vertical riveted seams. This will range up to 90 per cent. for large holders. For small holders it will vary between 75 and 85 per cent. ;

P = the pressure due to the water in lbs. per sq. in.

The latter may readily be found from the following :—

$$P = WD,$$

where,

W = the weight of a cub. ft. of water = 62·4 lbs. ;

D = depth below the surface of the section under consideration.

As regards the apportionment of the cost of gasholders, the following figures represent normal conditions :—

	Per Cent. of Total Outlay.
Bell, complete	35 to 45
Guide framing	18 to 23
Tank (steel)	35 to 45

Calculation of Pressure Thrown.

The pressure thrown is dependent upon the weight of the floating portion and its diameter. It may be found as follows :—

$$\text{Maximum pressure (ins. of water)} = \frac{549W}{D^2},$$

where,

W = weight of bell and water in lutes, in tons

D = diameter of holder in ft.

When dealing with a multiple lift holder take the mean diameter.

Waterless Gas Holders.

These holders comprise a vertical continuous shell of circular or polygonal cross-section having its two ends closed respectively by a bottom plate and a roof, the latter being usually fixed rigidly to the shell. A movable piston guided by wooden rollers slides up and down inside the shell, rising and falling to the change in contents of the holder. Additional pressure is obtained by concrete weights affixed to the piston deck. Waterless holders varying in capacity from 50,000 to 20 million cub. ft. are in use.

The various types of waterless holders differ mainly with regard to the method of sealing the piston and the shell. The 'Klonne' holder effects the seal by means of rubber impregnated cotton fabric interspersed and covered top and bottom with leather. The pad is lubricated by a special lubricant introduced through cups fitted to it at intervals. The 'Bamag-Meguin' holder employs a leather tube filled with oil from a reservoir placed in the centre of the piston of the holder. In the 'M.A.N.' holder the seal between the piston and inner shell is effected by an annular trough containing a quantity of prepared tar equal to not less than twice the pressure of the gas underneath the piston. Contact with the shell surface is by steel rubbing bars kept in position with counterweighted levers. This tar seal prevents gas leakage, lubricates the piston and preserves the interior surface of the shell.

The following advantages are claimed for the Waterless holder :—

1. Constant pressure.
2. Less weight than with water tank holder and consequently cheaper foundations.
3. Easy to extend while in use and more rapid construction and erection.
4. Eminently suitable for storage of dehydrated gas.
5. No risk of freezing up in cold weather.
6. No immersion of plates in water, reduced corrosion and lower painting costs.

Pressure Gasholders.

With the extension of the supply of gas to thinly-populated districts the problem of economical distribution of gas has arisen. One solution is to have a small pressure gasholder filled during

off-peak periods and which will feed back into the distributing system during the periods of heavy loads.

Pressure holders are normally built in units from 10.000 to 250,000 cub. ft. releasable capacity. Pressures range from 50 to 70 lbs. per sq. in. but higher pressures can be employed. As the cost is almost independent of the number of units, one can be installed initially and additions can be made later.

The following points are claimed for pressure gasholders :

(1) They are small and compact and can be cylindrical or spherical to suit the site.

(2) Can be used in high pressure distributing systems or to supply peak demands in low pressure systems.

(3) They are of heavy plate construction and those of the cylindrical shape can easily be protected against war conditions.

(4) Low painting costs ; low foundation costs ; no risk of freezing and no moving parts.

(5) Installations can be built to be entirely automatic in operation.

Inspection of Gasholders.

The examination of gasholders was rendered compulsory by the Factories Act, 1937.

Clause 33 refers specifically to gasholders :—

(1) Every gasholder should be of sound construction and shall be properly maintained.

(2) Every gasholder shall be examined externally by a competent person at least once in every period of two years and a record containing the prescribed particulars of every such examination shall be entered in or attached to the General Register.

(3) In the case of any gasholder of which any lift has been in use for more than twenty years, the internal state of the sheeting shall, within two years of the coming into operation of this section and thereafter at least once in every period of ten years, be examined by a competent person by cutting samples from the crown and sides of the holder or by other sufficient means, and all samples so cut and a report on every such examination, signed by the person making it, shall be kept available for inspection.

(4) A record signed by the occupier of the factory or by a responsible official authorised in that behalf, showing the date of construction as nearly as it can be ascertained of the oldest lift of every gasholder in the factory shall be kept available for inspection.

(5) Where there is more than one gasholder in the factory, every gasholder shall be marked in a conspicuous place with a distinguishing number or letter.

(6) No gasholder shall be repaired or demolished except under the direct supervision of a person who, by his training and experience and his knowledge of the necessary precautions against risks of explosion and of persons being overcome by gas, is competent to supervise such work.

(7) In this section the expression 'gasholder' means a water-sealed gasholder which has a storage capacity of not less than 5,000 cub. ft.

The Fourth Report of the Gasholder Committee of the Institution of Gas Engineers (*Transactions* 1937–39), gives the particulars to be noted at each examination to conform with the requirements of the Factories Act. Inspection of gasholders is undertaken by contractors or by the Insurance Companies specialising on engineering business.

COAL STORAGE.

At the present time it is necessary for gas works to keep in hand much larger stocks than were thought necessary some years ago. Whilst it is better to store coal under cover if possible, no serious deterioration takes place if it is stored in the open and the problem of coal handling is simpler as such devices as the drag line scraper can be used. Due to the oxidation of coal with a consequent rise in temperature the selection of coal for storage should be made with care.

Some coals are more prone to spontaneous combustion than others. The coal heaps should, if possible, be kept below 15 ft. in height, but 20 ft. should not be exceeded.

To enable the temperatures at the base of the coal heaps to be taken weekly, wrought iron pipes, 2 in. diamenter, with closed spiked ends, should be placed in the heaps before storage.

A thermometer can be lowered down these tubes. If it is found that the temperatures are rising above 100° F. the coal at these points should be moved and if possible carbonised.

It appears from researches carried out on the effects of storage on coal (*Trans. Inst. Gas Eng.*, Communication 201, by Jamieson and Skilling) that whilst the volumetric yield is but little altered, the calorific value and hence the thermal yield were reduced. The quality of the coke was also poorer.

Coke Storage.

One ton of coke occupies 85 cub. ft. (average).

For the convenience of dealing with stocks of other materials used on gasworks the following figures are given :—

One ton of broken coal occupies	40 cub. ft.
,, ,, cannel coal occupies	35 to 45 cub. ft. (varies considerably)
,, ,, anthracite coal occupies	35 to 39 ,,
,, ,, breeze occupies	60 to 65 ,,

,, ,, ashes	50 ,, (about).
,, ,, Portland cement	23 to 26 ,,
,, ,, loose earth	28 to 30 ,,

In gas undertakings the revenue from coke and breeze represents 25 per cent. of the total income and increasing care is given to the preparation of this solid smokeless fuel. In normal times the coal to be carbonised is carefully selected for its gasmaking and coking qualities. Durham and Somerset coals produce dense blocky cokes—these are ideal for steam raising and central heating plants. Yorkshire and Lancashire coals are less strongly coking and produce a more open coke which is more suited to use in the domestic grate. Coals from the Notts and Derby coalfields produce a less dense coke but the proportion of breeze is higher. Scottish coals are generally of poor coking power.

Preparation of Coke.

The demands of the local market for coke will bear very largely on the coals to be carbonised and more particularly on the type of plant in which such carbonisation will be effected. Static carbonisation produces coke which is less reactive but denser than that produced in continouus vertical retorts.

From the point of discharge from the retort until the placing of the coke in the consumers' store care must be taken to prevent the following :—

1. Combustion of coke due to insufficient quenching.

2. Excessive dust formation if insufficiently quenched. (A moisture content of about 5 per cent. is required to effect this.)

3. The degradation of the fuel by rough handling. The value of 1 ton of coke is at least three times the value of 1 ton of breeze.

Coke is therefore transported by rubber belt conveyors, screened with the minimum of violent movement and lowered into storage hoppers by inclined or spiral shoots. It is usual to store coke in the sizes in which it is sold. The types of screens used are :—

1. *Static.*—These require ample headroom and are generally unsatisfactory.

2. *Rotary Screen.*—The cylindrical screen is placed at an angle of 5°–10° and the coke descends. The efficiency of the screen is limited as so much of the mesh is inactive at any given time.

3. *Conveying Screen.*—These jigging screens convey and screen at the same time. The upkeep is high but they have the advantage of delivering into the correct hoppers without the use of belt conveyors.

4. *High Speed Vibration Screens.*—These have one, two or three decks and are most efficient.

With all screens handling coke, high upkeep costs must be expected, due to the abrasive nature of the material handled.

The storage facilities provided in bunkers should be adequate to store the coke made over the week end.

If a large amount of coke has to be stored in the summer in order to meet the winter demand, consideration should be given to stocking graded coke in its various sizes. Dumping should be by specially designed plant which 'places' the coke on the heap and reclamation by a Smith-Harmer loader which not only picks up the coke but also debreezes it as well.

The sizes of coke recommended by the Institution of Gas Engineers Committee of Enquiry on Coke Quality (1942) were :—

Name.	No.	Sizes : Square Mesh Screen.
Large or unbroken .	1	No upper limit. Over 1¾ ins.
2 ins. × 3 ins. . .	1a	Within limits 3½ in. to 1¾ ins.
Broken	2	,, ,, 2 ins. to 1 in.
Coke boiler nuts . .	3	,, ,, 1¼ ins. to ½ in.
Forge coke . .	4	,, the limits ¾ in. to ⅜ in.
Screened breeze . .	5	Unwashed fuel approximately ⅜ in. to ⅛ in. from which fines up to ⅛ in. have been removed.

It is also recommended that cokes be known by numbers.

Products of Distillation.

One ton of average gas coal will yield (approximately) the following products :—

Gas	14,500 cub. ft., or approximately 72·5 therms.
Coke	12 to 13 cwts., excluding breeze.
Breeze	1 cwt.
Tar	9 to 11 gallons.
Motor Spirit	2 to 3 gallons.
Ammoniacal liquor	32 to 40 gallons at 8 ozs.
Sulphate of ammonia	24 to 28 lbs.
Sulphur	5 to 7 lbs.
Cyanogen (HCN)	4 lbs.
Virgin liquor	10 to 12 gallons.

The yield of gas as given above is the normal quantity of straight coal gas obtained, but it should be borne in mind that the modern vertical retort in which 'steaming' is employed will give a yield of from 85 to over 100 therms per ton of coal.

(The sulphate of ammonia is obtained from the ammoniacal liquor, and not in addition to it. The virgin liquor is included in the figure given for total yield of ammoniacal liquor. The figure given for sulphur is that which may be recovered during purification of the gas, and does not include the quantity remaining behind in the coke.)

The approximate distribution of the elements of the original coal, and the manner in which each exists after the process of carbonisation, is illustrated in the following table :—

One ton of coal, consisting of :—

Carbon, 1,792 lbs., distributed as—	Lbs.
Coke	1,385
Breeze	107
In gas, as CO and CO_2	30
In gas, as hydrocarbons	130
In tar	122
As scurf, cyanide, etc.	18
Hydrogen, 123 lbs., distributed—	Lbs.
In gas and tar	98
As ammonia	1·0
As water	18·5
In coke	5
Oxygen, 197 lbs., distributed—	
In gas, as CO, CO_2, and combined in tar	49
As water	148
Nitrogen, 34 lbs., distributed—	
In gas (free)	11·8
In coke	14·6
In tar (combined)	1·0
As ammonia	5·8
As cyanogen	0·8
Sulphur, 18 lbs., distributed—	
As gaseous impurities and in liquor	6
In coke	12
Ash remaining in coke and breeze	75
Total . . .	2,240

Cost of Manufacturing Coal Gas.

The cost of manufacturing town's gas depends primarly upon the capacity of the works, its geographical position relative to suitable coal-fields, and the character of the plant in use. It must be borne in mind, too, that the actual cost of production (*i.e.* cost into gasholder) represents only less than one-half of the ultimate selling price, the remainder being accounted for by the cost of distribution, overhead charges, dividends, etc.

Gasworks Conveyors and Elevators.

The formula given below may be taken as giving a useful guide as to the capacity of bucket conveyors :—

$$\text{Capacity} = \frac{S \times B \times W}{96{,}768 \times P} \text{ tons per hour,}$$

where,

B = capacity of buckets in cub. ins. ;
S = speed of conveyor in ft. per minute ;
W = weight per cub. ft. of substance carried ;
P = pitch of buckets in ft.

The horse-power required to operate elevators and conveyors may be readily arrived at by adopting a coefficient of friction in accordance with the conditions under which the machine is working.

Let M = the weight of material carried in lbs.
W = the weight of the moving parts in lbs.
K = the coefficient of friction.
S = the speed of the conveyor or elevator in ft. per minute,

then, for

(*a*) Vertical elevator:

$$\text{H.P.} = \frac{M \times S}{33{,}000} + \frac{K \times S(M+W)}{33{,}000};$$

(*b*) Inclined elevator:

Let $a°$ = the angle of inclination with the horizontal, then,

$$\text{H.P.} = \frac{M \times S \times \sin a°}{33{,}000} + \frac{K \times S(M+W)\cos a°}{33{,}000};$$

(*c*) Horizontal conveyor:

$$\text{H.P.} = \frac{K \times S(M+W)}{33{,}000}.$$

As regards the value of K, the following figures may be taken:

0·15 for metal sliding on metal :
0·07 to 0·08 „ „ (well lubricated) ;
0·25 for wood sliding on wood.

Purification of Coal Gas.

The purification of coal gas is carried out in two stages, namely, by means of wet purification in the washers and scrubbers and afterwards in the dry purifiers. During the wet purification of the gas the alkaline ammonia is made use of for removing a portion of the acidic impurities, sulphuretted hydrogen and carbon dioxide. The two last-named are, therefore, absorbed with the formation of certain salts, which are themselves soluble in water. The resultant solution consists of water containing a certain proportion of these salts, and is known as ammoniacal liquor. In crude coal gas the ammonia content is usually in the neighbourhood of 1·5 per cent. by volume, and of this amount from about one-third to one-half will have been deposited prior to the gas reaching the wet purification plant. Hunt has given the following figures for the distribution of ammonia :—

	Per cent. of total.
Ammonia removed by condensation	42·7
„ „ first scrubber . . .	43·3
„ „ second scrubber . . .	14·0

When gas containing carbon dioxide and sulphuretted hydrogen comes in contact with a solution of ammonia both acid and normal salts are formed. Thus we have :

(*a*) $2NH_3 + H_2O + CO_2 = (NH_4)_2CO_3$ (normal) (*c*) $2NH_4OH + SH_2 = (NH_4)_2S$ (normal) $+ 2H_2O$.
(*b*) $NH_3 + H_2O + CO_2 = NH_4 HCO_3$ (acid) (*d*) $NH_4OH + SH_2 = NH_4 HS$ (acid) $+ H_2O$.

Composition of Gas Liquor.

The ammonia present in gas liquor is combined in two distinct ways. In the first place it is present as easily decomposable compounds such as carbonates and sulphides, and secondly, as

more stable compounds which will only undergo decomposition by heating in the presence of a caustic alkali. In general, the final mixture of gas liquor obtained consists of from 75 to 80 per cent. of the more unstable salts, i.e. 'free' ammonia, whereas the remaining 20 to 25 per cent. is made up of the more stable salts, i.e. 'fixed' ammonia. The possible constituents of gas liquor are enumerated below, although it must be borne in mind that any one sample of liquor will seldom contain all of the compounds given. In fact, some of those included are only met with on rare occasions.

Water, containing in solution:—

Ammonium carbonate	'Free' ammonia.	Ammonium chloride	'Fixed' ammonia.
„ bicarbonate		„ sulphocyanide	
„ carbamate		„ sulphite	
„ sulphide		„ thiosulphate	
„ hydrosulphide		„ sulphate	
„ cyanide		„ ferrocyanide	
„ polysulphide		„ acetate	

Also phenols, amines, and other nitrogenous bodies.

The amount of ammonia in gas liquor is in reality quite small, and varies between 1·5 and 2 per cent. In general, it will be apportioned as follows:—

	Per cent.
'Free' ammonia	1·2 to 1·6
'Fixed' ammonia . . .	0·3 to 0·4

The following figures relate to sulphuretted hydrogen and carbon dioxide:—

	Per cent.
Carbon dioxide in gas liquor .	1·3 to 2
Sulphuretted hydrogen . .	0·1 to 0·6

The distribution of the total ammonia in gas liquor varies, of course, to some considerable extent. The following table, however, refers to the average solution:—

	Per cent. of total ammonia.
Ammonium sulphides	6
„ carbonates	74
„ chloride	15
„ sulphocyanide	1·75
„ thiosulphate, sulphite, etc.	3
„ sulphate	0·25

The most effective manner of operating the washing and scrubbing plant is to ensure that the gas on first entering the apparatus is treated with the strongest liquor available. In each succeeding vessel the washing liquor employed becomes gradually weaker and weaker until, in the final scrubber, clean water should be employed. Where circumstances permit, it is preferable that the first washer should be operated with the liquor from the hydraulic main, for in this way both CO_2 and SH_2 may be considerably reduced.

The amount of water which must be added for the purpose of wet purification seems to vary to some considerable extent in accordance with the conditions prevailing.

The writer has found with Durham coal that the ammonia may be completely removed in ordinary coke filled tower scrubbers by adding 10–13 gallons per ton of coal carbonised. When mechanical washer scrubbers are in use the quantity of water required will be considerably less. If the gas is cooled after the exhauster and liquor having a free strength of under '1 oz.' is used, it should be possible to eliminate water from the washing plant.

Ammonia Lost.

The quantity of ammonia lost in the direction of that permitted to go forward from the final scrubber may be conveniently calculated as so many gallons of 10 oz. liquor.

$$\left.\begin{array}{l}\text{Quantity of 10-oz. liquor}\\ \text{lost per week (in gallons)}\end{array}\right\} = \frac{\text{Total grains of ammonia passing forward from scrubber per week.}}{1{,}522}$$

Impurities in the Gas at various stages.

Outlet of condensers—	Grains per 100 cub. ft.
Ammonia	200 to 300
Sulphuretted hydrogen	600 „ 900
Carbon dioxide	900 „ 1,400
Sulphur compounds	20 „ 45
Hydrocyanic acid	60 „ 80
Naphthalene	20 „ 25

Inlet of purifiers—	Grains per 100 cub. ft.
Ammonia	nil to 1·5
Sulphuretted hydrogen	450 „ 700
Sulphur compounds	20 „ 45
Hydrocyanic acid	50 „ 70
Carbon dioxide	750 „ 1,150

Outlet of purifiers—	Grains per 100 cub. ft.
Ammonia	nil
Sulphuretted hydrogen	nil
Carbon dioxide	750 to 1,150
Sulphur compounds	20 „ 45
Hydrocyanic acid	nil „ 10

(The last three named above may all be removed, or partially removed, by the employment of special processes, but in the majority of gasworks such processes are not resorted to.)

Removal of Sulphuretted Hydrogen.

Sulphuretted hydrogen is now almost universally removed by means of oxide of iron in one of its forms. Natural ferric oxide (bog-ore) is still largely employed for the purpose, although in recent years various artificial preparations have found a good deal of favour, chiefly owing to their lower cost. The natural bog ore is chiefly obtained from deposits in Holland, Belgium, and Ireland. In the dried state its composition varies between the following limits :—

	Per cent.
Hydrated ferric oxide (Fe_2O_3, H_2O)	60 to 65
Organic matter	15 „ 25
Silica	3 „ 6
Alumina	1

The active material in bog-ore and artificial preparations is not actually the iron oxide, but the oxide plus a certain quantity of water of combination, i.e. a hydrated ferric oxide. In addition to this moisture the material as used should contain a further quantity of water, usually from 20 to 30 per cent. The artificial oxides are employed with a similar degree of moisture. The made-up or artificial material, if of good quality, is usually rather more active than the natural product, owing to a rather higher content of ferric hydrate, which may reach so much as 70 to 75 per cent.

Reactions during the Removal of Sulphuretted Hydrogen.

The absorption of H_2S by the active oxide occurs in two distinct ways :—

$$(a)\ Fe_2O_3, H_2O + 3H_2S = Fe_2S_3 + 4H_2O.$$
$$(b)\ Fe_2O_3, H_2O + 3H_2S = 2FeS + S + 4H_2O.$$

In the first instance ferric sulphide is formed, whilst secondly the result is ferrous sulphide and some free sulphur.

When spent and inactive the material is removed from the purifier and subjected to the process of revivification, or exposure to the air, when the sulphides are oxidised to oxides and the material is ready for further use. The following are the revivification reactions :—

$$(a)\ 2Fe_2S_3 + 3O_2 + 2H_2O = 2Fe_2O_3, H_2O + 3S_2.$$
$$(b)\ 4FeS + 3O_2 + 2H_2O = 2Fe_2O_3, H_2O + 2S_2.$$

Oxide is generally laid in the purifiers on grids to a depth of from 8 to 10 ins. In some works, however, it is customary to employ layers as deep as 48 ins. In this case hurdle grids would be used to help break up the oxide.

A space of at least 2 ins. should be left between the top of one layer and the base of the sieves or grids of the layer immediately above. Oxide, as it becomes fouled increases in bulk, hence this precaution. Partial revivification *in situ* is nearly always arranged for in present-day systems. This is effected by admitting a small measured quantity of air to the purifiers along with the gas. The air may be taken from a small compressor and forced into the box or may be injected by means of steam. In other cases it is sucked in with the gas through a pipe attached to the main on the inlet side of the exhausters. When air is admitted at some point prior to the washers and scrubbers it should not be overlooked that undesirable reactions may be set up in the wet purification plant.

It is generally understood that the material in any one purifier cannot simultaneously extract sulphuretted hydrogen and undergo revivification. The assumption is not entirely accurate, but the process of sulphiding takes place at a very much more rapid rate than does the oxidation effect.

If the capacity of the purification plant is not ample the full effect of the admitted air will not be realised. The volume of oxygen required to revivify is given by the equation—

$$2H_2S + O_2 = 2S + 2H_2O.$$

Thus 0·5 per cent. of oxygen is sufficient to oxidise to sulphur 1 per cent. of sulphuretted hydrogen. As the H_2S content of the gas does not often exceed 1½ per cent. by volume 0·75 per cent. of oxygen or 3·7 per cent. of air is all that is required to produce this action in the purifiers. To obtain the full effect of the air, excess over that required theoretically must be admitted. On account of the reduction in calorific value due to the dilution of inert gases it is not generally desirable to add more than 3 per cent. air.

It is essential that the amount of air admitted to the gas stream shall be carefully controlled and apparatus is installed at some works for the purpose. The amount of air required is decided by chemical analysis and the system of governing applied maintains the same proportion of air whatever the fluctuations in make.

With continuous vertical retorts admission of excessive air will cause the calorific value of the gas to fall; the calorific value of the gas in the retort house will be raised by reduction in steaming and hence the volume of gas and the thermal yield from the plant will fall. Thus, with a continuous vertical retort house supplying to the district gas having a calorific value of 460 B.Th.U./cub. ft., if the unpurified gas contained 0·9 per cent. H_2S by volume and 4 per cent. air is admitted it can be shown that the reduction of air to 3 per cent. will allow for an increased thermal yield of 1·8 per cent.

Removal of Naphthalene.

If the gas is not treated for the removal of naphthalene on the works, it will in general contain from 6–12 grains per 100 cub. ft. Butterfield has pointed out that a million cub. ft. of gas cooled from 68°–50° F. may deposit 14 lbs. of naphthalene. The introduction of carburetted water gas plants has to a certain degree mitigated the naphthalene evil although its effect in this direction is somewhat erratic. Carburation with the aid of solvents was introduced by Botley, who injected, by means of a special spray, about 4 gallons of thoroughly atomised paraffin per million cub. ft. of gas. Botley found that petroleum oil was more suitable for the purpose than spirits such as benzol.

Where oil-washing plants for the extraction of benzol are installed the reduction in the naphthalene content of the gas will be automatic if the oil in circulation is maintained in good condition by frequent make up of clean oil or continuous tapping of the fractions containing the naphthalene.

Paraffin, water gas tar, anthracene oil and gas oil have all proved effective in stripping the naphthalene from the gas if an efficient washer is provided. The rate of oil circulation is quite low—20 gallons per million cub. ft. of gas washed.

The Recovery of Crude Benzol.

The 'stripping' of gas for the recovery of the aromatic series of hydrocarbons is now the regular practice in the majority of gas works. The coal gas, either in the semi-crude state (*i.e.* after the wet purification plant) or preferably when completely purified, is subjected to washing with a solvent, gas oil, green oil or spindle oil. The gas is washed with the solvent in a mechanical or static washer the normal rate of circulation being 100 gallons per ton of coal carbonised. The 'benzolised' oil which may contain up to 5 per cent. of benzene hydrocarbons is then taken to the still in which it is subjected to steam distillation. The benzol vapours with steam and other naphtha fractions are passed through a dephelegmator (this is a tubular heat interchanger), wherein the temperature being lowered by preheating the incoming oil the naphtha fraction is thrown down and is collected for sale or re-use. The remaining vapours pass up the fractionating column and the quality of the spirit is controlled by a water-cooled analyser. Only spirit of a low boiling point can pass through as vapour, the remainder being thrown back in a liquid state for further fractionation. The vapours are condensed and the water removed. The yield of benzol depends upon the rate of oil circulation and washing efficiency, but it should be possible to recover 3 gallons of crude spirit per ton of coal carbonised. The crude spirit will vary in composition, but in general 65–70 per cent. will distil over up to 120° C. and 80 per cent. up to 160° C. The portion which distils over will consist of about 80 per cent. of benzol, 15 per cent. of toluol and the remainder xylol.

The efficiency of benzol extraction depends on: (*a*) The completeness of stripping in the distillation plant; (*b*) Quality of the oil (freedom from water and naphthalene); (*c*) Temperature of the cooled oil. This should not exceed 80° F. and should be maintained 5° F. above the temperature of gas; (*d*) Quantity of the oil in circulation. The more oil is used the greater the efficiency; (*e*) Absorptive capacity of the wash oil used.

Spindle oil is used on many works in preference to gas oil, as no sludging of the oil is experienced. With gas oil the steam distillation gradually gets rid of the lighter fractions and with a sudden fall in temperature setting of the oil takes place. The yield of benzol with spindle oil as the absorber is slightly lower than with gas oil. Due to its higher viscosity some alteration to the design of plant may be required if maximum circulations are always worked.

The crude benzol is treated for the reduction of gum-forming hydrocarbons and sulphur impurities by washing with caustic soda and sulphuric acid prior to redistillation. The product obtained is well within the limits of National Benzole Association's Specification.

The Active Carbon Process.

The advantages claimed for this method are: (1) The benzol is recovered direct and is free from wash oil and impurities derived therefrom. The cost of refining is reduced. (2) A higher efficiency of recovery of the benzol from the gas. (3) Smaller heat and power requirements. The disadvantages of the system are: (1) The process is intermittent. (2) Naphthalene content of the gas must be low and may entail the use of oil washing plant for its extraction.

The gas carrying the adsorbable hydrocarbon vapours is brought into contact with activated carbon which retains the benzol and certain other constituents of the gas, *e.g.* unsaturated hydrocarbons, carbon disulphide. Owing to the liberation of heat cooling water is circulated. When saturated the adsorber is cut off from the gas stream and closed and then direct steam applied. The benzol vapours are collected and the process restarted. The plant at the Beckton works of the Gas Light & Coke Co. is designed to treat 75 million cub. ft. of gas in 24 hours and to produce 16,000 gallons of benzol.

Many plants for small and medium size works have recently been installed. It is claimed that with new or reactivated carbon the efficiency of benzol recovery may attain 99 per cent., and for sulphur removal 65 per cent.

These smaller size plants are designed to be automatic, the cycle of operations being controlled from a series of cams rotated at constant speeds. Some chemical supervision on the plant is required to see that, as the carbon ages, the necessary alterations in operating cycle are made. The consumption of steam on this type of plant is comparable with the ordinary plant employing wash oil and distillation under normal conditions. It is, however, in excess of that type of plant employing vacuum distillation and normal rates of oil circulation.

Dehydration of Gas.

Of the gas distributed in Great Britain one-third or 110,000 million cub. ft. is treated for the removal of water vapour. The advantages claimed for this are: (1) A saving in the cost of pumping syphons. (2) The prevention of water troubles in consumers' pipes and fittings. (3) The prevention of internal corrosion of mains and services with consequent stoppages. (4) Prevention of corrosion in meters.

The two methods employed on a commercial scale use either calcium chloride or glycerine as a dehydrating agent. Glycerine has a vapour pressure lower than water and the solution of calcium chloride in water has a low vapour pressure and is able to absorb moisture from gases having a greater partial pressure of water vapour.

The gas is washed with either medium in an efficient washer, the dewpoint of the outlet gas being the factor to be controlled.

With the calcium chloride process some of the diluted solution is tapped off and run over an evaporator and back to the main supply through a cooler. The strength of the washing solution is thus kept correct. With the glycerine process the glycerine is treated under a vacuum for the removal of the water vapour absorbed.

The cost of each process is very low.

Trouble has been experienced with gum deposit in apparatus on the district of some undertakings that have gas drying plants. This has been traced to the action of the very small quantities of oxides of nitrogen upon the unsaturated hydrocarbons in the gas. It is found that, where gas drying is not practised or where it takes place after storage in a holder where condensation can and does occur, no such trouble is experienced. With the present degree of knowledge it is recommended either (1) to instal gas dehydrating plants on the outlet of holders, or (2) to arrange to pass gas through a holder even if the main storage is for 'dry' gas.

Reduction of Organic Sulphur Compounds in Town Gas.

After the complete removal of sulphuretted hydrogen from gas, sulphur is still present as organic compounds. A considerable research into the problem of their elimination is yielding success and it is hoped that in the near future many commercial plants will be erected. The scope for gas, both in the domestic and industrial fields, will thereby be extended, and maintenance costs of apparatus reduced.

The organic sulphur compounds in purified (not debenzolised) coal gas are:—

Carbon disulphide . . .	15 grains per 100 cub. ft.
Carbon oxysulphide . . .	6 ,, ,, ,, ,,
Thiophen	9 ,, ,, ,, ,,
Mercaptan	2 ,, ,, ,, ,,
Total	32 ,, ,, ,, ,,

These figures are an average, but it is correct to say that with continuous vertical retorts a lower sulphur content is experienced than in gas from static carbonisation at a higher temperature. (It should be noted that the sulphuretted hydrogen contents of the two unpurified gases are in the reverse order.)

Very few plants designed expressly for the reduction of sulphur compounds are in use at present, but the extensive removal of such compounds is incidental in two methods of benzol recovery.

(*a*) ***Oil Washing.***—This method has already been described on p. 638. When dealing with coal gas it is found that a circulation of 8 galls. of solvent (gas oil) per 1,000 cub. ft. should suffice for the absorption of benzene and of all the thiophen and its higher homologues, whilst for the complete extraction of carbon disulphide a circulation of 32 galls. of solvent per 1,000 cub. ft. would be needed. Thus the normal oil-washing process with a circulation of 8 galls. of oil per 1,000 cub. ft. reduces the sulphur compounds by 40 per cent. whilst extracting between 2½ to 3 galls. of benzol per ton of coal carbonised. The use of the increased oil circulation, *i.e.* 32 galls. of solvent per 1,000 cub. ft. of gas washed results in excessive steam consumptions unless the distillation plant is specially designed. The Gas Light & Coke Company and Messrs W. C. Holmes have produced a plant employing this high oil circulation. The distillation is carried out at a temperature of only 170° F. in a partial vacuum. The steam consumption is similar to that of a normal plant. The efficiencies of benzol and sulphur removal are 90 per cent. and 75 per cent. respectively.

(*b*) *Active Carbon Benzol Absorption Process.*—This again is designed for benzol extraction. It is more efficient than the normal oil washing process in the removal of sulphur compounds from the gas. In this process, which is described in greater detail under 'Benzol,' the process of adsorption is carried out in vessels for periods of about 8 hours. During the early parts of the adsorption process the whole of both the thiophen and the carbon disulphide is removed, but as saturation of the carbon is approached the more volatile compounds (*e.g.* carbon disulphide) are displaced. Over a period of six months continuous working of the Beckton plant of the Gas Light & Coke Company, the sulphur content of the gas was reduced from 30·5 grains per 100 cub. ft. to 6·1 grains.

(*c*) *Catalytic Removal of Organic Sulphur Compounds from Coal Gas.*—A full scale plant for the catalytic removal of organic sulphur compounds from coal gas has been at work at the Harrow works of the Gas Light & Coke Company since 1938. The plant is fully described in a paper published in the *Gas Journal*, dated July 12, 1944.

The gas is brought into contact with the nickel subsulphide catalyst on china clay pellets after being treated for the removal of sulphuretted hydrogen and napthalene and being preheated in a heat interchanger. The temperature of the gas entering the catalyst vessels is maintained by burning some of the hydrogen in the gas by the addition of air. The gas then passes out through the heat interchanger, through a vertical washer cooler, wherein it is washed with a soda ash solution and a catch purifier box for the elimination of H_2S.

The table below shows the behaviour of the individual sulphur compounds in the Harrow plant.

ORGANIC SULPHUR IN GRAINS PER 100 CUB. FT.

		Mean Temperatures of Gas Leaving Catalyst.		
		280° C.	310° C.	360° C.
As Carbon disulphide	inlet	15·1	14·7	16·3
,, ,, ,,	outlet	5·0	6·4	0·9
,, ,, oxysulphide	inlet	8·3	6·0	6·1
,, ,, ,,	outlet	4·5	4·0	2·5
,, Thiophen	inlet	10·5	8·8	10·2
,, ,,	outlet	10·4	7·4	10·2
,, Mercaptan	inlet	1·2	3·9	1·1
,, ,,	outlet	0·5	1·3	0·0
Total	inlet	35·1	33·4	33·7
,,	outlet	20·0	19·1	13·6

When this gas is treated in an active carbon benzol absorption plant the sulphur compounds are further reduced to under 5 grains per 100 cub. ft.

The authors of the paper estimate that the cost in 1939 of a plant of 2 million cub. ft. of gas capacity would have been £7,500.

Running costs daily would have been:—

Interest and depreciation	394 pence per day.
Therms in H_2 consumed at 4*d*. per therm	458 ,, ,, ,,
Soda ash (0·73*d*. per lb.)	131 ,, ,, ,,
Labour and supervision	120 ,, ,, ,,

As the thermal output is 8,400 therms per day the cost of running the plant is 0·135 pence per therm. This figure includes the regeneration of the catalyst but represents working with a good load factor.

Use of Plant for Treating Furnace Atmospheric Gases.

Where there are special demands for a gas with a low content of total sulphur, as for example in the production of special furnace atmospheres, the catalytic process has proved very satisfactory for small scale operations. Some 40 units of this type have been in operation in various parts of the country for periods up to four years and the catalyst has frequently operated over this time without renewal or replacement. These small plants are fitted with external heating.

Contamination of Town Gas in Storage.

It is frequently found that gas freed from sulphuretted hydrogen stored in a water-sealed holder becomes contaminated due to the production of sulphides by the bacterial reduction of sulphates. The trouble is most acute in the autumn when the atmospheric temperature is lower than the gas holder water temperature. The water on the surface is chilled, sinks to the bottom and that at the bottom rises to the surface.

A simple and effective cure is aeration of the water. The water should be taken from the surface inside the tank, be passed over an aerating tray and returned to the space between the tank side and the outer lift. This scheme has the objections of the smell of the holder water and the fact that the sulphides are not removed but merely returned to sulphates upon which the bacteria feed. Chemical oxidants used are calcium hypochlorite, chlorine and hydrogen-peroxide. All these oxidant processes require accurate control to ensure that the holder water is not rendered unduly corrosive towards steelwork.

Precipitants such as ferrous sulphate, copper sulphate, zinc oxide and zinc acetate can be used to remove from the water in insoluble form either the sulphides or sulphates from which they are formed. The introduction of sulphates such as ferrous sulphate or copper sulphate is undesirable and zinc compounds are best employed (1) since zinc being electro positive to iron is unlikely to affect the rate of corrosive attack ; (2) zinc sulphide is not decomposed by coal gas ; (3) the addition of the oxide or acetate does not involve the introduction of undesirable acid radicles.

The use of bactericides to kill the bacteria would be the best solution of the problem but to date no satisfactory bactericide has been found. Naphthalene prevents the growth of bacteria but must be present in a concentration high enough to impart a considerable amount of naphthalene to the gas. Phenol must be employed in impracticably high concentrations.

Tar Distillation.

(Contributed by Harold Moore, M.Sc., A.I.C., F.C.S.)

The yield of coal tar depends very largely upon the volatile content of the coal; but, in addition, it is considerably affected by the design of the retort. Retorts in which heating is conducted gradually, and which ensure the rapid removal of the volatile products from the heat zone, yield the largest quantities of tar. The nature of the tar depends, to a slight extent, upon the type of coal used, but is much more seriously affected by the carbonising conditions. A rapid rise in temperature, with a high maximum temperature, tends to produce tar high in specific gravity, high in viscosity, rich in free carbon, and mainly consisting of aromatic hydrocarbons. Gradual heating, low maximum temperature, and rapid removal of the volatile products result in brown mobile tars, comparatively devoid of free carbon and rich in aliphatic hydrocarbons.

Horizontal retorts subject the coal to a very rapid heating with a high maximum temperature, whilst the volatile products have to pass along the heated retort walls, whereby they undergo cracking. The result is a viscous tar, rich in free carbon. Horizontal retort tars frequently contain over 20 per cent. They possess a specific gravity of about 1·2. In continuous vertical retorts the coal is slowly passed from the cool zone into a hotter zone, undergoing gradual heating, whilst the volatiles are removed from the cooler end of the retort, and, therefore, are not so liable to undergo cracking. The resulting tar possesses a specific gravity of about 1·08 and about 1 to 8 per cent. of free carbon. Inclined retorts give products of intermediate composition; whilst coke ovens yield tars of very varied composition, depending upon the design of the ovens.

Special processes for the low-temperature carbonisation of coal, such as the Coalite and Premier Tarless systems, yield brown low-gravity tars in which free carbon is almost entirely absent. Gas works and coke ovens supply nearly all the tar produced in this country. Tar produced in gas works is accompanied by ammoniacal liquor, and requires settling out previously to

distillation. The tar in distillation is usually divided into the following fractions in English distilleries :—

	Temperature.	Approx. Yield.
1. Crude naphtha	Up to 110° C.	3 per cent.
2. Light oil	110° to 200° C.	7 ,,
3. Crude carbolic oil . . .	200° to 240° C.	7 ,,
4. Creosote oil	240° to 270° C.	15 ,,
5. Anthracene oil	270° to finish	10 ,,
6. Residuum of pitch . . .	—	58 ,,

The finishing-point of the distillation is decided by the quality of pitch desired. The yields of the above products vary, of course, with the nature of the tars, horizontal retort tars yielding a residue of about 65 per cent. of pitch, whilst vertical retort tars give only about 50 per cent. of pitch. The benzene and toluene are mostly present in the crude naphtha fraction, the yield of benzene being about 2 gallons to the ton of tar. They are separated by distillation combined with washing with dilute alkali, which removes phenols, cresols, and other acidic bodies, followed by washing with dulite acid, which removes pyridine, quinoline, and other basic substances, and are finally refined by treatment with strong sulphuric acid, which removes certain sulphur-containing compounds and a portion of the unsaturated hydrocarbons originally present in the tar. Similar processes of refining are adopted for other fractions, though the strong acid treatment is usually applied only to the benzene, toluene, and solvent naphtha-containing fractions. The most common grades of these three distillates are sold under the names of 90*s*. benzol, 90*s*. toloul, and 90*s*. xylol. The 90*s*. benzol distils 90 per cent. of its volume at 100° C. by the tar distillers' retort test; 90*s*. toluol yields 90 per cent. at 120° C. by the same test; whilst 90*s*. solvent yields 90 per cent. at 160° C. The solvent fraction consists mainly of the three isomeric xylols. Naphthalene and anthracene are removed from the higher boiling fractions (naphthalene mainly from the carbolic oil fraction, anthracene from anthracene oil) by cooling and decantation, or by cooling and filtration.

The limiting temperatures of the fractions are liable to alteration, depending upon market conditions, whilst the distillation is frequently stopped at an earlier stage than that indicated in the above table, in order to yield a soft residue known as treated or refined tar, which is used for tar spraying on the roads. A soft finished residue is also frequently sold as pitch-creosote mixture, and used for the fuel market.

Benzol is mainly used for motor fuel, together with a considerable quantity of the toluol, though smaller amounts are employed in the synthetic chemical industry. Carbolic acid (phenol) and cresylic acid (cresols), obtained by alkali washing, both find their main market for the manufacture of disinfectants. Creosite oil is used for timber preservation and as fuel. The use of creosote as fuel is somewhat intermittent, depending upon the price of petroleum. Pitch is mainly used for road repairing, but also for many other purposes, a considerable amount being consumed for electric insulation.

WATER GAS.

Water gas plants give a high output of gas at calorific values between 205 and 600 B.Th.U. per cub. ft. within a few hours of starting up. These plants are normally used as auxiliaries to coal gas plants to provide for sudden peak loads caused by abnormal weather conditions. The reactions occurring in the generator of the water gas plant are as follows :—

$$(a)\ C + 2H_2O = CO_2 + 2H_2 - 33{,}170 \text{ B.Th.U.}$$
$$(b)\ C + H_2O = CO + H_2 - 52{,}900 \text{ B.Th.U.}$$

The carbon dioxide produced in the lower portion of the fire according to the equation (*a*) is then reduced to carbon monoxide on passing through the remainder of the fuel bed—

$$(c)\ CO_2 + C = 2CO - 72{,}000 \text{ B.Th.U.}$$

The extent to which the reaction (*b*) takes place depends largely upon the temperature prevailing in the lower part of the fuel bed. As the above reactions are of an endothermic nature the heat of the fuel bed is gradually absorbed, accordingly this is replaced at intervals by the process of 'blowing.' The reaction occurring during the 'blow' is of an exothermic nature being simply as follows :—

$$C + O_2 = CO_2 + 172{,}560 \text{ B.Th.U.}$$

The modern water gas plant consists of: (1) Generator fitted with a self-clinkering grate and annular boiler. (2) Carburettor fitted with a creeper attachment to the air main. (3) Superheater. (4) Waste heat boiler for cooling of waste gases.

The cycle worked on such a plant would be about 3 minutes' duration, of which 45 per cent. is used for the 'blow.' The 'down run' has now been superseded by the 'back run,' in which the

steam is admitted to the top of the superheater and travels backward through the vessels carrying heat back to the bottom of the fire. The 'back run' process has resulted in reduced coke consumption and increased gas production.

The modern plant is entirely automatic and the cycle of operations can be adjusted to meet the conditions of each works. The whole subject has been thoroughly investigated and reported upon by the Joint Research Committee of the Institution of Gas Engineers. (See *Trans. Inst. Gas E.*, 1930, 1932, 1934, 1935.)

A brief summary of their conclusions is given below :—

1. The charges for labour and capital are so important that when using C.W.G. (Carburetted Water Gas) as a coal gas auxiliary the total costs of manufacture are at a minimum when a plant is operated at high output. To obtain this

(a) the blast pressure should be such that with the maximum fuel bed temperatures allowed by clinker formation and wear and tear of grate the heat in the blow gases leaving the generator is no more than is required for carburetting ;

(b) the rate of steam supply to be as high as possible considering the quality of blue water gas made unless the rate of oil supply thus required leads to an excessive loss of efficiency.

2. The rates of air and steam admission are decided as shown above, the relative durations of the run and blow periods are fixed by the necessity of storing sufficient heat in the fuel bed during the blow to decompose the steam during the run. It is assumed that the fuel is of adequate density to withstand the blast pressure.

3. During periods when a low output of gas is required economies in raw materials and maintenance can be obtained as follows :—

(a) Clinker formation and hence wear and tear of grate are reduced by use of lower blast pressures.

(b) Improved decomposition of steam and oil and hence better quality gas result from slower rates of steam and oil admissions.

(c) When outside steam is expensive the plant can be made self supporting by increasing the heat in the blow gases.

4. A large proportion of the steam should be passed downwards through the fuel bed as there is then less tendency for heat to leave the generator in the blow gases, and there is also an improvement in quality of blue water gas.

5. With coke of normal grade nothing is gained by alteration in depth of fuel bed under steady conditions. The limits are set by

(a) A thin fuel bed increases the sensible heat loss in the blow gases leaving the generator ;

(b) too deep a fuel bed restricts unduly the air supply.

6. Coke of normal large grade (50 per cent. 3 in.–2 in.) gives a better performance than smaller grades which give a smaller output, lower thermal yield and poorer quality of blue water gas.

7. Slower rotation of the grate and reduced ejection of ashes improves the quality of blue water gas, the output and thermal efficiency as a greater proportion of steam can be admitted on the back run. If insufficient ash is extracted clinker troubles will follow.

8. Self-clinkering generators operate at a greater output than hand clinkered machines and at the same time give a greater thermal yield of blue water gas per 1,000 lbs. of coke and at a better quality.

9. The chief advantage of the generator boiler on a self-clinkering generator is the reduction of charges per therm C.W.G. until it can be established that a similar output can be obtained from a generator of the same size without a boiler. On outputs below peak the presence of the boiler is advantageous under circumstances in which it is economical in raw materials to maintain the plant self supporting in steam.

10. To obtain the highest output and the greater yield of blue water gas from the coke it is specially important to secure complete admixture of the blow gases and secondary air at the top of the carburettor.

For the manufacture of carburetted water gas having a calorific value of about 450 B.Th.U. per cub. ft., the materials required are as follows :—

Coke	32–40 lbs. per 1,000 cub. ft. of gas.
Oil	1·5 gallons of oil per 1,000 cub. ft. of gas.
Steam	0–30 lbs. per 1,000 cub. ft. of gas.

A set fitted with generator and waste heat boilers can be self-supporting in steam.

The cost of carburetted water gas is mainly influenced by the cost of the enriching oil, and for calculation the yield from 1 gallon of oil can be taken as 1·25 therms.

The impurities in water gas consist of carbon disulphide and sulphuretted hydrogen, which are present in the following quantities :—

	Grains per 100 cub. ft.
Sulphuretted hydrogen	110 to 120
Carbon disulphide	10 to 15

As regards water gas tar, S. Carter has given the following analysis :—

Specific gravity	1·0665
	Per cent.
Benzol	1·11
Naphtha	2·33
Creosote oil	21·35
Naphthalene	4·09
Anthracene oil	15·91
Pitch	56·70

SULPHATE OF AMMONIA.

Average neutral commercial salt contains :—

Ammonia	25·5 per cent.
Equal to	
Nitrogen	21·0 per cent.
Free acid	nil.
Moisture	0·5 per cent.

Materials required for the manufacture of 1 ton of sulphate of ammonia :—

Liquor, approximately	3,400 gallons of 8 oz. strength.
Acid ,,	18 cwts. at 80 per cent. strength.
Lime ,,	3 cwts.

The sulphate of ammonia recovered per ton of coal varies in this country between 24 and 28 lbs.

Equation for formation :—

$$2NH_3 + H_2SO_4 = (NH_4)_2SO_4.$$

Gallons of liquor × ounce strength × 0·0823 = lbs. of sulphate.

Concentrated Gas Liquor.

Due to the fall in the selling price of ammonium sulphate from £14 in 1924 to as low as £5 per ton in 1932 many of the smaller plants for its manufacture were run at a loss. Whilst the selling price for ammonium sulphate has to some extent improved, it is found more profitable for the smaller undertakings to distil the liquor and to manufacture concentrated gas liquor containing up to 20 per cent. ammonia by weight. The subject is dealt with fully by P. Parrish in a paper to the Institution of Gas Engineers (*Trans.* 1938–1939). He gives a cost statement for the production of concentrated gas liquor in a plant having a capacity of 4,000 tons of concentrated gas liquor containing 20 per cent. ammonia by weight per annum.

Steam.—To produce 1 ton of concentrated gas liquor containing 20 per cent. NH_3 by weight at 96 per cent. efficiency 13·9 tons of gas liquor needed

Steam consumption = 18 per cent. by weight on crude liquor handled.

$$\text{Steam needed} = \frac{18}{100} \times 13{\cdot}9 = 2{\cdot}52 \text{ tons.}$$

	Cost/Ton.
Supplied at 15 lbs. per sq. in. at 12 pence per ton	2*s.* 6*d.*
Supervision	9*d.*
Cooling water	3*d.*
Repairs and maintenance	6*d.*
Depreciation at 7½ per cent. and interest at 5 per cent.:—	
Capital cost £5,600.	
Annual charge £700	3*s.* 6*d.*
Overheads and contingent expenses	1*s.* 0*d.*
Total manufacturing costs per ton	8*s.* 6*d.*

$$\text{Cost per unit of ammonia} = \frac{8s.\ 6d. \text{ per ton}}{20 \text{ units}} = 5d.$$

USEFUL MEMORANDA.

A Calorie is the amount of heat required to raise 1 kilogramme of water 1° Cent.; correctly from 0° to 1° Cent. This is the *large* calorie, which is the unit employed on gas works.

1 British Thermal Unit	= 0·252 calories.
1 Calorie	= 3·968 B.Th.U.
1 Therm	= 100,000 B.Th.U.
Therms	= cub. ft. × calorific value per cu. ft. ÷ 100,000.
Cu. ft.	= therms × 100,000 ÷ calorific value per cu. ft.

Calorific Power of Various Substances.

	B.Th.U. per lb.		B.Th.U. per lb.
Coke-oven coke	14,436	Petrol, specific gravity 0·684	20,923
Peat, 5 per cent. water	9,900	Shale oil	18,217
Wood, pine	9,153	Blast-furnace oil	16,080
„ oak	8,316	Heavy tar oil	16,050

Flow of Gas in Mains.

Pole's Formula.

Let Q = the discharge of gas in cub. ft. per hour.
d = the diameter of pipe in inches.
p = pressure of gas in inches of water,
s = specific gravity of gas, air being 1.
l = length of pipe in yards.

then,

$$Q = 1350d^2\sqrt{\frac{p\,d}{s\,l}}\,;\; d = \sqrt[5]{\frac{Q^2 s\,l}{(1350)^2 P}}\,;\; p = \frac{Q^2 s\,l}{(1350)^2 d^5}\,;\; l = \frac{(1350)^2 d^5 p}{Q^2 s}.$$

Unwin's Formula for High Pressure Gas Mains.

Let D = diameter of pipe in ft.
S = specific gravity of gas (air being 1).
L = Length of pipe in ft.
P_1 = initial pressure in lbs. per sq. inch absolute.
P_2 = final pressure in lbs. per sq. inch absolute.
C = coefficient of friction $= 0{\cdot}0044\left(1+\frac{1}{7D}\right)$.
U_1 = initial velocity of gas in feet per second.
U_2 = final velocity of gas in feet per second.
W = area of pipe in sq. ft.
Q = discharge in cub. ft. per hour,

then,

$$Q = 1{,}323{,}250\sqrt{\frac{P_1^2 - P_2^2}{P}\cdot\frac{P_1^2}{P_2^2}\cdot\frac{D^5}{CSL}}\,;\; U_1 = 468\sqrt{\frac{D}{CSL}\cdot\frac{P_1^2 - P_2^2}{P_1^2}}\,;\; U_2 = \frac{P_1}{P_2}U_1.$$

Table of Constants for Friction in Gas Mains.

Diameter of Main in Ins.	Diameter of Main in Ft. = D.	Area of Main in Sq. Ft. = W.	Value of C = Coefficient of Friction $= 0\cdot0044\left(1 + \frac{1}{7D}\right)$

Flow of Gas in Service Pipes.

To determine the correct size of service pipe to be installed or to determine the maximum rate of flow from a pipe, the table evolved by Lacey and given below should be used (*Trans. Inst. Gas E.* 1923).

This table gives the flows in cub. ft. per hour corresponding to $\frac{1}{10}$ in. loss of pressure between the ends of various lengths of straight pipes of nominal diameters from ⅛ in. to 3 ins. Specific gravity 0·50.

Length of Pipe (Ft.)	Nominal Diameter of Pipe (Ins.).								
	⅛	¼	⅜	½	¾	1	1¼	1½	2	
10	3	<u>14</u>	33	72	130	240				
20		7	<u>18</u>	49	88	165	340	530		
30			12	<u>38</u>	70	130	270	420	890	
40				29	60	110	235	360	770	2240
50				23	<u>52</u>	98	210	320	680	1980
60					47	89	190	290	620	1800
70					40	<u>81</u>	170	260	560	1630
80						75	160	240	520	1510
90						71	150	230	490	1420
100							<u>140</u>	215	460	1340
150							110	170	370	1070
200							96	<u>150</u>	310	900
250								130	280	795
300								115	250	710

The underlining of certain figures in the table indicates the greatest length of pipe of a particular diameter which in practice, it has been found desirable to lay.

Bends, toes and elbows can be allowed for by adding to the overall net length of pipe the lengths given in the table below. The gross length obtained can then be used in the preceeding table.

Nominal Diameter of Pipe.	Addition to be made to Over-all Length of a Pipe (in ft.) for Increased Resistance introduced by Fittings.		
Ins.	Elbows.	Tees.	90° Bends.
$\frac{3}{8}$ to 1	2	2	1
$1\frac{1}{4}$ to $1\frac{1}{2}$	3	3	$1\frac{1}{2}$
2	5	5	2
3	8	8	3

Use of Gas in Industry.

In recent years the amount of gas used for industrial purposes has steadily risen and it is estimated that, during 1943, 98,000 industrial consumers used 103,160 million cub. ft. of gas or 28 per cent. of the whole gas sold in this country. Some of the typical processes employing gas are given below:—

Industry or Trade.	Process.
Iron and Steel	Billet heating for rolling and forging. Foundry—Core and mould drying, ladle heating. Annealing. Rolling mills. Forging.
Non-ferrous Metals	Melting, annealing, forging, stamping, brazing.
Engineering (Automobile and Aircraft)	Every kind of heat treatment, brazing, stoving paint-stoving ('infra-red' process), running-in-engines.
Engineering (Electrical and Radio)	Manufacture of cable, wire, lamps, valves, instruments. Soldering.
Engineering (Light Alloys)	Melting, refining and every form of heat treatment.
Engineering (General)	Annealing, normalising, carburising, hardening, plate cutting.
Tube and Wire	Billet heating, annealing, patenting, galvanising bright annealing. Heating of solutions, tanks and lead pots.
Agriculture	Grain drying, dairy equipment.
Ceramic	Firing of earthenware, china, porcelain. Drying.
Chemical and Chemical Plant	Heating of stills and evaporators. Soap manufacture. Paint and varnish manufacture. Dye manufacture.
Cremation	Furnace heating.
Food, etc.	Large-scale bread and biscuit baking. Confectionery. Brewing.
Glass	Melting, annealing, working, finishing.
Plastics	Platen heating.
Printing	Type-metal melting.
Textile	Singeing of cloth and yarn.
Turkish Baths	Production of steam, vapour and hot air.

Gas Meters.

The original consumers' gas meters were of the wet type similar in operation to the Wet Station Meter.

The original 'lights' type dry meter has been improved in the 'Standard,' High Capacity, and later in the small High Capacity I.G.E. types. The improvements have been made in the design of diaphragm, valve gear and general layout. The table below gives the capacity and sizes of the various types of meter. The table shows, particularly in the larger sizes, the reduction in the space occupied by the later types.

Size or Denomination.			Capacity. Cub. ft./hr.	Height in ins. approx.	Base Dimensions.	Space occupied. Cub. ins. approx.
Lights.	Standard	High Capacity.

Gas Tests.

Gas Tests as Prescribed by the Gas Referees.

As gas is now sold on the therm basis the determination of calorific value is the most important of the official tests. In addition, tests are made for pressure and freedom from sulphuretted hydrogen.

Tests for Calorific Value.

The apparatus to be used for ascertaining the calorific value of the gas supplied by Gas Undertakers who have sold in the preceding year more than 100 million cub. ft. of gas must include a calorimeter for the production of a continuous record of the calorific value of the gas supplied. The instrument must be one of the following three:—

(1) The Boys Recording Calorimeter.
(2) Fairweather Recording Calorimeter.
(3) Cambridge Scientific Instrument Company's Thomas Recording Calorimeter.

The apparatus to be used for testing the calorific value of gas supplied by undertakers who have not sold 100 million cub. ft. of gas in the preceding year is a Boys Non-Recording Calorimeter. As an alternative to a recording instrument of the above types the Gas Referees may prescribe the provision of an inferential recorder used in conjunction with a Boys Non-Recording Calorimeter.

The types of inferential recorders approved are:—

The Sigma B.ThU. Recorder No. 3.
The Simmance Calorgraph type R.

The record of inferential recorders will be used only for adjusting the average calorific value ascertained from the results of testings made with the Boys non-recording calorimeter, according to the fluctuations of calorific value which have been shown by the inferential recorder to have taken place in the intervals between testings.

In cases in which it appears necessary to the Gas Referees a Recording Calorimeter or an inferential recorder, can be prescribed for testing places for Gas Undertakers who have not sold more than 100 million cub. ft. of gas in the preceding year.

Tests for Calorific Value with Non-Recording Calorimeter.

These are carried out by observations taken by means of a calorimeter illustrated in fig. 1, in which water flowing is heated by a double burner consuming about $\frac{1}{15}$ cu. ft. per minute. The calorimeter having been set up, the burners are lighted and the water flow is so adjusted that the difference between he inlet and outlet temperatures is about 20° C. The heating of the calorimeter is allowed to proceed for not less than 45 mins. While the hand of the meter is making four revolutions, four readings of the inlet thermometer and fifteen readings of the outlet thermometer are taken at intervals, during which period the discharged water is collected in a measuring vessel. The temperature of the surrounding air, of the gas in the meter, and of the effluent gas are also observed. The mean of the four readings of the inlet temperature is subtracted from the mean of the fifteen readings of the outlet temperature, and the difference is multiplied by 11·976 and by the number of litres of water collected. The product is divided by the tabular number.* The difference in degrees Fahrenheit of the temperature of the effluent gas and the surrounding air is multiplied by $\frac{3}{5}$, and this is added to the result previously found if the effluent gas is the warmer of the two, or subtracted if the effluent gas is cooler. The result is the gross calorific power of the gas in British thermal units per cu. ft. (*c*).

In addition to the foregoing, the amount of condensed water resulting from the combustion of the gas is measured. For this purpose the condensation water is led into a measuring vessel not less than 20 mins. after the calorimeter has been set up. The amount collected in not less than 30 mins. is measured, and the time of collection accurately noted. The number of cubic centimetres collected is multiplied by the number of seconds taken for four revolutions of the meter and by the constants 1·86 and 3·968 (*a*). The number of seconds during which the water is collected is multiplied by the tabular number (*b*). The first product (*a*) divided by the second (*b*) and subtracted from the gross calorific power (*c*) gives the net calorific power in British thermal units per cubic foot.

The meters used for these tests are of the 'wet' type, having a calibrated capacity of $\frac{1}{12}$ cu. ft. per revolution of the drum. The drum carries an index hand moving over a dial divided

* The tabular number depends upon the barometer reading and the temperature of the gas passing through the meter.

into 100 divisions, and the meters are provided with a thermometer for measuring the gas temperature.

Testing of Non-saturated Gas.

Undertakers supplying non-saturated gas are entitled to a modification of the ordinary method. Before stating the modifications the Gas Referees require evidence of the degree of dryness of the gas over the distributing system. The degree of dryness is determined by a hygrometer of the Gas Light & Coke Company's pattern, made by Scientific Supplies or Negretti and Zambra, and certified by the Gas Referees.

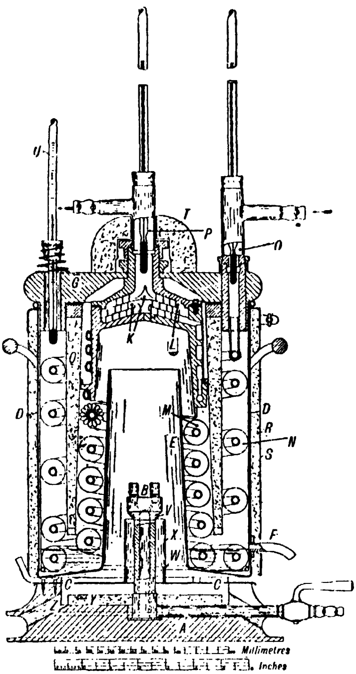

FIG. 1.

Test of Sulphuretted Hydrogen.

The gas is passed through a glass vessel in which are suspended six strips of bibulous paper moistened with a solution of 6·5 grams of acetate of lead crystals in 100 c.c. of water. The gas having been turned on full for three minutes, one of the strips is compared with a strip similarly moistened but not exposed to the gas. The gas is taken as exhibiting a trace of H_2S if the exposed is unmistakably darker than the unexposed strip.

Testing the Pressure of the Gas.

A test for pressure may be made at any time at any testing station and should be made on each occasion on which the Gas Examiner visits the testing place to make other testings, or to verify the readings of a recording calorimeter.

Tests are made with U gauges filled with water.

ACETYLENE.

(Contributed by the late Professor Vivian B. Lewes, F.C.S., F.I.C.)

Acetylene, which is a gaseous compound of hydrogen and carbon, represented by the formula C_2H_2, is a colourless gas with a density of 0·92. As ordinarily prepared, it has a strong and very penetrating odour, but when purified from minute traces of other gases, invariably present with it in its crude state, has a not unpleasant ethereal odour. It can be converted into a liquid at a pressure of 21·53 atmospheres, at a temperature of 0° C., and liquefies under ordinary atmospheric pressure when cooled to a temperature of − 82° C. The critical point of the gas is 37° C., and at this temperature the pressure has to be raised to 68 atmospheres for its liquefaction.

Acetylene is readily soluble in water, which at normal temperature and pressure takes up about its own volume of the gas; its solubility in other liquids is given in the following table:

100 Volumes of		Volumes of Acetylene.	100 Volumes of		Volumes of Acetylene.
Brine	absorb . .	5	Fusel oil	absorb . .	100
Water	,, . .	110	Benzene	,, . .	400
Alcohol	,, . .	600	Chloroform	,, . .	400
Paraffin	,, . .	150	Acetic acid	,, . .	600
Carbon disulphide	,, . .	100	Acetone	,, . .	2,500

Extended researches by Bistrow and Liebreich upon the toxic properties of acetylene show that it acts upon the blood in much the same way as carbon monoxide, but exhaustive experiments show that it is less poisonous than ordinary coal gas.

Acetylene forms compounds of an explosive character with copper and silver, and at first this was thought to be a great drawback to its general use; but experience has shown that these fears were unfounded, and that brass gas fittings, when gas-tight, can be used with perfect safety.

Acetylene, when heated, polymerises, like most hydrocarbons, i.e. it is partly or wholly split up, and the resulting gas is usually a mixture of acetylene itself and poorer gases, such as hydrogen, methane, etc., while tarry compounds and even solid carbon are formed, if the heating is carried far enough.

This is a matter of the utmost importance to acetylene users. For lighting purposes, it means that a poor light is given; for oxy-acetylene welders it means that the temperature at the blowpipe is reduced considerably, indeed in some cases it has proved impossible to make satisfactory welds, owing to the poor quality of the gas.

These troubles arise almost exclusively with water-to-carbide generators, which are often faultily designed, so that overheating is bound to occur.

Experiments lately carried out by the French Acetylene Office have shown that polymerisation starts in an ordinary commercial generator at about 130° C., *i.e.* at a much lower temperature than was originally believed to be the case. Unfortunately many generators sold in this country act by driving the water away from the carbide container, when a certain amount of gas has been generated, leaving the live carbide surrounded by a mass of moist lime sludge, which is again surrounded by a blanket of acetylene. Acetylene, however, is a far poorer conductor of heat than water. At the instance of the writer, the heat conductivity of acetylene was ascertained by the National Physical Laboratory, we believe for the first time. It was found to be 0·000043 c.g.s., or only about one thirty-second of that of water. If, therefore, decomposing carbide is surrounded by acetylene instead of by water, only about 3 per cent. of the heat is carried off in a given time, which could be carried off by water, and the writer has seen sludge become actually visibly red under such conditions.

It is therefore of the utmost importance that acetylene users should be careful to see that they select acetylene generators in which there is always an ample supply of water in constant contact with the carbide, or constantly surrounding the carbide containers. It may also be pointed out that the better the carbide is, the more quickly it is attacked by water and, in consequence, the greater the quantity of heat liberated in a given time by its decomposition.

A new type of acetylene generator which differs radically in its generating chamber from anything previously used, although of extremely simple construction, has been put on the market in this country. The system has been in considerable use for about two years, and has given complete satisfaction.

In contact with air acetylene inflames at a temperature of 480° C. and burns with a flame which, when properly spread out so as to obtain a large quantity of oxygen, emits more light than any other gaseous compound of carbon and hydrogen.

Gas.	Candle hours per 5 cub. ft.	Carcel hours per cub. metre.	Gas.	Candle hours per 5 cub. ft.	Carcel hours per cub. metre.
Methane .	5·2	3·5	Propane .	56·2	40·0
Paris gas .	13·2	9·6	Ethylene .	70·0	49·0
London gas .	16	11·5	Butylene .	123·0	86·0
Ethane . .	35·7	25·0	Acetylene .	240·0	168·0

Professor Clowes has shown that acetylene has a wider range of explosibility when mixed with air than any other combustible gas, the limits in percentages being as follows:

	Per cent.		Per cent.		Per cent.
Acetylene . .	3 to 82	Carbon monoxide	13 to 75	Methane . .	5 to 13
Hydrogen . .	5 to 72	Ethylene . .	4 to 22		

Acetylene is made commercially by acting upon a compound known as calcium carbide (CaC_2) with water, when acetylene gas is liberated and calcium hydrate (slaked lime, $Ca(HO)_2$) is formed.

Calcium carbide is made by fusing together very pure coke (or high-carbon anthracite coal) and very pure lime by the intense heat of the electric furnace. No other way of heating the mixture to the required temperature has yet been discovered, although many attempts have been made; for instance, by the use of the oxy-acetylene blowpipe.

Acetylene generators, in which the interaction of the calcium carbide and water to generate the gas takes place, may be either automatic or non-automatic. In the former class, devices are used to stop the generation of the gas automatically, by cutting off the supply of water or the supply of carbide, thus doing away with the need of a large store-holder for the gas, whilst in the non-automatic class the action is allowed to continue until all the carbide is decomposed, the gas being stored in a holder from which it is used as required.

In making acetylene, water may be brought in contact with the carbide either by adding it to the carbide, or by adding the carbide to water.

The overwhelming majority of acetylene generators in practically all countries are now constructed on the water-to-carbide system.

Of late years the automatic type of apparatus for the generation of acetylene has almost entirely superseded the non-automatic type, owing to the very large quantity of acetylene now being required for the oxy-acetylene welding process.

Experience has shown that automatic generators can be constructed with a high factor of efficiency, while the capital outlay per unit of gas generated is considerably less than in the case of non-automatic apparatus.

Owing also to the much smaller space occupied by the automatic type, it has also been found much more convenient for private use.

Until comparatively recent times, the pressure customary in acetylene generators was from 4 to 8 inches water-column, these limits having been found to give the most satisfactory results for lighting purposes. The advent of the oxy-acetylene welding blowpipe, however, soon caused experiments to be made with higher pressures, with the most favourable results. To-day the general tendency in most countries is to have the acetylene under slightly higher pressure than the oxygen in the welding blowpipe, it being claimed that less oxidation of the metal took place under these conditions and that there was less chance of the right proportion of the two gases being interfered with by accidental obstruction in the blowpipe, and, lastly, there was less tendency for the flame to flash back.

In consequence of this movement, the Governments of the United States, Canada, Switzerland, and Denmark now allow a maximum pressure of 1 atm. in acetylene generators for welding, and Germany is on the point of adopting this maximum pressure also. Very interesting details of tests have been published by the Government Bureau of Standards in the United States.

The oxy-acetylene blowpipe has been most successfully used for a considerable time for case-hardening various parts of machinery, and in particular the gear-wheels and other parts of motor cars. Lately a most important development has taken place in this direction, the blowpipe having come into the most extensive use, not only for cutting and repairing rails, but for applying an exceedingly hard surface, to a depth reaching even the high figure of ½ inch and more, to the entire rail system of electric tramways.

The improvement shown in the wearing properties of rails is shown by the following figures
